- 22955 <ABSTRACT>Stratigraphic sequences within the Red River-Stony Mountain Province record two major environmental cycles in a vast area of epicontinental seas. The Red River Cycle began with a transgressive phase in the middle Edenian that reached its maximum in the early Maysvillian, and was followed by a regressive phase during the later Maysvillian and early Richmondian. The transgressive phase of the Stony Mountain Cycle reached its peak in the middle Richmondian, and was followed by a regressive phase during the later Richmondian and Gamachian. In general, the greatest water depth and most open marine conditions were attained during the first cycle, and seas were shallowest and most restricted toward the end of the second cycle. Recognition of the transgressive maxima, when deposition was most widespread, permits chronostratigraphic correlation throughout the province (and likely beyond). Bioevents involving evolution and dispersion of solitary rugose corals in the Red River-Stony Mountain Province, as well as fluctuations in the relative abundance taxa, were closely related to changes in water depth and degree of environmental restriction during the two cycles. The first major evolutionary event took place during the transgressive maximum of the Red River Cycle, when water depth in some areas exceeded the limit for corals and they were confined to basin margins and structural highs. The second occurred at the end of the Red River regressive phase, when most areas became inhospitable and corals were restricted to the centres of cratonic interior basins and to cratonic margin areas of the province. Corals became widely dispersed during the subsequent transgressive phase of the Stony Mountain Cycle. Late in the regressive phase of that cycle, taxa were introduced from outside the red River-Stony Mountain Province, and the endemic corals became extinct.</ABSTRACT>

- 22981 <ABSTRACT>In the Late Ordovician Red River-Stony Mountain Province of North America, four closely related genera of solitary rugose corals are represented exclusively by liberossessile species: salvadorea, Grewingkia, Deiracorallium, and Lobocorallium. These rugosans

benefitted from innovative and in some cases unique strategies involving corallum form, which improved stability with respect to the substrate and currents, and took advantage of water flow during life. Trochoid form was a compromise for ensuring adequate stabilization of the corallum by sediment, while keeping the calice rim sufficiently elevated above the substrate. In life orientation with the convex cardinal side of the corallum facing down, triangulate and trilobate cross-sectional shapes offered resistance to lateral tipping or rotation. Depressed coralla resisted gravity-induced subsidence or tilting. With the convex side facing downcurrent, the streamlined shape of compressed and triangulate forms improved stability by reducing drag. Trilobate form may have had a drag-reducing splitter plate effect. Strategies for drag reduction were especially beneficial for corals inhabiting relatively high-energy environments, but the greatest significance may have been in reducing fatalities due to dislodgement during storms. The hydrodynamic behavior of coralla in life position, especially if leaning downcurrent, resulted in beneficial water flow. Vortices ascending from the substrate on the downcurrent side provided the polyp with water drawn from both the mainstream and the substrate surface. Such circulation facilitated feeding, enhanced the quantity and variety of food, and delivered other necessary substances. Wastes and gametes could be effectively expelled from the polyp and removed downcurrent without entrainment into the food-bearing flow. Functional analysis of the fascinating range of corallum forms in the Red River-Stony Mountain Province provides insight into paleobiology and paleoecology, which is applicable to many Paleozoic solitary rugosans.

23031 <TITLE>Corallite size and spacing as an aspect of niche-partitioning in tabulate corals of Silurian reefs, Racine Formation, North America.</TITLE>
23032 <SOURCE>Lethaia 33, 1: 55-63.</SOURCE>
23033 <ABSTRACT>Tabulate corals are common in reefs of the Silurian (Wenlockian) Racine Formation in Wisconsin and Illinois, North America. Variation in size and spacing of corallites in this fauna represents an aspect of niche-partitioning that is probably related to feeding. Corallite morphospace, represented by a plot of corallite diameter versus number of corallites per square cm, is characteristically partitioned among favositines, alveolitines, halysitines, syringoporids, and heliolitines, usually with minimal overlap between these major taxonomic groups. Within all groups except alveolitines, morphospace occupied by each major taxon is partitioned further between forms with small corallites and forms with larger corallites. This is probably related to differences in feeding, with larger corallite forms specializing in tentacular capture of larger prey, and smaller corallite forms specializing in smaller prey involving capture by cilia-directed sheets of mucus as well as by tentacles. Feeding-based differences among tabulates augmented niche-partitioning effected by colony form and relation to substrate. Cerioid, cateniform, coenenchymal, and fasciculate colony types in the Racine fauna were primarily adapted to a soft substrate. Ragged edges of colonies indicate growth during episodic sedimentation and colonies were partially buried during life. Most tabulates are scattered through wackstone and packstone and were not major contributors to reef growth. [original abstract]</ABSTRACT>

- 23071 <SOURCE>Geodiversitas 28, 2: 199-226.</SOURCE>
- 23072 <ABSTRACT>The revision of the types and "topotypes" of Hadrophyllum orbigny Milne-Edwards & Haime, 1850 brings new data on this species and on the genus Hadrophyllum. The type species, H. orbigny, is known from the Eifelian (costatus-kokelianus conodont zones) of Eastern Americas Realm. A lectotype is selected in the original material. A detailed study of the morphology shows important variations concerning the shape of the corallum, the length of the cardinal septum, the interseptal ridges and the fossuloids. The septal apparatus consists of costosepta, it is why the "epitheca" is lacking. The corallum is massive, no dissepiments nor tabulae, and the wall is septothecal. The fibrous nature of the septa is pointed out. The polyp enclosed widely the corallum; H. orbigny was capable of automobility. The synonymy of the genus is reviewed; only two species can be referred to it, the type species and H. asturicum. The systematics of the "Hadrophyllidae" is revised, especially the Weyer's one (1975) and two new sub-families, the Hadrophyllinae and the Microcyclinae n. subfam., are erected.</ABSTRACT>

- 23150 <ABSTRACT>The paleobiogeographic distribution of stromatoporoids in
North America during the Devonian displays a progressively westward
retreat in the Eastern most occurrences of the group throughout most of
the period. When viewed in paleogeographic terms, this Recent westward
retreat represents a Devonian northward and equatorward retreat. It is
concluded that during the Early Devonian eustatic sea level was the
major factor controlling stromatoporoid distribution. The influx of
siliciclastic sediments, resulting from the Acadian Orogeny in
particular, progressively forced stromatoporoids from the then southern
parts of North America during the Middle and Late Devonian. It was not
until the latest Devonian (Famennian) that global cooling seems to have
had a significant impact on stromatoporoid distribution in North
America.</ABSTRACT>

- 23176 <ABSTRACT>This note is the third in a series of supplements to the
checklist published as U.S. Geological Survey Bulletin 1387 (Sando

1974). * The original checklist is an objective list of formally named coral species that were described from rocks of Mississippian, Pennsylvanian, and Permian age through 1973. The first supplement (Sando 1980) made additions and corrections to the original checklist through 1978, the second (Sando 1986), through 1983. * The present paper adds coverage of the literature through 1989 and includes one name missed previously. * The format followed herein is the same as that of the original checklist. [original introduction to the checklist]

23265 <TITLE>Palaeacis cuneiformis Haime 1857, in Milne-Edwards 1860, emended: its morphology, ontogeny, and stratigraphic significance.</TITLE>
23266 <SOURCE>Univ. of Louisville Studies in Paleontology and Stratigraphy 5: 27 pp., 5 pls, 8 text-figs., 2 tables.</SOURCE>
23267 <ABSTRACT>An orientation of the corallum is established and the growth sequence is ascertained by determination of the order of addition of corallites and development of surface ornamentation. Palaeacis cuneiformis ranges from the Middle Meramecian Salem Formation to the Middle Chesterian Glen Dean Formation, but in any frequency of numbers, it is definitive for the Salem Formation. Several other species of Palaeacis have stratigraphic significance within the Mississippian System of North America; further, Palaeacis enormis - P. bifida - P. obtusa - P. cavernosa - P. carinata seem to represent an evolutionary lineage.</ABSTRACT>

23344 <SOURCE>Journal of Paleontology 54, 1: 85-92.</SOURCE>
23345 <ABSTRACT>The western North American Lower Permian colonial rugose Heritschioides Yabe 1950 (Coelenterata: Anthozoa) has a short cardinal septum and an inconspicuous open, septal, cardinal fossula. Waagenophyllum columbicum Smith 1935, the type species, is redescribed and the type specimen refigured to demonstrate existence of these and other characters. Eight other nominal species and 2 unnamed ones are verified as Heritschioides from Alaska, Nevada, and Oregon. The genus also occurs in California. Reports of it in Texas, Japan, and Russia are doubtful or erroneous.</ABSTRACT>

23369 <TITLE>Research on coelenterate biology in Canada through the early twentieth century.</TITLE>

- 23370 <SOURCE>Archives of Natural History 19, 1: 55-68.</SOURCE>
- 23371 <ABSTRACT>This paper traces the history [of research] on Canadian coelenterates after 1854. During the nineteenth century preliminary exploration of the Canadian fauna was done primarily by Canadian geologists or by foreign scientists, particularly from the United States of America. In the early twentieth century, the study of coelenterates developed within Canada. A.B. Macallum examined the composition of the medusae Aurelia and Cyanea, J.P. Munich, C. Mclean Fraser, and R.E. Foerster did taxonomic work on, respectively, the anthozoa, hydroids and hydromedusae. Each contributed more widely to the development of marine biology in Canada, especially to the establishment of the Biological Board of Canada, later the Fisheries Research board.</ABSTRACT>

- 23409 <SOURCE>FC&P 26, 1: 17-21.</SOURCE>
- 23410 <ABSTRACT>A phylogenetic analysis including some Amazonian lophophyllid corals and similar forms from the Midcontinent region in USA was done. The Amazonian forms included *Stereostylus lemzi* and *S. mendesi*; whereas *Lophophyllidium proliferum*, *L. girtyi*, *L. compressum*, *L. minutum*, *L. idonium*, *L. ignotum*, *L. angustifolium*, *Stereostylus lenis* and *S. perversus* are the North-American species under analysis. *S. leinzi* and *S. mendesi* were regarded as metaspecies, for their lack of synapomorphies. having *L. ignotum* as sister group according to the cladogram produced (Figure 1). * The inclusion of the Amazonian

metaspecies into the genus *Lophophyllidium* is also suggested. The derived phylogenetic tree brings new insights to the North-American species, as follows: (1) *S. perversus* should be included in the genus *Lophophyllidium* and (2) either the range extensions of *L. proliferum*, *L. compressum*, *L. girtyi* and *Stereostylus perversus* are older than previously considered or their type localities are of Morrowan age. The paleobiogeographic pattern depicted by the phylogenetic tree suggests a faunal connection between the Amazon Basin and the US Midcontinent region during the late Morrowan (Figure 2). * The information provided by another phylogenetic analysis including *Lophophyllidium palaeum* and *L. wewokanum* (Meridas Andes, Venezuela) and *L. sauridens* (Western Interior, New Mexico, United States) also supports the previous phylogenetic tree and further suggests (1) either a longer range extension for the Venezuelan species or (2) a Morrowan age to the Merida part of the Palmarito Formation (Figure 3 and 4). 23460 <TITLE>Growth dynamics of neoproterozoic calcimicrobial reefs, Mackenzie Mountains, Northwest Canada.</TITLE>
23461 <SOURCE>Journal of Sedimentary Research 67: 37-45.</SOURCE>
23462 <ABSTRACT>Neoproterozoic buildups of the Little Dal Group grew in a deep-water epicratonic basin. These kilometer-scale reefs display aggradational and progradational geometries comparable to those described from Phanerozoic reefs. Four phases of reef growth correspond to four regional shale-to-carbonate packages in laterally equivalent offshore strata. The lower, shaly part of each package is interpreted to reflect transgressive to highstand deposition. The upper carbonate part of each package reflects carbonate precipitation in the water column as a result of postulated basin restriction and increased salinity during sea-level lowstand. Reefs nucleated at the beginning of the first major transgressive event. Reefs typically aggraded during transgressive intervals, but could also prograde or contract, likely depending on the rate of relative sea-level rise versus reef growth rate. Reefs prograded during regressions, probably owing to reduction of accommodation space. They shed talus at lowstand in response to increased erosion and / or progradation over unstable substrates. Reef growth ended with return of shallow-water conditions. The overall architecture of aggradation and progradation demonstrates that the Neoproterozoic calcimicrobial reef ecosystem was capable of responding to environmental changes in the same way as the more extensively studied, ecologically complex, and faunally diverse buildups of the Phanerozoic.</ABSTRACT>

23525 <TITLE>Occurrence of the siliceous sponge spicule Konyrium (Hexactinellida) in the Upper Cambrian of the Mackenzie Mountains, northwestern Canada.</TITLE>
- 23526 <SOURCE>Journal of Paleontology 76, 3: 763-766.</SOURCE>
23527 <ABSTRACT>[…] because spicule form is not restricted to individual taxa and many sponge species secrete a variety of spicule shapes, it is difficult to gauge true siliceous sponge diversity and to explore their biostratigraphic utility using only isolated spicules. * An exception to this biostratigraphic limitation is provided by unusual, probably hexactinellid, spicules belonging to the two known

- species of konyrium. Consisting of radially disposed blades (in the Upper Cambrian) or **"flying buttresses"**; termed **"arches"**; (in the Middle Ordovician), this distinctive group seems to be unique and aberrant in siliceous sponge spicule shape, in that no modern counterparts have yet been reported (e.g., Koltun, 1970; Boury-Esnault and Rützlér, 1997). In this paper I document the occurrence of Konyrium mariae Bengtson, 1986, in the Upper Cambrian (Steptoean) of northwestern Canada... [excerpts from a short note] </ABSTRACT>

23552 <SOURCE>Journal of Sedimentary Petrology 53, 4: 1051-1096.</SOURCE>
23553 <ABSTRACT>Bioherms and biostromes in the Lower Cambrian Forteau Formation of southern Labrador and western Newfoundland are rich in skeletal and nonskeletal components and display a wide spectrum of synsedimentary and postdepositional cements. Through petrography, cathodoluminescence, and microprobe analysis, three styles of particle preservation can be differentiated:1. skeletons with excellent fabric retention as nonferroan calcite (trilobites and Salterella) or both ferroan and nonferroan calcite (echinoids and sponge spicules);2. skeletal molds completely filled by nonferroan calcite spar, or occasionally a second stage of equant ferroan calcite and dolomite as well (archaeogastropods, hyolithids, brachiopods, ?coelenterates, and Chancelloria);3. fibrous to microcrystalline components which are now either well preserved as nonferroan calcite or are molds filled by equant ferroan calcite and dolomite or both (ooids, archaeocyathans, and the alga Renalcis). Synsedimentary cements, localized, to reefs, are:1. rays or botryoids in which each acicular crystal is a spar-filled mold; or2. rinds of fibrous calcite commonly with fascicular-optic properties or a partially dissolved fabric in which the solution voids are now filled with iron-rich, equant calcite cement.</ABSTRACT>

23577 <TITLE>Environmental and substrate control on Paleozoic bioerosion in corals and stromatoporoids, Anticosti Island, eastern Canada.</TITLE>
23578 <SOURCE>Palaios 19, 3: 292-306.</SOURCE>
23579 <ABSTRACT>Bioerosion was a common process affecting corals and stromatoporoids in reef and off-reef facies on the carbonate ramp that spanned the Ordovician-Silurian boundary on Anticosti Island. The probable worm boring Trypanites was the dominant macroboring, penetrating more than 40% of 2,500 massive tabulate corals and stromatoporoids examined, occasionally in dense concentrations. The frequency of macroboring was influenced by conditions at the facies level reflected by changes in grain size, water depth, storm reworking of sediments, and the nature of the skeletal mass bored. These factors regulated exposure time of the host-substrate surface to the watermass and thus influenced bioerosion. Bored specimens are most common in muddy off-reef facies, moderate in sandy off-reef facies, and less common in reefs. In off-reef facies, storm-enhanced deposition and reworking of sediments were most important in the burial of eligible host substrates. In reefs, the high competition for space by encrusting epizoa, combined with sedimentation, limited macroborers that preferred to excavate dead skeletal substrates. Skeletal density was the most important property of the host substrate in controlling boring frequency. Macroboring favored a dense host skeleton likely for its enhanced mechanical strength and adaptability for unlined borings, despite requiring greater energy for excavation. High-relief host skeletons were bored more frequently than tabular forms, since their greater capacity to shed sediment would have resulted in more prolonged exposure above the seafloor. The probable bivalve boring Petroxestes pera is rare. Temporal changes in boring frequency appear to reflect local shifts in facies and relative sea level. Mass-extinction events near the O/S boundary, which eliminated some host corals and stromatoporoids, had no apparent effect on boring frequency.</ABSTRACT>

23629 <TITLE>Colonial coral assemblages and associated fossils from the late
Ordovician Honorat Group and White Head Formation, Gaspé Peninsula,
Quebec.</TITLE>
23630 <SOURCE>Papers of geological Survey Canada 80-1C: 13-28.</SOURCE>
23631 <ABSTRACT>Four distinct coral assemblages are recognizable in the Late
Ordovician rocks of Gaspé Peninsula, two in the Honorat Group and two
in the White Head Formation. The Honorat Group faunules consist of an
association of: * Favistina honoratensis Bolton, Calapoecia
anticostiensis Billings and Saffordophyllum sp. A, overlain by *
Plasmoporella rarivesiculosa n.sp., Propora sp., and Paleofavosites sp.
A, along with the stromatoporoid Beatricea (Aulacera) sp. * The White
Head Formation assemblages consist of: * Propora conferta Milne-Edwards
& Haime, P. speciosa (Billings), Calapoecia anticostiensis
Billings, Catenipora sp. aff. C. aequabilis (Teichert), Paleofavosites
sp. B., Lobocorallium vaurealensis (Twenhofel), and Bodophyllum (?) sp.
in the lower assemblage, and * Paleofavosites capax (Billings), Propora
sp. aff. P. speciosa (Billings), Catenipora sp. and Lobocorallium
vaurealensis (Twenhofel) in the upper assemblage. Several of the White
Head species are common to Late Ordovician rocks of Anticosti Island,
Quebec. [original summary]</ABSTRACT>

Gulf of St. Lawrence, Quebec.</TITLE>
23682 <SOURCE>Paleontological Society Memoir 41 (Journal of Paleontology 60,
4, suppl.): 35 pp., 14 pls, 5 figs, 1 table.</SOURCE>
23683 <ABSTRACT>New collections, as well as original type material, of Lower
and Middle Ordovician sponges from the Mingan Island Archipelago are

described and figured from the Mingan and Romaine Formations. *Archaeoscyphia minganensis* (Billings, 1859), *Hudsonospongia minganensis* Raymond and Okulitch, 1940, *H. irregularis* Raymond and Okulitch, 1940, *H. duplicata* Raymond and Okulitch, 1940, *Zittlella varians* (Billings, 1861a), and *Eospongia roemeri* Billings, 1861, are redescribed from original type specimens and new collections. The species *Archaeoscyphia pulchra* (Bassler, 1927), *Rhopalocoelia clarkii* Raymond and Okulitch, 1940, *Psarodictyum magnificum* Raymond and Okulitch, 1940, and *Lissocoelia ramosa* Bassler, 1927 are reported and described from the Mingan Islands for the first time. To these sponges are added the new species *Anthaspidella amplia*, *Archaeoscyphia undulata*, *Hudsonospongia nodosa*, and *Zittlella grossa*, which are described from type specimens from the Mingan Formation. The assemblage from 12 localities from the Mingan Formation, and one from the Romaine Formation, represents one of the most diverse demosponge faunas from eastern North America. Sponges in most of the localities accumulated as transported debris or lag gravels, but locally, some grew in small reefoidal mounds and also accumulated as adjacent debris. 23707 <TITLE>Enigmatic fossil encrusting an Upper Ordovician rocky shore on Hudson Bay, Canada, is a coral.</TITLE>

23708 <SOURCE>Journal of Paleontology 74, 1: 179-180.</SOURCE>

23709 <ABSTRACT>An enigmatic encruster from the Upper Ordovician rocky shore exposed near Churchill, Manitoba, was recently described by Johnson et al. (1998). The specimen was found attached to a quartzite boulder enclosed in carbonate matrix. The matlike, calcareous fossil consists of densely packed, vertical, cylindrical columns with upward-radiating structures issuing from their centers. It was identified as a new genus and species, *Storeacolumnella hudsonensis*, of uncertain taxonomic affinity but with possible characteristics of sponges and calcareous green algae. In particular, the radiating structures within columns were compared with spicules of a sclerosponge and with the siphon system of siphonous green algae. * We are engaged in a comprehensive study of corals from the locality at which the enigmatic encruster was obtained. Based on material prepared to date, and following an examination of the two thin sections illustrated by Johnson et al. (1998, fig. 3), we can demonstrate that their specimen is a heliolitid tabulate coral. It represents the genus *Ellisites* Dixon, Bolton, and Copper, 1986. 23733 <TITLE>Ordovician lithistid sponges of the Great Basin.</TITLE>
23734 <SOURCE>Dissertation published by Nevada Bureau of Mines and Geology (NBMG) open-file report 94, 1; 140 pp., 16 pls.</SOURCE>
23735 <ABSTRACT>[The introduction into the characters used for classification of lithistid sponges includes a discussion of biospecies- and morphospecies-concepts, as well as morphological and phylogenetic methods in the taxonomy of sponges. Spicule types, skeletal architecture and canal systems realized by the lithistid demosponges are described and illustrated. Further the special problems of taxonomic classification within the polyphyletic **Lithistida**; are summarized. Descriptive systematic paleontology is the major part of this work. All the sponge genera and species investigated belong to the Orthocladina, which have been investigated after thorough statistical analyzes of traditional classification characters such as channel distribution and pore size. The new findings leads to important revisions of the Orthocladina.] Extract from the abstract: Fossiliferous strata with abundant lithistid demosponges were studied at several horizons and localities within the Lower and Middle Ordovician Pogonip Group of the Great Basin. The collection of over 700 excellently preserved lithistid sponges from these localities has allowed a much-needed description and revision of the suborder Orthocladina. The family Anthaspidellida has been redefined to include only those orthoclads with a fairly regular channel disposition and a skeleton typically dominated by dendroclones that horizontally join adjacent trabs. A new family, the Strepsoleidae, has been erected to hold those genera that have a more irregular channel pattern and a skeleton in which polyclonid dendroclones usually connect to each other to traps of different distances from the exterior. The taxonomy of many previously described sponges has also been revised. Four new genera and thirteen species are described.</ABSTRACT>

23759 <TITLE>Borings in solitary rugose corals of the Selkirk Member, Red River Formation (Late, Middle or Upper Ordovician), southern Manitoba.</TITLE>
23760 <SOURCE>Canadian Journal of Earth Sciences 17: 272-277.</SOURCE>
23761 <ABSTRACT>Borings occur in solitary rugose corals from the Selkirk Member of the late Middle or Upper Ordovician Red River Formation in southern Manitoba. They are assigned to *Dictyoporus garsonensis* n. ichnosp., which was produced by algae, and *Trypanites weisei* Magdefrau 1932, made by spionid polychaete annelids. Most, and possibly all, borings occurred while the host corals were alive and in life position. The location and relative abundance of borings support interpretations that unattached curved solitary corals lay with the convex cardinal side in the sediment and the concave counter side facing upward during life, whereas straight conical forms were oriented upright in the sediment. These ichnospecies suggest that host corals lived in very shallow marine environments. [original summary]</ABSTRACT>

23772 <TITLE>Late Ordovician solitary rugose corals of the Stony Mountain Formation, southern Manitoba, and its equivalents.</TITLE>
23773 <SOURCE>Journal of Paleontology 57, 5: 924-956.</SOURCE>
23774 <ABSTRACT>Two large cratonic interior basins, the Williston and Hudson, were situated within the Red River - Stony Mountain Solitary Province, which occupied most of North America during Late Ordovician time. *Helicelasma selectum* (Billings 1865), *Deirocorallium angulatum gunni* n. subsp., *Lobocorallium trilobatum trilobatum* (Whiteaves 1895), and *Bighornia* cf. *B. patella* (Wilson 1926) are known from the Stony Mountain Formation of southern Manitoba. The presence of identical species in Saskatchewan and Wyoming suggests that one assemblage inhabited the Williston Basin. The Hudson Basin assemblage comprises species that also occur in the Williston Basin, species closely resembling Williston Basin forms, and taxa that do not occur in the Williston Basin. Solitary Rugosa within the Red River - Stony Mountain Province in eastern North America are most closely related to those of the Williston Basin. The eastern cratonic margin assemblage includes species that were introduced from the continental interior, species not found in the interior, and the genera *Streptelasma* and *Bodophyllum*, which were restricted to cratonic margin areas of the province. Taxa in

western Canada and northern North America appear to be most closely related to those of the Hudson Basin. Assemblages in the southwestern United States are not known at the specific level, but the presence of Bighornia, Deiracorallium, and triangulate to trilobate species of Grewingkia and possibly Lobocorallium indicates that they belong to the Red River - Stony Mountain Province. Studies of Ordovician solitary Rugosa suggest that cratonic interior basins were centres of evolution, diversification, and dispersion. The Middle to Late Ordovician diversification of Paleozoic corals coincide with the Tiptecanoe transgression, which was the most extensive in the Phanerozoic, and with the initial development of cratonic interior basins, which were characteristic of much of the Paleozoic. These factors may have been important in the Ordovician radiation of the Paleozoic fauna; in general.

23786 <SOURCE>Bulletins of American Paleontology 81, 314: 1-116.</SOURCE>
23787 <ABSTRACT>This study comprises comprehensive taxonomic, paleoecologic, biostratigraphic, and paleobiogeographic analyses of latest Ordovician (Richmondian and Gamachian; Ashgill) solitary rugose corals in eastern North America. The corals are assigned to three provinces distinguished on the basis of assemblages and characteristic species. The distribution of these provinces, as well as taxa within them, was determined by regional environmental parameters related to paleogeography. [initial fragment of extensive summary; described taxa are: Streptelasma divaricans (Nicholson 1875), Grewingkia canadensis (Billings 1862), G. deltensis n.sp., and G. rustica (Billings 1858) in Richmondian of the Province; Helicelasma randi Elias 1981 and Bighornia cf. B. patella (A.E. Wilson 1926) in the Maquoketa Subprovince; Streptelasma rankini n.sp., S. affine (Billings 1865), Helicelasma selectum (Billings 1865), Deiracorallium angulatum (Billings 1862), Grewingkia penobscotensis n.sp., G. pulchella (Billings 1865), Grewingkia sp., Lobocorallium trilobatum vaurealense (Twenhofel 1928), Kenophyllum? sp., Bodophyllum neumani n.sp., Bodophyllum? sp., B. englishheadense n.sp., Bighornia cf. B. patella (A.E. Wilson 1926), and Paliphyllum ellisense (Twenhofel 1928) in the Maritime Subprovince; Streptelasma leemonense n.sp., Streptelasma sp., S. subregulare (Savage 1913), and Bodophyllum shorti n.sp. in the latest Ordovician (?Gamachian) Edgewood Province]</ABSTRACT>

23811 <TITLE>Late Ordovician solitary rugose corals of the St. Lawrence Lowland, Quebec.</TITLE>
23812 <SOURCE>Journal of Paleontology 64, 3: 340-352.
<http://www.jstor.org/pss/1305581></SOURCE>
23813 <ABSTRACT>Two species of solitary rugose corals occur in Late Ordovician strata of the St. Lawrence Lowland. *Grewingkia canadensis* (Billings 1862) appears in the upper part of the Nicolet River Formation (upper St. Hilaire Member) and is far more common in the overlying Pontgravé River Formation. A single specimen of *Streptelasma divaricans* (Nicholson 1875) is known from the Pontgravé River. Their presence confirms that this area is situated within the Richmond Province and that the upper Nicolet River, as well as the Pontgravé River, is Richmondian in age. Solitary Rugosa were introduced to this biogeographic province during an early Richmondian transgression, marked in the upper Nicolet River Formation by a coarser clastic interval. That event permits correlation between the St. Lawrence Lowland in the eastern part of the Richmond Province and the North American type Upper Ordovician (Cincinnatian Series) of the Cincinnati Arch region in the western part of the province. A comparative morphologic, paleoecologic, and biostratigraphic analysis of solitary corals indicates that normal, low-energy conditions were interrupted occasionally by high-energy events (probably storms) during deposition of the upper Nicolet River and Pontgravé River Formations. Water depth increased northwestward in the St. Lawrence Lowland area. Deposition of these siliciclastic prodelta to delta front sediments was generally continuous and the sedimentation rate was usually high because of rapid basin subsidence and comparatively close proximity to the Taconic Mountains. In the western part of the Richmond Province, farther from the source area, carbonate as well as clastic sediments accumulated, periods of nondeposition were more frequent, and the sedimentation rate was relatively low. Corals disappeared from the St. Lawrence Lowland area during the Richmondian, when delta top facies of the Bécancour River Formation succeeded the Pontgravé River Formation due to a glacio-eustatic regression and progradation of the Queenston Delta. - 23876 <TITLE>A Late Ordovician fossil assemblage from an outlier north of Aberdeen. Lake, District of Keewatin.</TITLE>
23877 <SOURCE>Bulletin geological Survey of Canada 321: 1-26.</SOURCE>
23878 <ABSTRACT>A Late Ordovician fossil assemblage is described from limestone of an outlier on the Canadian Shield, north of Aberdeen Lake, District of Keewatin. The megafaunal assemblage includes the coral genera Palaeophyllum, Lobocorallium. Bighornia, Grewingkia, Saffordophyllum, Trabeculites, Calapoecia, Protochiscolithus, Paleofavosites, Tollina, and Troedssonites, and a new species of the cephalopod Armenoceras. Most of the coral species are characteristic of the Churchill River Group of the Hudson Bay area. The conodont fauna includes the biostratigraphically diagnostic species Plegagnathus dartoni s.f., P. nelsoni. s.f. and Belodina profunda, indicating a late Maysvillian to Richmondian age. Three new species of Panderodus are described, but not named formally, and a species of walliserodus similar to Silurian forms is described and discussed. [original summary]

<TITLE>Stromatoporoids and colonial corals hosting borers and linguloid brachiopods, Ordovician of Manitoba, Canada.</TITLE>
<SOURCE>Palaeoworld 19, 3-4: 249-255.</SOURCE>
23917 <ABSTRACT>There have been very few published reports of stromatoporoids

and colonial corals with borings that contain linguloid brachiopods; all are from the Ordovician and/or Silurian in just four areas of eastern Canada and northwestern Europe. Here, we report the discovery of an earlier Ordovician occurrence, in both stromatoporoids and corals, and expand the geographic range of such associations to central Canada. In the Upper Ordovician Selkirk Member of the Red River Formation, southern Manitoba, the stromatoporoid *Stratodictyon* and tabulate coral *Protrochiscolithus* commonly contain cylindrical macroborings representing the ichnogenus *Trypanites*, almost certainly produced by worms. In a few specimens, a small proportion of borings contain single linguloids. The linguloids occur predominantly in borings with relatively large diameters, but their occurrence with respect to boring length and their vertical location within borings are random. They are interpreted as nestlers that occupied vacant borings throughout life. Although some of the borings were covered over by subsequent growth of the host or recolonization of its surface, there is no evidence of embedment structures in stromatoporoids or corals that would indicate interaction of the host with either the borers or linguloids. This is comparable to occurrences in the Ordovician of Manitoulin and Anticosti islands in eastern Canada, in that the linguloids are found within *Trypanites* borings without associated embedment structures. In the Silurian of Anticosti, Gotland, and the Welsh Borderlands, however, some borings were further developed into embedment structures during upward growth of the hosts, indicating that these relationships involved some type of symbiosis. 23928 <TITLE>Endobiotic Cornulitids in Upper Ordovician Tabulate Corals and Stromatoporoids from Anticosti Island, Quebec.</TITLE>

23929 <SOURCE>Journal of Paleontology 84, 3: 518-528.</SOURCE>

23930 <ABSTRACT>Conoidal shells of *Cornulites celatus* n.sp. occur commonly within host coralla of *Propora conferta* Milne-Edwards and Haime, 1851, sensu lato, from the Laframboise Member of the Ellis Bay Formation (Ashgill: Upper Ordovician) at Pointe Laframboise on western Anticosti Island. Examples have also been found at the same locality in the tabulate corals *Paleofavosites* sp., *Acidolites arctatus* Dixon, 1986, and *A. compactus* Dixon, 1986, and the stromatoporoid *Ecclimadictyon* sp., but not in other associated tabulate coral species. Growth interference between the shells and their hosts indicates a commensal relationship. *C. celatus* apparently had a more limited paleoenvironmental range than its principal coral host species, which occurs abundantly elsewhere on the island without its endobiotic partner. The diagnosis of *Cornulites* is emended to include forms having a two-layered shell wall with a distinctive outer layer consistently preserved as prismatic calcite. This new species extends the known stratigraphic range of cornulitids in commensal relationships with corals and stromatoporoids from the Silurian back to the Upper Ordovician. 23954 <TITLE>Paleobiologic and evolutionary significance of corallite increase and associated features in *Saffordophyllum newcombae* (Tabulata, Late Ordovician, southern Manitoba).</TITLE>
23955 <SOURCE>Journal of Paleontology 74, 3: 404-425.</SOURCE>
23956 <ABSTRACT>Saffordophyllum newcombae Flower, 1961, displays unique abilities and an unprecedented range in types of corallite increase. Cerioid growth was characteristic, but colonies on soft substrates could grow in a tollinaform manner during early astogeny. The capacity for recovery from damage and partial mortality is amazing. Rejuvenation may have been accompanied by peripheral expansion in some cases. Rapid regeneration could involve axial increase. Circular lacunae that formed during recovery became sites of rapid lateral increase or corallite decrease. * Two types of axial increase occurred within coralla. Lateral increase was concentrated mainly along the basal wall and adjacent to certain circular lacunae. In typical cerioid parts of the corallum, lateral increase seldom yielded "adult" corallites, but incipient lateral offsets could be numerous. The level of colony integration was probably moderately high. There was likely soft-tissue continuity among polyps, coordination of polyp behavior, subjugation of individuals for the good of the colony, and perhaps astogenetic control. * Saffordophyllum newcombae is considered to be a tabulate coral, although one type of axial increase is similar to that in a few rugose corals and the other type of axial increase as well as possible peripheral expansion resemble modes of increase in some coralline sponges. Lateral increase is considered compatible with cnidarian rather than poriferan biology. Corallite size is typical of tabulates. Saffordophyllum may not be the direct ancestor of favositid tabulates, and may not even be closely related to them; S. newcombae is very different from Paleofavosites and Favosites. * The remarkable range in forms of increase discovered in S. newcombae demonstrates the critical need for detailed paleobiologic studies, if we are to understand the early evolutionary history of corals and to establish reliable criteria for distinguishing various coral groups and homeomorphs. 23967 <TITLE>Paleobiologic features of *Trabeculites maculatus* (Tabulata, Late Ordovician, southern Manitoba).</TITLE>
23968 <SOURCE>Journal of Paleontology 78, 6: 1056-1071.</SOURCE>
23969 <ABSTRACT>Detailed analysis of certain growth characteristics in *Trabeculites maculatus* contributes to an understanding of the paleobiology and phylogeny of early tabulate corals. Some coralla of *T. maculatus* contain peculiar, vertically oriented cylindrical lacunae (open areas) that are lenticular, or in one case circular, in cross section. The nature of these structures and their relation to adjacent corallites suggest that they were formed by the coral in response to soft-bodied biotic associates of unknown taxonomic affinity. *Trabeculites maculatus* is an unusual tabulate coral featuring both axial and lateral modes of corallite increase. Axial increase was common, often occurring in association with rejuvenation following injury and less commonly involving normal, undamaged corallites. Lateral increase of normal corallites was typical, but this form of increase could also be involved in the termination of lacunae and occurred in response to a divergent growth pattern around the circular lacuna. Corallite decrease was fairly common, usually taking place adjacent to lenticular lacunae but in some cases involving normal corallites not associated with lacunae. Corallite fusion was uncommon; it could be either temporary or permanent. Conspicuous relocation of corallites and restructuring of corallite arrangement generally involved mass rejuvenation and/or regeneration, usually over a large surface area of the corallum. The growth features in *T. maculatus* are fundamentally the same as those in the co-occurring *Saffordophyllum newcombae*, including types of axial increase unknown in other tabulate corals. The basic paleobiologic similarity of these species supports the interpretation that the genera they represent are closely related phylogenetically. The relationship of these taxa to other tabulates, however, remains unresolved.</ABSTRACT>

23980 <TITLE>Life-history strategies of a species of *Catenipora* (Tabulata; Upper Ordovician; southern Manitoba, Canada).</TITLE>
23981 <SOURCE>Lethaia 39, 2: 141-156.</SOURCE>
23982 <ABSTRACT>Detailed study of coralla by transverse serial sections permits the determination and evaluation of life-history strategies (survival and growth characteristics) in response to different physical environments, for *Catenipora foersteri* Nelson, 1836 from the Selkirk Member, Red River Formation, in Manitoba. We recognize various modes of corallite increase: one type of axial increase, four types of lateral increase, and agglutinated patches of corallites in association with normal, undamaged corallites; and one type of axial increase, one type of lateral increase, and temporary agglutinated patches from the recovery processes of corallites damaged by sediment or bioclast influx. In addition, the formation of new ranks by lateral increase is the most effective method for rapid growth of a corallum or for reconstructing part of a corallum damaged by physical disturbances. Fluctuations in the tabularial area of corallites occur in cycles over vertical intervals ranging from 3.20 - 7.90 mm. We consider each cycle to represent annual growth. Average annual growth of three coralla ranges from 4.20- 6.27 mm. According to correlations between annual

growth cycles and other growth characteristics, a high frequency of offsetting is associated with rapid vertical growth. Specifically, annual growth is relatively high in association with episodes of sediment or bioclast influx, probably generated by storms. In some coralla, however, annual growth is highest in the cycle characterized by few new corallites or by extraordinarily high rates of offsetting by normal, undamaged corallites as well as damaged corallites. This suggests that the vertical growth could also be affected by factors other than storm-related disturbances.</ABSTRACT>

23994 <SOURCE>Journal of Paleontology 62, 3: 424-426.</SOURCE>
23995 <ABSTRACT>The early tabulate coral Lamottia heroensis has been identified from the Ion Member of the Decorah Formation (Upper Ordovician) in northeast Iowa. This extends the stratigraphic range of this species upward from Lower Chazyan to Kirkfieldian, and extends the geographic range from the Vermont - New York border area to include the north-central Midcontinent. Thin section and SEM studies strongly support the contention that the longitudinal pattern of alternating light and dark bands observed in corallite walls reflects a primary structural grain rather than a secondary diagenetic feature.</ABSTRACT>

24032 <TITLE>The earliest Helicosalpinx from Canada and the global expansion of commensalism in Late Ordovician sarcinulid corals (Tabulata).</TITLE>
24033 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 215, 1-2: 99-110.</SOURCE>
24034 <ABSTRACT>Spiral embedment cavities that formed around metazoan endosymbionts are preserved in the septa and intercorallite spaces of Columnopora and Calapoecia corals from Manitoulin Island, Ontario. These are the oldest described Helicosalpinx asturiana, and this report extends the range of these trace fossils from the Richmondian (Ashgill, Upper Ordovician) to the Givetian (upper Middle Devonian). The sinistrally coiled traces show regular morphology, suggesting a physiological basis for their shape. Coral growth parameters are not affected by the presence of Helicosalpinx, suggesting that the endosymbiont was not parasitic and not in direct competition for resources with the host. H. asturiana is interpreted as trace fossil evidence of commensalism. Two additional endosymbiotic traces occur in Late Ordovician Columnopora. The particular association of straight, cylindrical Chaetosalpinx with Columnopora is widespread during the Richmondian. A dependent association is suggested to have originated between the endosymbiont and Columnopora prior to the Richmondian expansion and to have continued into the Hirnantian (latest Ordovician). The association between this endosymbiont and host is the earliest known temporally and globally significant inter-metazoan symbiosis. Although host corals, Columnopora and Calapoecia, did not survive the end-Ordovician mass extinction events, both Chaetosalpinx and Helicosalpinx occur in other host corals during the Silurian and Devonian.</ABSTRACT>

24046 <SOURCE>Canadian Journal of Earth Sciences 15, 12: 2006-2020.</SOURCE>
24047 <ABSTRACT>The tetradiids were the most common tabulate coral component of the Ordovician (Caradocian-Ashgillian) sequence in the Manitoulin District, locally abundant enough to form biostromal accumulations. Five species, assigned to four genera, including a new subgenus Paenetradium, are recognized in the section. In sequence, from oldest to youngest, these species are: Tetradium (Tetradium) undulatum n.sp. from the Cloche Island Formation; Rhabdotetradium giganteum n.sp., Paratetradium capella n.sp., and Phytopsis cf. raceiaosum (Raymond) from the Cobourg Formation; and T. algae, or bryozoans, and, in biostrome concentrations, grew in very shallow waters.</ABSTRACT>

24058 <TITLE>Coral microatolls and a probable Middle Ordovician example.
</TITLE>
24059 <SOURCE>Journal of Paleontology 64, 1: 39-43.</SOURCE>
24060 <ABSTRACT>A disc-shaped massive colony of *Tetradium*, from the Middle Ordovician Bobcaygeon Formation in southern Ontario, displays features of a coral microatoll. This is the first pre-Holocene coral microatoll yet described, indicating that some tabulate corals in level-bottom communities were growing as microatolls as do many modern colonial skeleton-secreting organisms. The microatoll therefore is not strictly a Quarternary or even a Cenozoic phenomenon, but has a fossil record that may span most of the Phanerozoic. This indicates that the special conditions necessary for microatoll growth have existed outside of reef environments, and were present before the advent of scleractinian coral reefs. It may be possible to use ancient microatolls to estimate absolute water depth at low tide, thereby providing a means for estimating maximum water depth on a local and regional scale.</ABSTRACT>

</TITLE>
24072 <SOURCE>Canadian Journal of Earth Sciences 32, 9: 1393-1400.</SOURCE>
24073 <ABSTRACT>Tetradiids are common Ordovician fossils in many parts of the world. Their occurrence in the western interior of North America has been noted, but they have never previously been described from this region. *Rhabdotetradium garsonense* n.sp. occurs in the Selkirk Member of the Red River Formation at Garson, Manitoba (Late Ordovician, Maysvillian). This species is characterized by small corallites with diameters commonly 0.6 - 1.1 mm; in transverse sections these are separated from one another or occur in clumps or chains. The variability of corallite arrangement within single coralla of this species illustrates the difficulty of discriminating tetradiid genera. The diagnosis of *Rhabdotetradium* is revised to more clearly delineate the boundary between it and *Paratetradium*, which has corallites arranged contiguously in elongate chains.</ABSTRACT>

24085 <SOURCE>Boletín de la Real Sociedad Española de Historia Natural, Sección Geológica 92, 1/4: 177-186.</SOURCE>
24086 <ABSTRACT>Tetradiid corals are abundant in the uppermost Pooleville Member of the Middle Ordovician Bromide Formation in South-central Oklahoma (USA). The regressional Pooleville Member consists of a series

of stacked peritidal carbonate cycles, culminating in a regional unconformity. The vertical succession of facies in each cycle suggests an on-shore to off-shore transition from intertidal/supratidal desiccated microbial laminites, through bioturbated, poorly fossiliferous marls and micrites, to deeper subtidal fossiliferous marls and grainstones. Tetradiids occurred in the subtidal portion of each cycle. In successive cycles, the subtidal portion was shallower, or closer to shore, than that of the immediately preceding cycle. The highest two cycles contain massive Tetradium, with microatolls confined to the highest cycle. The third highest cycle contains a Phytopsis (bundled tetradiid) biostrome and the next cycle down contains the finely-branching Rhabdotetradium. The occurrence of different tetradiids in successive cycles suggests a bathymetric gradient in tetradiid morphology with massive Tetradium in the shallowest settings and branching tetradiids in deeper settings. Recent scleractinian corals show a similar generalized bathymetric morphology gradient in many Indo-Pacific reefs. Pooleville Tetradium microatolls are the second oldest described metazoan microatolls, the oldest also being Tetradium.

 24112 <ABSTRACT>The new thin-walled vasiform dictyospongid hexactinellid, Tiddalickia manitobensis, is described from the Ordovician Red River Formation at McBeth Point on Lake Winnipeg, Manitoba. Vertical spicule bundles are an outer? part of the wall and horizontal spicule bundles an inner? different level within the wall. Bundle quadrules are only half the size of those in Tiddalickia quadrata Rigby and webby, 1988. A complete anthaspidellid lithistid, Aulocopella winnipegensis Rauff, 1895, is described from a glacial erratic recovered from near Reston, Manitoba. [original abstract]</ABSTRACT>

24150 <SOURCE>Canadian Journal of Earth Sciences 15, 12: 1987-2005.</SOURCE>
24151 <ABSTRACT>A 4 m thick section in the late Ordovician sequence on Manitoulin Island revealed four successively shallowing carbonate environments, each with a distinctive fossil assemblage. The lowermost quieter water, muddy level bottom community was dominated by the brachiopod Zygospira. Next, increased laminar current action attracted smaller colonies of the tabulate corals Tetradium and Columnopora, and locally small banks of corals and stromatoporoids were built up. In the protected shallow subtidal community following, encrusting algae (Girvanella) and upright match-stick Hedstroemia were more important, alongside Columnopora. cup corals, and a diverse association of thick-shelled bivalves and gastropods. The short-term paleoecological succession terminated under turbulent conditions with large colonies of

- Labechia, rugose coral colonies of Cyathophylloides and tabulate corals such as Tetradium forming what is called the wekwemikong biostrome.

- 24176 <SOURCE>Sedimentary Geology 145: 173-187.</SOURCE>
- 24177 <ABSTRACT>Paleontological and lithological studies of a carbonate mound provide the necessary data from which characterizations for that mound or locality can be constructed. These data-based characterizations are convenient mechanism for making qualitative comparisons with other mounds, as has been done in some previous studies that discussed Middle Ordovician (now considered Upper Ordovician) mounds of the Appalachian Basin. Each of these studies had a different focus, including the paleoecology of individual mound localities, issues of ecological zonation, and regional stratigraphical investigation. Quantitative comparisons are precluded among these studies because each mound was sampled using different procedures, resulting in paleontological data sets of dissimilar density and depth. Two mound localities from carbonates of the Upper Ordovician Chickmauga Group (Stones River equivalent) of Jefferson and Blount counties, AL, were chosen for study to investigate the application of random sampling techniques to mound populations in outcrop. One mound from each locality was completely censused to generate population compositional and structural data. The location and higher-level identification of each macrofossil on the surface of these mounds were recorded. These bryozoan-dominated data sets represent the best estimates available concerning the underlying population of mound constructors., dwellers, and occasional " visitors". Rarefaction analysis was used to predict the number of randomly chosen fossils needed to detect the major taxonomic groups from each of these populations. A computer program (TARGET) was written to validate rarefaction predictions by conducting random sampling experiments using census data sets. The program prompts for input of three user-defined variables that set the parameters of a sampling experiment and then throws randomly located sampling boxes at the mound data set, recording the results. Statistical analysis of results from these sampling experiments validated the predictions of rarefaction analysis and led us to employ a conservative approach for sampling

- additional mounds at these localities.</ABSTRACT>

- 24216 <ABSTRACT>These reefs defy the standard paradigm of reef evolution because the microbial framework and limited biota contrast markedly with the highly fossiliferous nature of other Middle and Upper Ordovician examples. Although ostensibly still marine, this indicates an ecologically stressed environmental setting. The Yeoman-Lake Alma transition and many similarly abrupt losses of faunal diversity in epeiric carbonate successions have been traditionally considered to record the onset of hypersalinity. A hitherto overlooked ecological factor is invoked instead: increased water temperature, a phenomenon that could have occurred in tropical epeiric seas when they became more restricted. 24280 <SOURCE>Bulletins of American Paleontology 108, 347: 1-148.</SOURCE>
24281 <ABSTRACT>A distinctive assemblage of colonial corals occurs in uppermost Ordovician (Gamachian) to lowermost Silurian (lower Rhuddanian) strata within the east-central United States. This Edgewood Assemblage is strikingly different from Late Ordovician assemblages that preceded it in other parts of the North American cratonic interior, and differs from the Silurian assemblage that succeeded it. The Edgewood Assemblage existed during an important time of global environmental change and mass extinction. Some of the taxa have an Ordovician character; these include the youngest North American tetradiid, which is among the last representatives of an important Ordovician order. Other taxa represent first appearances of typically Silurian forms: the oldest definite plasmopodid, the earliest North American Halysites, and the first pycnostylid. [first fragment of extensive summary]</ABSTRACT>

24292 <TITLE>Biostratigraphy and biogeographic affinities of latest Ordovician to earliest Silurian corals in the east-central United States.</TITLE>
24293 <SOURCE>In Webby B.D. & Laurie J.R. (eds.): Global Perspectives on Ordovician Geology - Proceedings of the Vith International Symposium on the Ordovician System, University of Sydney, Australia, 15-19 July 1991; A.A. Balkema, Rotterdam]: 205-214.</SOURCE>
24294 <ABSTRACT>Uppermost Ordovician (Gamachian) to lowermost Silurian (lowermost Llandovery) strata in the east-central United States contain a distinctive association of corals, the Edgewood Assemblage. This assemblage is dominated by solitary Rugosa of the genus Streptelasma. Other Rugosa, including the solitary forms Keelophyllum, Grewingkia, and Bodophyllum, and colonial forms Pycnostylus and Palaeophyllum, are rare. The solitary rugosans were evidently derived from species previously restricted to the North American continental margin, and are similar to those in the Dalmanitina Beds (Hirnantian) or possibly lowermost Llandovery beds of Ostergotland, Sweden, and the Guanyinqiao Beds (Hirnantian) of Guizhou Province, China. Among the Tabulata, Paleofavosites, Propora, and Halysites are most common. Catenipora, Aulopora, Rhabdotetradium, Protaraea, Acidolites, and Plasmopora are rare. Closest affinities are with tabulates in the Ellis Bay (Gamachian) and Becscie (uppermost Gamachian-lowermost Llandovery) formations of Anticosti Island and the Grande Coupe beds (Ashgill), Matapedia Group, of Gaspé Peninsula, Quebec. The Edgewood Assemblage and succeeding Silurian coral assemblage are useful for age determination and correlation of Gamachian to lower Llandovery (Rhuddanian) strata in the east-central United States.</ABSTRACT>

24305 <TITLE>Coral Diversity, Ecology, and Provincial Structure During a Time of Crisis: The Latest Ordovician to Earliest Silurian Edgewood Province in Laurentia.</TITLE>
24306 <SOURCE>Palaios 13, 2: 98-112. <http://www.jstor.org/pss/3515483></SOURCE>
24307 <ABSTRACT>The latest Ordovician to earliest Silurian Edgewood Province in the cratonic interior of Laurentia contained a post-extinction coral fauna. These corals inhabited a broad range of shallow-marine, carbonate environments. Diversity generally increased along a gradient from restricted, low-energy, relatively turbid conditions, to open, high-energy, low-turbidity conditions. Changes in diversity involved progressive addition or subtraction of stenotopic species within a single association dominated by opportunistic, ecologic generalists. Patterns and trends in diversity, abundance, and distribution reflected locally variable environmental parameters and an overall gradient from the continental interior toward the open ocean. Structural characteristics of the Edgewood Province differed from those of Late Ordovician pre-extinction and Early Silurian recovery faunas in the Laurentian cratonic interior. These included the low total diversity, the abundance and strong dominance of a single, solitary rugosan species, and the lack of distinct, specialized, recurring species associations. The origin, overall structure, and fate of the province were determined by factors operating on a broad scale. Nutrient enrichment and related environmental destabilization in the Laurentian epeiric sea during the end-Richmondian regression were probably significant factors in extinctions among Late Ordovician "perched faunas"; including corals. This would have occurred as nutrients provided by runoff from expanding terrestrial areas became concentrated in the shrinking sea. During the Gamachian and early Rhuddanian, elevated nutrient levels and environmental instability within the small sea were likely instrumental in maintaining the structure of the Edgewood Province. By the late Rhuddanian, transgression had expanded the sea and reduced the effects of runoff sufficiently to permit the Silurian recovery of corals.</ABSTRACT>

24333 <ABSTRACT>Acidolites Lang, Smith and Thomas occurs in upper Middle and Upper Ordovician, Lower and lower Middle Silurian rocks of Ontario and Quebec. On Anticosti Island, Quebec, the genus is represented by A. tenuis (Billings) in the Upper Ordovician (Gamachian) Ellis Bay Formation; the new species A. arctatus, A. compactus and A. helianthus in the Ordovician-Silurian boundary beds at the top of the Ellis Bay Formation; the new species A. arctatus, A. compactus and A. lindstromi in the lower Llandoveryan Becscie Formation; A. arctatus in the mid-Llandoveryan Gun River Formation; and an unnamed species in the upper Llandoveryan Jupiter Formation. The lower Llandoveryan Clemville Formation of the Gaspé Peninsula, Quebec, contains Protaraea clemvillensis Park, now considered to be Acidolites. The upper Middle to lower Upper Ordovician Cobourg Formation near Ottawa, Ontario, contains A. cf. arctatus, formerly included in Protaraea vetusta (Hall). The lower Wenlockian Amabel Formation in southern Ontario contains a species of Acidolites as yet unnamed.</ABSTRACT>

24357 <TITLE>New information on latest Ordovician to earliest Silurian solitary rugose corals of the east-central United States.</TITLE>
24358 <SOURCE>Oklahoma Geological Survey, Bulletin 145 [Chaplin J.R. & Barrick J.E. (eds.): Special Papers in Paleontology and Stratigraphy - A Tribute to Thomas W. Amsden]: 113-125.</SOURCE>
24359 <ABSTRACT>New information on latest Ordovician to earliest Silurian solitary Rugosa of the east-central United State is of biostratigraphic, paleoecologic, and paleoenvironmental significance. The distribution of these corals indicates an age of Early Llandoveryan for the youngest strata of the Keel Formation in south-central Oklahoma. Basal beds of the Cochrane Formation, which overlies the Keel, are evidently diachronous, ranging in age from the Early Llandoveryan to late Early or younger Llandoveryan. In west-central

Illinois and northeastern Missouri, solitary corals indicate that the Bowling Green Dolomite is a discrete unit that is younger than the Noix Limestone and Bryant Knob Formation and the Cyrene Formation, which is a lateral facies equivalent of the Noix-Bryant Knob. In northeastern Illinois, *Streptelasma subregulare* occurs beneath a bed containing Early Llandoveryan graptolites in the Schweizer Member of the Wilhelmi Formation. That coral has a range of Gmachian to early Early Llandoveryan, and it remains a possibility that Schweizer strata below the position of the graptolite bed are Gmachian in age. Coralla of *S. subregulare* are abundant on several beds immediately above stromatolites in the basal Wilhelmi at one locality, suggesting that the species could live in very shallow water and thrived when normal marine conditions appeared during the latest Ordovician-earliest Silurian transgression that brought seawater over the eroded surface of the underlying Maquoketa Group. Directional orientations of those coralla indicate currents from the south and possibly southwest. Data from the Mosalem Formation in northwestern Illinois and eastern Iowa confirm that solitary rugose corals of the Edgewood and Silurian assemblages do not co-occur and that the Edgewood assemblage was succeeded by the Silurian assemblage. </ABSTRACT>

24370 <TITLE>Rugose coral morphology during time of crises: the latest Ordovician to earliest Silurian Edgewood Province in Laurentia.</TITLE>

24371 <SOURCE>Bulletin of the Tohoku University Museum 1 [Proceedings of the 8th International Symposium on Fossil Cnidaria and Porifera]: 034-040.</SOURCE>

24372 <ABSTRACT>Analysis of the post extinction Edgewood rugosan fauna reveals that basic morphologic patterns related to the latest Ordovician mass extinction are similar to those for the Late Devonian and latest Permian mass extinctions. Advantageous characters during times of crisis are solitary form, fasciculate colony type, simple morphology, and high variability. Characters associated with susceptibility to extinction are colonial form in general, cerioid colony type in particular, and complex morphology. * Nutrient enrichment and related environmental destabilization in the Edgewood sea probably favored solitary corals and colonies with low integration. Such conditions would have been ideal for the dominant species *Streptelasma subregulare*, a solitary, morphologically simple but extraordinarily variable, opportunistic, ecologic generalist. Solitary and fasciculate corals were perhaps best able to cope with increased movement of sediment, which may have occurred during the latest Ordovician regressive phase. * Within the Edgewood Province, diversity and morphologic complexity generally increased along an environmental gradient from low energy, relatively turbid, restricted conditions, to high energy, low turbidity, comparatively open conditions. Only species that produced morphologically simple skeletons were able to survive in restricted, presumably stressful conditions. The more complex coralla of species confined to favorable open marine conditions may have permitted firmer attachment of polyps and greater polyp activity. This would have been advantageous for survival in higher water energy and for rejection of coarser sediment. The ability of *S. subregulare* to produce a wide range of morphologies suitable for survival throughout the environmental gradient was evidently instrumental in its success during this time of crisis. 24397 <SOURCE>Contr. Biol. Geol. Milwaukee Public Museum 61: 1-95.</SOURCE>
24398 <ABSTRACT>Twenty species of colonial rugose and tabulate corals from the Late Ordovician Ely Springs Dolomite of the Eastern Great Basin in Nevada and Utah are described. Included are two new tabulate species. Agetolites budgei and Catenipora sheehani. The colonial corals from the basal Ibex Member include Calapoecia anticostiensis and Nyctopora sp. Colonial corals from the Lost Canyon Member are Calapoecia anticostiensis, Paleofavosites poulsenii, P. okulitchi, P. sp. cf. P. capax, P. mccullochae, Palaeophyllum sp. cf. P. radugini, P. gracile, P. humei, ? Billingsaria parvituba, Agetolites budgei n.sp., Catenipora workmanae, C. sp. cf. C. foersteri, and Tollina sp. Colonial corals from the Floride Member include Calapoecia anticostiensis, C. sp. cf. C. coxi, Paleofavosites poulsenii, P. mccullochae, P. okulitchi, P. sp. cf. P. transiens, P. sp. cf. P. capax, and ? Billingsaria parvituba. The colonial corals from the Ely Springs Dolomite are characteristic of the 'Arctic Ordovician' faunal belt. [original summary]</ABSTRACT>

24409 <TITLE>Late Ordovician and Early Silurian stromatoporoid sponges from Anticosti Island, eastern Canada: crossing the O/S mass extinction

- boundary.</TITLE>
- 24410 <SOURCE>NRC Research Press, Ottawa, 163 pp., 28 text-figs., 28 pls. ISBN 13 9780660199306</SOURCE>
- 24411 <ABSTRACT>During Late Ordovician and Early Silurian time, from 450 to 428 million years ago, stromatoporoid sponges were some of the most common and abundant fossils in shallow water tropical settings of the Anticosti Basin (Gulf of St Lawrence). They formed dense, massive coralline skeletons of calcium carbonate, some up to a meter or more across, especially in reef environments, but also in deeper waters of the Anticosti shelf, down to the margins of the photic zone, where light faded. The Anticosti Basin reveals one of the most fossiliferous carbonate sequences worldwide for rocks of this age, straddling a global mass extinction boundary, and thus revealing not only those taxa that became extinct, but also how the seas were repopulated in an equatorial setting after the mass extinction. The mass extinction has been correlated to globally cooling climates of the time, and southern hemisphere glaciation in North Africa. This monograph describes, for the first time, the skeletal architecture of these abundant and exquisitely preserved sponges from Anticosti, and includes more than 300 skeletons selected from ca. 2000 field localities [3000 skeletons from 200 localities?!], assigned to 14 genera, of which 4 are new, and 35 stromatoporoid species, of which 18 are new. These are illustrated by 56 figures and plates and fill a major gap in our global knowledge of the reef building stromatoporoids, especially during the Early Silurian and latest Ordovician. All materials are precisely geographically and stratigraphically defined from the Vaureal through Chicotte formations over a nearly a kilometer thick section, and their ecologic distribution plotted across shallow to deeper water facies. Oil and gas exploratory drilling in the Gulf of St Lawrence will ultimately reveal what happened in the deeper water offshore facies, not exposed on Anticosti Island itself. - 24424 <ABSTRACT>Bioerosion was a significant process in the destruction of reef-building skeletons in early and mid-Paleozoic marine carbonate settings. Ordovician-Silurian corals and stromatoporoids from Anticosti Island show a limited diversity of macroborings, dominated by Trypanites, but also includes rare of an Ordovician bivalve boring (Petroxestes pera), described for the first time in Early Silurian stromatoporoids. Two problematic embedment structures, one containing lingulid brachiopods, resemble borings but did not contribute to bioerosion. The distribution of the embedment structures and Petroxestes pera are restricted by facies and skeletal substrate. Trypanites is relatively nonspecific, occurring in reef and off-reef facies and in most skeletal substrates; it does not appear to have been affected by the Late Ordovician mass extinction.</ABSTRACT>

24435 <TITLE>Encrusting corals on a latest Ordovician to earliest Silurian rocky shore, southwest Hudson Bay, Manitoba, Canada.</TITLE>
24436 <SOURCE>Geology 15: 15-17.</SOURCE>
24437 <ABSTRACT>Paleozoic tabulate corals are generally thought to have been free standing, with flattened disc-shaped to dome-shaped morphology providing a degree of stability in shallow-water, high-energy environments. The ability to encrust has previously been suggested by patterns of competitive overgrowth in certain species. Definitive proof of encrustation by favositid corals is exhibited in an extraordinary example of an ancient rocky shore exposed for 350 m on Hudson Bay near Churchill, Manitoba. Carbonate strata attributed to the Upper Ordovician Port Nelson or Lower Silurian Severn River Formation locally transgress a massive Precambrian quartzite. An ancient shoreface is clearly marked by large, smoothly eroded boulders of the dark quartzite, commonly 2-10 m in diameter. The boulders are buried in coarse carbonate debris, but corals up to 20 cm in diameter are found cemented directly onto the surface of some boulders. Deep pitting of many boulders to a depth of 2-3 cm was contemporaneous and may have been promoted by unpreserved encrusters such as sponges or anemones.

24450 <ABSTRACT>Trypanites is the dominant macroboring in corals and stroms, [40% bored] at the Ordovician/Silurian boundary. Boring frequency increased in denser and higher forms and is postulated to have been directly proportional to water depth. There is no change in boring frequency at the O/S boundary. Denser colonies offer borers greater strength and allow them to avoid lining borings. Skeletons that were buried rapidly are less bored. [abbreviated abstract] </ABSTRACT>

24461 <TITLE>Reefs during the multiple crises towards the Ordovician-Silurian boundary: Anticosti Island, eastern Canada, and worldwide.</TITLE>
24462 <SOURCE>Canadian Journal of Earth Sciences 38, 2: 153-171.</SOURCE>
24463 <ABSTRACT>Multiple latest Ordovician (Rawtheyan-Hirnantian) glaciations in central Africa, with concomitant global sea-level lowstands and cooler, restricted, equatorial carbonate shelves and ramps, interrupted by warmer interstadial highstands, had a dramatic global impact on the

tropical shallow-water reef ecosystem and carbonate production. With the Ordovician-Silurian boundary strata on Anticosti Island as a global standard for a carbonate shelf-ramp setting, the latest Ordovician and earliest Silurian reveal three reef phases, ended by three extinctions. The first extinction, towards the end of the Rawtheyan, affected the last *Richmondian*-type reefs (Vaureal Formation, Mill Bay Member). The second extinction was less pronounced, ending with reefs at the base of the Prinsta Member (Ellis Bay Formation), interpreted as the top of the *Normalograptus extraordinarius* graptolite subzone. The third and most severe extinction phase capped the Laframboise patch reef complex (Ellis Bay Formation), at the top of the *Normalograptus persculptus* Zone. In the paleotropics, the Hirnantian interglacials showed higher biodiversity than either the preceding Rawtheyan or following Rhuddanian (early Llandovery) warm intervals, a feature perhaps achieved by high innovation rates via introduction of *Silurian* reef biotas during the Hirnantian. The Anticosti reef succession is compared with latest Ordovician reefs from northwestern Europe (Baltic Basin and UK), the northwestern margins of Gondwana (Spain and Austria), the Urals, Siberia, Kazakhstan, northeast Russia, and China. Reefs show a global decline from the late Caradoc through late Ashgill, marked by hiatuses towards the O-S boundary. A protracted 3-4 million-year recovery phase for Early Silurian tropical marine biotas, generally without reefs, marked the succeeding Rhuddanian; full reef recovery was delayed until the mid-Aeronian. 24487 <TITLE>Paleoenvironments and paleocommunities in the Ordovician-Silurian sequence of Manitoulin Island.</TITLE>

24488 <SOURCE>Michigan Basin geol. Soc., spec. Pap. 3: 41-61.</SOURCE>

24489 <ABSTRACT>During Middle Ordovician (Caradocian / Blackriverian) to Late Silurian time (Ludlovian / Lockportian) the Manitoulin area on the northeastern fringes of the Michigan Basin were covered by shallow, subtropical to tropical seas. The area was situated south of the paleoequator with a continental landmass composed of weathered, probably hilly, unvegetated Precambrian rock terrain to the North and East. Prevailing long-shore current systems probably moved water counter-clockwise from the Appalachian region as deduced from the presence and thickness of black, green and red shales during Late Ordovician and Early Silurian, and the probable location and size of

paleo-continent. Dominance of carbonate sediments and occurrence of red beds in the sequence, presence of rich calcareous algal flora, stromatoporoid, tabulate and rugose coral fauna, prominent sponge-coral biostromes of the Ordovician, bioherms of the Manitoulin Dolomite (Llandoveryan), biostromes of the Fossil Hill Formation and bioherms of the Amabel Formation (Wenlockian-Ludlowian) indicate equatorial climates and prevailing shallow conditions. Deeper water phases and phases characterized by rapid influx of mud in shallow waters, periodically prevented growth and proliferation of benthic communities. The figures show a reconstruction of the different communities corresponding to the special facial development. </ABSTRACT>

24526 <TITLE>The corals of the Brassfield Formation (Middle Llandovery; Lower Silurian) in the Cincinnati Arch region.</TITLE>
24527 <SOURCE>Bulletins of American Paleontology 75, 305: 1-457.</SOURCE>

- 24528 <ABSTRACT>Fifty-four species of corals (29 rugose, 19 tabulate, 6 heliolitid) have been identified from the Brassfield Formation (limestone, dolomite and claystone of mid-Llandovery [Lower Silurian] age) in the Cincinnati Arch region of the United States. Included are one new rugosan genus (Schizophylactis), four new rugosan species (Streptelasma scoleciforme, Dinophyllum semilunum, Paliphyllum regulare, Pycnactis tenuiseptatus), three new tabulate species (Favosites densitabulatus, Catenipora favositomima, Syringolites vesiculosus), and one new rugosan subspecies Paliphyllum suecicum Neumann 1968 brassfieldense). Coral assemblages of different, apparently environmentally controlled character are concentrated in the north and the southeast parts of the region. The Brassfield coral fauna appears to have been largely restricted to the present Cincinnati Arch region during mid-Llandovery time. Closest affinities on the species level during this period are with the corals of Anticosti Island (Canada). Eight of twelve species pre-date the mid-Llandovery, some existing as early as the Late Ordovician. The oldest members of the Brassfield coral fauna were found in a number of areas throughout the world, rather than in a single ancestral homeland. At least half the coral species survived the end of the mid-Llandovery, and spread into a large portion of the submerged continental areas of the world.</ABSTRACT>

- 24554 <ABSTRACT>The Brassfield Formation is a parcel of dolomite, echinodermal limestone, and silty clay, well-exposed in the vicinity of the Cincinnati Arch (southeast Indiana, southwest Ohio and north-central Kentucky) of the United States. Berry and Boucot (1970) assign it an age of Middle Llandovery, making it one of the oldest Silurian units in North America. * In recent studies of the Brassfield, I have found that it contains a coral fauna of considerable richness, both as to numbers of specimens and taxonomic variety. Of interest is the fact that this is the first appearance in the fossil record of a considerable number of species, which are found later in the Silurian in other parts of the world. [initial part of a short note presenting distribution of Rugosa, Tabulata and Heliolitida within the Brassfield Formation]</ABSTRACT>

</SOURCE>
24580 <ABSTRACT>A recently discovered Silurian reef tract in the high Canadian Arctic has an exposed length of more than 150km and is locally more than 500m thick. The reefs occur within a Silurian ramp and rimmed shelf-margin sequence about 2km thick. Conodont biostratigraphic data indicate that the reefal strata are late Llandovery to Ludlow in age, and reefs are composed largely of coral-microbial boundstone, The corals are mainly digitate rugosans and large halysitids, associated with fewer stromatoporoids and lithistid sponges. However, most of the reefal strata consist of microbialite, which encrusts skeletal metazoans or is massive or thromboidal. Microbialite microstructure consists mainly of clotted micrite or laminated micrite associated with common Renalcis, other calcimicrobes, and locally abundant early marine cements. Other reef rock types include stromatactis-rich lime mudstone, cementstone, zebroid stromatactis-bearing lime mudstone, crinoidal grainstone, and, rarely, stromatoporoid boundstone. The reefs formed on the shelf margin and prograded basinward in three distinct phases during wenlock and Ludlow time. Underlying Llandovery, shelf-margin facies are highly dolomitized and may represent an original stromatoporoid boundstone. Overlying late Ludlow to Pridoli carbonates were deposited on a prograding carbonate ramp, dotted with small coral-stromatoporoid and other biostromes. 24591 <TITLE>Growth rates of Middle Palaeozoic corals and sponges: Early

- Silurian of Eastern Canada.</TITLE>
24592 <SOURCE>Proceedings 8th International Coral Reef Symposium 2: 1651-1656.</SOURCE>
24593 <ABSTRACT>Vertical annual skeletal growth rates were compared for 27 species of tabulate corals, solitary and colonial rugose corals, and two species of stromatoporoid sponges from the shallow water, tropical, biostromal Upper Llandovery Fossil Hill Fm. of Manitoulin Island, northern Ontario. All displayed clear periodicity in density band variations from internal tabulae, cysts, lamellae, septa and pillars, or external annuli, indicating a common environmental growth factor. Growth banding is attributed largely to seasonal cycles: finer circadian growth banding was not observed, lunar peaks were difficult to verify. Growth rates varied from 2 to 9 mm/yr for tabulates, from 4.3 to 27.2 mm/yr for rugosans and 0.8 to 3.1mm/yr for stromatoporoids. Growth rates had a strong genetic component varying generically and architecturally, with rugosans able to grow faster than tabulates, and with stromatoporoids exhibiting the slowest rates. Such rates are comparable to growth rates in some Recent hermatypic scleractinians, suggesting that mid- Palaeozoic corals possessed zooxanthellate symbionts. Stromatoporoids, like living cryptic sponges, possibly lacked symbionts: their growth rates were among the slowest measured.</ABSTRACT>

24604 <TITLE>Guild structure and tiering in a high-diversity Silurian community, Milwaukee County, Wisconsin.</TITLE>
24605 <SOURCE>Palaios 06: 465-478.</SOURCE>
24606 <ABSTRACT>Fine-grained, inter-reef carbonates of the Silurian (Wenlockian) Racine Formation, Milwaukee County, Wisconsin, formed in a generally quiet-water environment below wave base. These strata preserve a level-bottom community which contains 27 guilds and 89 species of skeletal macrofauna. No sedimentary transport of the fauna is apparent, but breakage of shells by predation and reorientation and dispersal of skeletal material by bioturbation are significant taphonomic features. Most suspension-feeding guilds are represented by epifaunal sponges, corals, bryozoans, brachiopods, conocardiids, cornulitids and annelids which occupied a tier from 0 to 2cm above the bottom. This tier was also occupied by a vagile fauna of gastropods and trilobites. Most skeletal material, as determined by point count, was produced by three guilds of suspension-feeding crinozoans which occupied two higher tiers, from 2 to 6cm and 6 to 25cm above the bottom. Soft-bodied burrowers included suspension-feeding worms which fed at the sediment surface and extended to at least 2cm depth, and a lower tier of deposit feeding worms which extended to about 10cm depth. Three guilds of cephalopods represent predators within the community. The brachiopod component of this community represents a typical Silurian "Dicoelosia community"; a type of Silurian assemblage which has been previously characterized as an ecologically simple, brachiopod-dominated fauna. Detailed results from the Racine study suggest that many so-called Silurian brachiopod communities were actually tiered, high-diversity communities dominated by crinozoans.</ABSTRACT>

24631 <SOURCE>University of Iowa, unpublished M.Sc. thesis; 40 pp.</SOURCE>
24632 <ABSTRACT>Coral and stromatoporoid abundance, composition, diversity, and colony shape were studied in this level bottom community, these groups become more abundant as sea level shallows upwards but there is no change in composition or diversity in the sequence. Stromatoporoid height-width ratios increase upsection possibly caused by decrease in sedimentation rate and increase in energy. Stromatoporoid width increases upward throughout the sequence. Stromatoporoid height increases in the lower two-thirds of the sequence possibly caused by increased light, temperature, and longer life spans due to decreased sedimentation.</ABSTRACT>

24644 <SOURCE>Journal of Paleontology 53, 3: 642-650.</SOURCE>
24645 <ABSTRACT>Squameolites dissectus n.sp., Stelliporella cf. S. podolica Bondarenko and other Stelliporella-like corals occur sparsely in biohermal and bioherm flank rocks of the Red Bay Formation on Somerset Island. Heliolitids referable to these genera, although more common in Europe and Asia, have rarely been reported in North America. Two of the stelliporid specimens possess characters that suggest a further assessment is necessary of the status and relationship of the genera Stelliporella wentzel, Derivatolites Bondarenko and Podollites Bondarenko. The morphological variability in these species strongly confirms the need to base new taxa on assemblages rather than single specimens.</ABSTRACT>

24658 <ABSTRACT>A large collection of heliolitid coral from the Silurian Limestone Point Formation and La Vieille Formation of northern New Brunswick is described. They include at least seven species. Two species of Propora, two species of Plasmopora and three species of Heliolites are recognized, of which several are new in North America and one new species of Heliolites is erected. Analysis of variance statistics on detailed measurements of morphological parameters used in taxonomy, based on a series of sections cut through selected colonies, indicate that any random section except that cutting the most juvenile stage of growth will provide a good estimate of the colony mean and variance for each parameter.</ABSTRACT>

24669 <TITLE>Upper Silurian Heliolitine corals, Canadian Arctic: Taxonomic method, keys to identification, and biogeographic relationships.</TITLE>
24670 <SOURCE>Journal of Paleontology 73, 6: 1002-1014.</SOURCE>
24671 <ABSTRACT>Taxonomy of heliolitine corals, and tabulate corals in general, benefits from analysis of larger assemblages of coralla that approximate populations. Quantitative data derived from such assemblages allow intraspecific variation to be tested rigorously and illustrated, and similar, co-occurring species to be discriminated using normal patterns of continuous population variation. Field collection and analysis necessarily involve recording and comparing assemblages from the full spectrum of sedimentary facies available at any one stratigraphical level and from the maximum available stratigraphic range. The large published taxonomic literature on heliolitine corals is a daunting obstacle to identification at the species level because a substantial part appears to involve taxonomic splitting to a degree inconsistent with variation known in modern coral species. The heliolitine corals studied occur in Ludlow-age ramp and shelf carbonate facies in the Boothia Uplift region in the southern Arctic archipelago of Canada. The population approach resulted in discrimination of 18 morphotaxonomic species, belonging to five genera and four families. A few select morphologic characters, incorporated in simple identification keys, are particularly helpful in distinguishing the 11 heliolitid and four stelloporellid species present, and are useful in screening the voluminous literature on species of Heliolites. Six of the species compare closely to Silurian species reported from central Kazakhstan, west Siberia, and Northern China; few are shared with other regions. The principal affinities are consistent with occurrence in the Uralian-Cordilleran paleogeographic region in the Silurian northern hemisphere. Eight species do not appear to be recorded in published literature elsewhere and are apparently endemic.</ABSTRACT>

24683 <SOURCE>Journal of Paleontology 64, 1: 44-60.</SOURCE>
24684 <ABSTRACT>The Early to Late Silurian sedimentary rocks of the Limestone Point and La Vieille Formations of Northern New Brunswick and the Anse a Pierre-Loiselle, La Vieille, and Gascons Formations of the Gaspé Peninsula possess diverse and abundant tabulate coral faunas that include six species of Heliolitidae distributed among Heliolites and Stelligiporella. Two species, Heliolites laxus and Heliolites distinctus are new. A revised concept of the genus Heliolites is proposed. The Heliolitidae from this region show a substantial degree of endemism and are most similar to northern European faunas. * The distribution of individual heliolitid species was under a high degree of facies control. The heliolitids are more restricted in distribution than are other groups of Tabulata in this region and are most abundant in open shelf and carbonate bank facies.</ABSTRACT>

24695 <TITLE>Species Definition in Heliolitine Corals of the Lower Douro Formation (Upper Silurian), Canadian Arctic.</TITLE>
24696 <SOURCE>Journal of Paleontology 63, 6: 819-838.</SOURCE>
24697 <ABSTRACT>Specimens representing Heliolites diligens Bondarenko 1966, H. aff. H. luxaboreus Yang 1978, and H. tchernyshevi Bondarenko 1966, are common and Heliolites sp. and Stelligiporella sp. are rare in diverse coral assemblages associated with lithistid sponge reefs in deep shelf or ramp limestone facies of the Douro Formation. Heliolites diligens, a more widely adapted, possibly opportunistic species, occurs abundantly in lower diversity stromatopoid / coral assemblages from nonreefal, shallower shelf limestone facies. Detailed systematic study of approximately contemporaneous populations of these Ludlovian heliolitid species shows that all are morphological variable; assessment of this variability qualitatively and quantitatively is critical to species definition and recognition. Heliolites diligens is the most variable, with wide intercolony variation in septal development, corallite wall configuration, and spacing of horizontal skeletal elements. This apparently represents morphological plasticity rather than differences that can be ascribed to distinct species. Conspicuity of the more extreme and dissimilar variants can be inferred from study of large assemblages of coeval specimens. The other species, with more narrowly defined, discrete variation fields, are more readily distinguished from each other.</ABSTRACT>

24708 <TITLE>Heterochronic evolution in the *Heliolites* interstinctus-decipiens lineage of the Chaleur Bay region, eastern Canada.</TITLE>
24709 <SOURCE>Lethaia 23, 1: 11-20.</SOURCE>
24710 <ABSTRACT>A study of the *Heliolites* interstinctus-decipiens lineage from the Silurian of the Chaleur Bay region, eastern Canada, indicates that most morphological characters of this lineage, including tabularium diameter, coenenchymal tubule diameter and corallite spacing, remain relatively invariable through a Llandovery to Pridoli interval of about 20 million years. In contrast, septal development and corallite wall crenulation show pronounced evolutionary changes due to heterochrony, as shown by comparison of astogenies throughout the lineage. The reduction of septa and the replacement of crenulate corallites by smooth ones in the *decipiens* type descendent appear to have been by paedomorphosis from the *interstinctus* type ancestor. The problems of speciation in this lineage are discussed including the alternative hypotheses of a speciation event in the early Ludlow or a phyletic trend within a single species whose longevity is due in part to the stabilization processes of niche separation.</ABSTRACT>

24721 <TITLE>Silurian Proporidae and Plasmoporidae (Anthozoa, Tabulata) from the Chaleurs Bay Region, Canada.</TITLE>
24722 <SOURCE>Journal of Paleontology 64, 2: 184-199.</SOURCE>
24723 <ABSTRACT>Six species belonging to the families Proporidae and Plasmoporidae occur in the Lower and Upper Silurian rocks of the Limestone Point and La Vieille Formations of northern New Brunswick and of the Anse a Pierre-Loiselle, La Vieille, and Gascons Formations of the Gaspé Peninsula of Quebec. The three species of Propora are widely distributed but show varying faunal affinities, while both species of Plasmopora, *Plasmopora logani* and *Plasmopora corrugata*, are new and are almost endemic. Revised concepts of Propora and Plasmopora are proposed. The holotype specimen for the type species of *Camptolithus* was examined and confirms the genus as distinct from Propora, rather than a synonym as has been previously suggested. * The facies distribution of these corals is variable. In general, the proporids, which mostly occur in facies indicating shallow carbonate banks and patch reefs, are more restricted in distribution than the plasmoporids, which occur in these facies and also in others representing a variety of open-shelf environments.</ABSTRACT>

- 24735 <SOURCE>Palaios 8: 18-30.</SOURCE>
- 24736 <ABSTRACT>Heliolitine corals occur in the Ludlow-age Douro Formation on Somerset and neighboring islands. The corals occur in argillaceous carbonate rocks deposited on a regionally extensive ramp. Contemporaneous coral assemblages from different areas show marked differences in community characteristics that reflect a range of paleoenvironments, some more suited and others less suited to the heliolitines. Some of the paleoenvironmental differences are implied more strongly by the coral assemblages than by regionally subdued variations in enclosing carbonate facies. Optimal conditions for heliolitine corals in the region were apparently in a mid-ramp position, as suggested by numerically abundant, diverse, low-dominance species assemblages, with a greater proportion of flat-based and discoid colonies. These grew more rapidly and to larger sizes, had greater longevity, and show less growth interference from sedimentation than contemporaneous assemblages elsewhere in the formation. Variations in growth form in different species suggest differences in the relative importance of inheritance and environment as controls.</ABSTRACT>

<http://www.jstor.org/pss/1306476></SOURCE>
- 24749 <ABSTRACT>Heliolitine corals are closely associated with lithistid sponge-dominated reef mounds in Ludlow carbonate ramp facies on Somerset Island. The corals occur abundantly in argillaceous, fossiliferous wackestone immediately flanking and capping the reef mounds, less commonly in calcilutite mudstone within the reefmounds, and with sharply decreasing abundance in nodular argillaceous wackestone to mudstone away from the reef mounds. Exhaustive field collection, and systematic study that included biometric analysis of collected assemblages, indicates that ten heliolitine species are present, including the new species *Heliolites furyi*, *H. garnieri*, and *H. greineri*, and two unidentified species, *Heliolites* sp. A, and *Podollites?* sp. The occurrence of *H. subdecipiens* Klaamann 1984, *H. tchernyshevi* Bondarenko 1966, *H. cf. H. rariformis* Tchi 1976, *Stelliporella* cf *S. podolica* Bondarenko 1971, and *Squameolites anomalus* Tchi 1976 indicates an affinity with Eurasian rather than North American faunas of equivalent age. Many new species have been ascribed to *Stelliporella* since the mid- 1970s; most lack the diagnostic axial structures of the genus and are more appropriately regarded as belonging to *Heliolites*. Newly defined structures termed septal florets occur commonly in *H. garnieri* and very rarely in three other species of *Heliolites*. Effective taxonomic use of septal development requires very careful study because of the degree of intraspecific and intracolony variation in some species.</ABSTRACT>

24773 <TITLE>Fossilized polyp remains in Silurian Heliolites (Anthozoa, Tabulata) from Nunavut, Arctic Canada.</TITLE>
24774 <SOURCE>Lethaia 43, 1: 60-72.</SOURCE>
24775 <ABSTRACT>Calices within a substantially silicified corallum of Heliolites garnieri Dixon, 1996, from the lower part of the Barlow Inlet Formation (Ludlow) on south-western Devon Island, contain what appear to be the silicified remains of soft tissues of coral polyps. These remains apparently represent the peristomal portion of an oral disc, incorporating a symmetrical radial array of 12 spicules (intra-polyp sclerites), and a membrane-like, possibly epidermal structure. These remains, and more non-descript material in a few coralla belonging to two other species of Heliolites, occur at local intra-corallum discontinuities where polyps died, but the surrounding colony continued skeletal construction. Their preservation indicates that, before the organic remains were fully destroyed by decomposition, they were rapidly enclosed and sealed by precipitation of micro crystalline quartz or a precursor, and that the failed calices were capped rapidly by local construction of basal epitheca. Clusters of hollow microspheres were also preserved at these discontinuities, suggestive of micro-organisms with a predilection for sites of tissue decay; these microbial decay agents possibly helped to isolate microenvironments conducive to early precipitation of silica. 24787 <SOURCE>Journal of Paleontology 68, 2: 218-223.
<http://www.jstor.org/pss/1306063></SOURCE>
24788 <ABSTRACT>Several specimens of the small hexactinellid, Cyathophycus mackenziensis n.sp., were collected from pale brown, shaly mudstone of the Road River Formation. The sponges are of Wenlock age and were collected from near Avalanche Lake, Mackenzie Mountains, Northwest

Territories, Canada. The small, steeply obconical sponges have skeletons in crudely ranked quadrules to at least third-order, with first-order openings generally 2mm high and 1mm wide. Successive orders decrease in stages approximately half that of larger elements. A moderately irregular dermal(?) layer with circular parietal gaps is suggested in some specimens. The new species is consistently finer textured than either the type species *Cyathophycus reticulatus* Walcott, 1879, or the later described *Cyathophycus quebecensis* Dawson, 1889.

24812 <TITLE>Upper Silurian lithistid sponge reefs on Somerset Island, Arctic Canada.</TITLE>

24813 <SOURCE>Sedimentology 31: 25-50.</SOURCE>

24814 <ABSTRACT>The Upper Ludlow Douro Formation contains the first reported Silurian sponge reefs. These relatively small (5-35m diameter) mound-shaped structures contain, on average, 35% lithistid demosponges. Reefs are surrounded by irregular haloes of crinoid debris; abundance and diversity of all fossil groups decrease away from the reefs. Each reef is underlain by a lens of crinoid wackestone to grainstone rich in crinoid holdfasts; trepostomate bryozoans, solenoporacean algae and rhynchonellid brachiopods are locally common. The bulk of each reef consists of lime mudstone with abundant lithistid sponges. This is capped by a thin layer of wackestone with abundant tabulate and rugose corals and fewer lithistid sponges, calcareous algae, trepostomate bryozoans and stromatoporoids. This zonation, in which a sponge colonization community was replaced by a coral diversification community, is similar to that reported from some Middle Ordovician, Upper Jurassic and Holocene sponge reefs. * The Douro sponge reefs were relatively low structures, with about 3m maximum topographic relief. They grew on a broad carbonate platform, probably in warm, tranquil, turbid waters of normal or near-normal marine salinity. Periodic influxes of terrigenous mud adversely affected reef size, and caused biotic changes. Some of the reef lime mud was derived from non-reef sources, but significant quantities were also produced on the reefs. Reefs underwent syndimentary lithification, bioerosion and minor storm erosion. Fabrics and compositions of sparry calcite in cavities record three generations of meteoric cementation. Originally siliceous spicules of the lithistid sponges were dissolved and the moulds later filled with sparry calcite. Early dissolution of siliceous spicules is

- common in reef environments, and may have caused fossil sponges to be under-represented in ancient reefs.</ABSTRACT>

- 24852 <SOURCE>US Geol. Survey Prof. Paper 777: 66 pp., 16 pls.</SOURCE>
- 24853 <ABSTRACT>Corals representing 13 families of Silurian Rugosa from limestones and dolomites of the central and southwest Great Basin are described, classified and figured. Coral-bearing Silurian beds of this province occur in two contrasting carbonate rock facies: the eastern dolomite belt and the intermediate limestone belt. A third major Silurian rock suite characterizes the western, or Pacific Border, belt, which extends from the western Great Basin to northern California and southeastern Alaska. * On the basis of rugose corals and associated fossils, the Great Basin Silurian is subdivided as five coral zones, lettered A through E in ascending order. These provisional zones are a result of detailed stratigraphic studies and geologic mapping of reference sections in areas extending from the Inyo Mountains northeastward to the Roberts Mountains and northern Simpson Park Mountains. * Of importance environmentally, as well as with the identification and correlation of Great Basin Silurian, are the large

dasycladacean algae associated with Rugosa. As the genus Verticillopora, these algae appear to have peaked in coral zone D. * Rugose corals of special importance in correlation with distant Silurian rocks are Palaeocyclus, Dalmanophyllum, Kodonophyllum, Mucophyllum, Arachnophyllum, Toquimaphyllum, and the lykophyllids. The closest foreign correlations are with the Gotland section, a Silurian carbonate standard for western Europe. Fairly close similarities are recognized with Silurian of Czechoslovakia and Eastern Australia.

- 24892 <ABSTRACT>Four early Silurian (Llandovery) coral assemblages are present in the type region of the Chaleurs Group. The assemblage Paleofavosites spp.- Acidolites clemvillensis (Parks) occurs in the Clemville Formation; it is overlain by the Favosites forbesi Milne-Edwards & Haime - Heliolites interstinctus (Linnaeus) - Alveolites sp. assemblage in the Anse Cascons Formation. The two upper assemblages are more closely related. The Syringopora compacta (Billings) - Heliolites subtubulatus (McCoy) - H. interstinctus - Phaulactis sp.- Palaeocyclus rotuloides (Hall) assemblage dominates the lower beds of the Anse a Pierre-Loiselle Formation, and is succeeded by S. compacta - Acanthohalysites encrustans (Buehler) - Subalveolites depressus (Parks) - Palaeocyclus porpita (Linnaeus) assemblage in the lower beds of the La Vieille Formation. The wenlock coral Thecia swinderniana (Goldfuss) first appears some 100m above this upper assemblage. [original summary]</ABSTRACT>

24944 <ABSTRACT>Stromatoporoids from the Brassfield Formation (Early Silurian, Llandoverly) near Fairborn, Ohio, provide substrata for a diverse epizoic community. The stromatoporoids were colonized by at least 28 taxa including bryozoans, cnidarians, echinoderms, annelids, and endolithic organisms. Analysis of the occurrence, diversity, distribution and coverage of the epizoans recognized patterns of site-selective attachment. The upper surface of the stromatoporoids has a slightly higher epizoan coverage than the lower surface. Concentric zones outlined from the margin also had differences in area and percent coverage. On their upper and lower surfaces epizoan occurrence decreased from the margin to the interior. Epizoan coverage of the lower surface also decreased inward. On the upper surface the echinoderms were randomly distributed. Bryozoans, cnidarians and miscellaneous taxa including borers, cornulitids and spirorbids were distributed nonrandomly. Over 95 percent of the area analyzed is not covered by epizoans. However, epizoans are commonly clumped or in direct contact with one another. These physical interactions are the result of site-selective attachment by epizoans in close proximity rather than competition for available surface.</ABSTRACT>

- 24996 <ABSTRACT>Tabulate fossils are among the more characteristic fossils of the Silurian period, but because only their skeletons have been preserved, their taxonomic position and mode of life have been uncertain. Although they are generally placed in the phylum Coelenterata (Cnidaria), the recent discovery of living sclerosponges that share architectural affinity with some tabulates, has renewed debate about the evolutionary relationships of the latter. In particular, the tabulates have been assigned to the sponges (phylum Porifera). I report here the discovery of fossilized polyps in a Favosites from the Silurian of Quebec. This incontrovertibly demonstrates that the tabulates belong to the phylum Cnidaria, and details of the soft-part morphology suggest that the Tabulata form a group distinct from other corals. - 25008 <SOURCE>002 Bulletin of Canadian Petroleum Geology 36, 4: 379-387.</SOURCE>
- 25009 <ABSTRACT>The Upper Silurian West Point Reef Complex of Gaspé consists of a variety of mixed carbonate - siliciclastic lithofacies representing, in total, deeper-water basin, shallow shoal, barrier

reef, fore reef, lagoon and intertidal environments of a shallow-water platform. Stromatoporoids, tabulate corals and algae dominate the fossil assemblage. Favositids, halysitids and heliolitids are the most important of the tabulate corals within the complex. Alveolitids and proporids are rare, and most syringoporids occur symbiotically with Stromatoporoids. Five species of Favosites, four of Paleofavosites, three of Heliolites, two of each of Alveolites and Caunopora, and one of each of Halysites, Syringopora, Cladopora, Striatopora, Thamnopora and Propora have been identified. Favositids were generally more tolerant of a wide range of ecological conditions, and Favosites forbesi was the most varied, abundant and tolerant species. It has many of the characteristics of an opportunistic species. Heliolites decipiens had similar ecological distributions except that it is rare to absent in facies representing shallow water, high energy environments. Favosites hisingeri, Paleofavosites epinosus, Halysites nitida and most heliolitid species are commonly associated with deeper-water, mixed siliclastic - carbonate sediments of the open platform but are otherwise rare. Paleofavosites epinosus and Heliolites daintreei are especially characteristic of these deeper-water sediments. Paleofavosites asper is restricted to shallow water limestones and biohermal algal reefs. Cladopora sp. occurs in most facies, but is only common in the limestones of subtidal environments. Syringoporids occur almost entirely as the symbiotic Caunopora in a variety of stromatoporoid-dominated facies. Favosites niagarensis, Paleofavosites epinosus and Heliolites decipiens also occur as transported cobbles in basinal facies. Water energy evidently was important in controlling tabulate coral and stromatoporoid distribution, with tabulate coral preferring calm and stromatoporoids more turbulent conditions.

 25020 <TITLE>Spicules in Silurian Tabulate Corals from Canada, and implications for their affinities.</TITLE>
 25021 <SOURCE>Palaeontology 51, 1: 173-198.</SOURCE>
 25022 <ABSTRACT>Specimens of Favosites from upper Llandovery strata of Anticosti Island show three types of calcite structures, herein interpreted as spicules, preserved within their calices and on top of the last tabula. This is stratigraphically younger material, some 50m higher than fossils described two decades earlier, in which calcified polyps, each with 12 retracted tentacles, were noted. These more recently found structures show striking similarities in form and position to point, collaret and capstan spicules found in the soft tissues of modern pipe corals, i.e. the Octocorallia (Alcyonacea). Where preserved in a distinct pattern on top of the calcite tabulae, the spicular sclerites in Favosites occur in a particular sequence. Twelve individual, or sometimes six pairs of, triradiate point spicules have shrunk to a cirlet near the middle of the calice (resting on the last, outermost, tabula). Surrounding the point spicules are 3-6 cirlets of curved, usually perforated, lenticular collaret spicules; and surrounding these are scattered, much smaller, capstan spicules. The spicules display variability, probably ontogenetic, in their form and relative sizes; and they are more similar in form to calcareous spicules of alcyonacean corals than to those known from calcareous sponges. Structures with 12-fold radial symmetry in Heliolites, originally described by one of us as **septal florets**,

- consist of elements that are considered comparable with the point spicules found in Favosites. They have been recognized in ten species of Heliolites from Silurian (Wenlock-Ludlow) strata in the Canadian Arctic islands. [original abstract]

25033 <TITLE>Reproduction and life strategies in the Paleozoic tabulate coral Paleofavosites capax.</TITLE>
25034 <SOURCE>Lethaia 23: pp ?</SOURCE>
25035 <ABSTRACT>Asexual and sexual modes of colony formation in a tabulate coral Paleofavosites capax are recognized from the early Silurian Gun River Formation of Anticosti Island, Quebec. Colonies produced by asexual fragmentation comprise monospecific "clumped populations ". They are characterized by circular and concave bases, and lack a protocorallite origin of colony growth. Sexually produced colonies, where in situ, are always dispersed and characterized by conical bases with a definite protocorallite point origin of colony growth. Asexual colony formation by fragmentation in P. capax appears to have been an adaptation to a habitat of muddy substrates. Sexual reproduction in this species probably played a minor role but was necessary for the maintenance of gene diversity and long-distance dispersal. A comparison of corallite size distributions between populations demonstrates that intrapopulation variation in the "dispersed population" and the conical colonies in "transported populations" of P. capax is significantly larger than the variation in the "clumped populations ". It is suggested that this difference reflects the two modes of reproduction. The above observations are significant to systematic studies because they show that estimates of species morphologic parameters can be seriously biased even when based on a relatively large sample size from a well-defined population if that population is largely a result of asexual colony formation.</ABSTRACT>

25047 <SOURCE>Canadian Journal of Earth Sciences 27: 1143-1158.</SOURCE>
25048 <ABSTRACT>Diverse Early and Late Silurian tabulate coral faunas occur in the Baie des Chaleurs region. Analysis of relative abundance data of tabulate corals from the Limestone Point and la Vieille formations of northern New Brunswick and the Anse à Pierre-Loiselie, La Vieille, and Gascons formations of the southern Gaspé Peninsula allowed the recognition of three recurrent large-scale biofacies: the Propora-Helioites, Cystihalysites, and Syringopora biofacies. The Syringopora Biofacies lacks the characteristics that would allow a zonation to be produced, but in each of the other biofacies, two zones are erected. These can be applied throughout the Baie des Chaleurs region and may be used for correlation with other areas having faunal

- affinities with this region.</ABSTRACT>

25059 <TITLE>First report of allogeneic fusion and allorecognition in tabulate corals.</TITLE>
25060 <SOURCE>Journal of Paleontology 65: 65-74.</SOURCE>
25061 <ABSTRACT>Adult intercolony fusion occurs in Paleofavosites capax (Billings) and P. asper (d'Orbigny) in the Silurian of Anticosti Island. This represents the first documented example of allogeneic fusion seen in tabulate corals. The occurrence of allogeneic fusion and non-fusion and the documentation of antagonistic behaviour in the same species attest to the presence of some degree of allorecognition specificity, now well established for modern corals, already in these Silurian corals. The implication is that the evolution of allorecognition systems, probably by polymorphism at allorecognition loci, was already well established 400 million years ago in corals. Banding, probably seasonal, appears to be more likely environmentally than genetically controlled.</ABSTRACT>

25073 <SOURCE>Journal of Paleontology 48, 3: 553-555.</SOURCE>
25074 <ABSTRACT>Growth lines and a central junction line seen on the underside of tabulae in silicified Favosites (Silurian, Iowa) are apparently the same as those noted on scleractinian dissepiments. In living genera, these may be equated with the presence of symbiotic algae and life in sunlit water. It is suggested that favositid tabulate corals have analogous growth lines for the same reason.</ABSTRACT>

25086 <SOURCE>Journal of Paleontology 61, 6: 1125-1147.</SOURCE>
25087 <ABSTRACT>A large collection of Silurian halysitids, mainly from the Limestone Point, La Vieille, and Petit Rocher Formations of northern New Brunswick, includes nine species distributed among Catenipora Lamarck, Halysites Fischer von Waldheim, and Cystihalysites Tchernyshev. One species, Cystihalysites belledunensis, is new, and, of the others, half are previously unknown in the Chaleur Bay region and

half have been described before from this area. All species are defined using both qualitative and quantitative data. Statistical analysis of serial sections of a corallum of *Cystihalysites belledunensis* suggests that any random section of a halysitid will yield quantitative data representative of that colony. Preliminary analysis of the relationships between species distributions and stratigraphy and sedimentary associations suggests strong facies-control on the distribution of the four most abundant species. Both *Catenipora simplex* (Lambe) and *Catenipora micropora* (Whitfield) occur mostly in outer shelf facies. *Cystihalysites belledunensis* n.sp. and *Cystihalysites encrustans* (Buehler) never occur together, the former being found in predominantly high-energy inner shelf facies and the latter in the outer shelf facies.

25099 <SOURCE>Journal of Paleontology 65, 5: 715-726.</SOURCE>
25100 <ABSTRACT>The uppermost Lower Silurian and Upper Silurian Gascons and West Point Formations of the Southern Gaspé Peninsula were deposited under a broad range of environmental conditions from deep offshore-shelf to reef facies. Halysitid and auloporid tabulate corals occur in a number of facies and show a high degree of endemism. Two species of Halysitidae and three species of Auloporidae are found in these formations. Both halysitids have been previously described from this region. The auloporids include the new species *Syringopora minuta* and an other species that may represent the first known silurian occurrence of the fletcherillid genus *Pseudofletcheria*. A neotype for the halysitid *Cystihalysites amplitibulatus* (Lambe) is proposed.

25112 <SOURCE>Journal of Paleontology 61, 2: 268-283.</SOURCE>
25113 <ABSTRACT>A large collection of silurian *Syringoporidae*, mainly from the Limestone Point and La Vieille formations of northern New Brunswick, includes one new species and three species previously described from this area. *Syringopora lambei* n.sp. is distinguished from the superficially similar *S. bifurcata* Lonsdale by its larger corallites with much broader axial tubes and less frequent corallite contacts. Similar problems which have existed in the past in the distinction of *S. compacta* Billings and *S. retiformis* Billings can be resolved, as shown in this study, on the basis of the larger, geniculate and densely-packed corallites of *S. retiformis*. All four species are defined using more quantitative data than has previously been applied to syringoporid taxonomy. A new lectotype for *S. compacta*

is proposed. Recognition of epibionts on a corallum of *S. bifurcata* as virtually identical to the *S. bifurcata* epithelial scales; used to distinguish *Syringocalyon* Termier et Termler from *Syringopora* Goldfuss argues strongly against the continued recognition of the former as a separate genus. Preliminary analysis of syringoporid distributions in relation to stratigraphy and sedimentary associations suggests strong facies and paleoenvironmental control on these distributions. For this reason and because of their long stratigraphic ranges, no well-defined biozonal scheme can be proposed at this time. </ABSTRACT>

25151 <SOURCE>Berliner geowissenschaftliche Abhandlungen E18: 243-255.</SOURCE>

- 25152 <ABSTRACT>Astraeospongium is found to form secondary calcareous basal skeletons and thus may be attributed to the morphological grouping " coralline sponges". In A. meniscum, a bowl-shaped sponge with a massive skeleton of octactins, the ontogenetically youngest and still uncemented spicules are found at the upper, concave surface, particularly close to the edge. Towards the bottom, the spicules soon become altered through epitaxial cementation and recrystallization. From this skeletal architecture can be inferred that the soft tissues occupied only the uppermost portions of the basal skeleton. The skeletal structure is in many respects similar to that of the recent Petrobiona massiliana, although the ecological adaptations of the two species are fundamentally different. - 25165 <ABSTRACT>Abundant hexactinellid and lithistid sponges occur in Ludlow (Silurian) platform slope strata of the Cape Phillips Formation, Canadian Arctic Islands. The following are new: in the Anthaspidellidae Miller, 1889, Rhodosispongia simplex n.gen and sp., Climacospongia snowblindella n.sp., and Climacospongia undulata n.sp.; in the Sphaerocladina Schrammen, 1910, Caryospongia tuberosa n.sp.; in the Hexactinellida Schmidt, 1870 Malumispongium? cornwallisi n.sp., of the monospecific superfamily Malumispongium Rigby, 1967. Other previously described sponges recognized in the study assemblage include Hindia sphaeroidalis Duncan, 1879 and Caryospongia juglans Rauff, 1894. These occur in association with abundant Archaeoscyphia sp. in thin, laterally extensive lithistid sponge biostromes which thrive on platform slope sediments during the Late Silurian. Based on the dominant dendroclone forms in the skeletons of these and other genera, Anthaspidellidae can be divided informally into two groups: (i) the polyclonids, possessing complex skeletons built of variable dendroclones types, including I-, X-, and Y-shape dendroclones, and accessory spicules, including rhizoclonal, chiastoclonal, and monactines; and (ii) the monocloneids, possessing simpler parenchymal canal systems and skeletons constructed mainly of I-shaped (amphiarborescent) dendroclones and lacking accessory spicules. The classification, based chiefly on skeletal architecture, suggests two main evolutionary trends in the family. The monocloneids generally maintained structural simplicity, inherited from the probable ancestral monactinellid, whereas the polyclonids evolved a varied and complex skeletal architecture that was more successful. 25215 <TITLE>Paleoecology of framebuilders in early Silurian Reefs
(Brassfield Formation, southwestern Ohio).</TITLE>
25216 <SOURCE>Palaios 17, 3: 237-248.</SOURCE>
25217 <ABSTRACT>The framebuilding fauna of an Early Silurian (Aeronian,
Llandoveryan), Brassfield Formation reef from west-central Ohio is
examined in detail. Brassfield reefs are among the very few Silurian
reefs of the mid-continent United States that are not dolomitized.
Species-level taxa identified in the framebuilding fauna include two
favositid corals, two poropid corals, two halysitid corals, two
colonial rugosan corals and at least four stromatoporoids. Favositids,
crinoid holdfasts, and bryozoans are distributed fairly evenly across
the reef; colonial rugosans and solitary rugosans are more abundant
along the windward side of the reef; and stromatoporoids are more
abundant on the leeward side. The Brassfield reef fauna resembles that
from the Jupiter Formation (Aeronian), Anticosti Island, and the
Manitoulin Formation (Aeronian), Manitoulin Island; however, there are

differences in total diversity and composition. Paleogeographic positioning, local water depth, and access to open-ocean circulation are inferred as reasons for the differences among Aeronian reefs.

25333 <SOURCE>002 Bulletin Canadian Petrol. Geol. 40: 1-23.</SOURCE>
25334 <ABSTRACT>Near Gascoyne Inlet, the topmost Douro and lowermost Barlow Inlet Formations record overall upward shallowing from ramp to shallow shelf conditions. This transitional sequence contains bioherms of various sizes, from small isolated reef mounds 1 to 2m across to larger, compound reef mounds over 50m thick and 60m across, as well as distinctive inter- and pre-reef mound facies. The larger reef mounds show stages intermediate in character between those in sponge-dominated reef mounds of the Douro Formation and in larger stromatoporoid-crinoid-dominated reefs in the Barlow Inlet Formation. 25346 <SOURCE>Palaios 8, 4: 325-338. <http://www.jstor.org/pss/3515264></SOURCE>
25347 <ABSTRACT>The Racine Formation of southeastern Wisconsin contains a diverse reef fauna of Silurian (Wenlockian) age. A collection of more than 10,000 specimens from this fauna includes 191 species and 38 guilds of reef constructors, binders, bafflers and dwellers. Constructors and binders include stromatoporoids, tabulates, rugosans and bryozoans; bafflers include branching tabulates and dendroid rugosans. Only locally do these groups form a skeletal framework, and for the most part, their remains are separated by reef matrix. Reef dwellers are represented by diverse guilds of brachiopods, gastropods, cephalopods, trilobites and echinoderms, and they also include receptaculitids, sponges, solitary rugosans, bryozoans and bivalves. Tiering within the fauna is well developed and probably extended to a height of 1m above reef surfaces. This reef fauna exhibits higher species diversity, greater numbers of guilds and more extensive tiering than Silurian level-bottom communities. Relatively few of its taxa, however, are restricted to Silurian reef environments. Constructors, binders and bafflers in the reef fauna have morphologic and taxonomic parallels in level-bottom communities, as do nearly all taxa of reef dwellers. Higher diversity in the reef fauna is not a function of specialized reef guilds and species, but results from packing of more species into the same guilds which are present in level-bottom communities. In this regard, the Silurian reef fauna differs fundamentally from that of today and reflects the generally low grade of ecologic complexity of the Paleozoic evolutionary fauna.</ABSTRACT>

25372 <SOURCE>International Association of Sedimentologists, Special Publication 23 [C.L.V. Monty, D.W.J. Bosence, P.H. Bridges & B.R. Pratt (eds): Carbonate mudmounds, their origin and evolution]: 151-169.</SOURCE>
25373 <ABSTRACT>Four silurian microbial buildups occur on Ellesmere Island in three main depositional settings: (i) on the edge of a drowned Ordovician platform margin; (ii) on the slope of a progradational platform; and (iii) on, and slightly basinward from, the slope of a backstepped Silurian platform. Buildups in the first setting are up to 1140m thick, 15km wide, and more than 25km in length. Some show a four-part facies succession, indicating upward shallowing through the first three parts, and then deepening in the last. These facies are, from base to top: (i) a sparsely fossiliferous, bioturbated lime mudstone; (ii) a microbial boundstone and microbialite lime mudstone; (iii) a stromatoporoid-rich floatstone and boundstone; and (iv) a microbial boundstone and microbialite-rich lime mudstone. 25384 <TITLE>Lower Silurian (Aeronian) megafaunal and conodont biofacies of the northwestern Michigan Basin.</TITLE>
25385 <SOURCE>Canadian Journal of Earth Sciences 34: 753-764.</SOURCE>
25386 <ABSTRACT>Lower silurian (Llandovery- Aeronian) carbonates of the Burnt Bluff Group, represent a transect along a southward dipping ramp that extends from tidal flat to basin environments. Benthic megafaunas include an ostracod biofacies (tidal flat), stromatoporoid-coral biofacies (very shallow, subtidal), pentamerid, crinozoan and crinozoan-stromatoporoid biofacies (deeper subtidal) and a crinozoan-sponge biofacies (distal ramp and basin). The crinozoan-sponge biofacies which includes diverse small crinoid ossicles, 19 types of siliceous sponge spicules, at least 65 other taxa, has a biota similar to those of silurian continental margins. Megafaunal biofacies indicate an Early Silurian gradient going from the shoreline in the north to water depths of perhaps 60 m in the south. The Burnt Bluff Group contains conodonts of the Icriodella discreta -

- Icriodella deflecta zone as an onshore biofacies with Panderodus, Kockelella, Ozarkodina, Icriodella and Oulodus as an offshore biofacies with Panderodus, walliserodus and Aspelindia. </ABSTRACT>

- 25412 <ABSTRACT>Vertical tension fractures that crosscut proximal flank beds exposed in the Pipe Creek Junior Quarry in north-central Indiana formed during compaction of underlying interreefal carbonate mud, and are commonly filled with well-sorted pisolitic grainstone made up of coated grains ranging up to 1 cm in diameter. Pisolith cortices are petrologically indistinguishable from marine cement between pisoliths, from marine cement lining tension fractures, and from marine cement lining vugs in surrounding flank beds. Isotopic signatures for these components are also consistent (δ13C = -0.6 to 2.3‰ PDB; δ18O = -8.7 to -3.9‰ PDB). In addition, pisolites are present exclusively within tension fractures, and commonly show lateral size grading, with grain size increasing toward fracture interiors. These features show that pisoliths are in fact mobile marine cements that precipitated from Silurian seawater in syndimentary tension cracks that formed soon after deposition of flank beds. Requisite conditions for the formation of such large coated grains include high-energy, shallow-water settings, where sea level is generally coincident with the depositional surface of the reefal complex. This origin supports an interpretation that allochthonous material forming flank beds was predominantly generated immediately upslope on wave-swept platforms, that in situ accumulation of biotic debris was insignificant in the formation of Pipe Creek Junior complex, and that many of the larger Silurian reefal buildups like Pipe Creek Junior throughout the midwestern United States probably had a similar origin.</ABSTRACT>

25423 <TITLE>Silurian pinnacle reefs of the Canadian Arctic.</TITLE>
25424 <SOURCE>Palaios 8: 172-182.</SOURCE>
25425 <ABSTRACT>Silurian pinnacle reefs, the first described in the Canadian Arctic Archipelago, are exposed on Ellesmere and Devon islands. Two main reef trends occur, one of early middle Llandovery to middle Ludlow age and a second of middle Ludlow to Late Silurian or Early Devonian age. Reefs of both phases contain lime mudstone cores: some are stromatolite-rich, and others consist predominantly of microbialite-rich lime mudstone or microbial boundstone. Facies sequences of both reef phases show evidence of upward-shallowing overall, but in the older reefs, isochronous capping facies are dominated either by coral-microbial boundstone, an unusual reef facies for the Silurian, or by stromatoporoid boundstone and floatstone. This difference perhaps reflects variation in wave stress and the apparent ability of a few corals thickly encrusted by, or associated with, microbial boundstone and skeletal algae to withstand greater wave energy than a stromatoporoid-coral-rich reef community.</ABSTRACT>

25438 <ABSTRACT>Reefs of the Lower Silurian Chicotte Formation are the largest and most faunally diverse known on Anticosti Island, Quebec. They reach up to 25m in thickness and 250m in diameter and are present predominantly at two intervals, forming a lower and upper reef cluster. Remnants of bioherms are represented on the present-day wave-cut terrace as 60 to 100m diameter, subcircular erosional depressions known as Philip structures or as outcrop. The bioherms were relatively low structures, with approximately 3 to 5m maximum synoptic relief, some of which developed on hardgrounds and possible paleokarst surfaces of crinoidal wackestone and packstone. Dominant skeletal framework builders and sediment producers within all of the reefs are laminar to low domical stromatoporoids, colonial cerioid and fasciculate rugose corals, colonial tabulate corals, and cryptostome bryozoans. Vertical zonation of reef biota is evident within well-exposed reefs of the lower reef cluster. Three to four stages are recognizable: 1) a low-diversity tabulate dominated pioneering community including large tabulate coral colonies (halysitids and favositids), and few stromatoporoids (clathrodictyids, ecclimadictyids), fasciculate rugosans, large generally monotypic stalked crinoids, and shelly benthos (brachiopods, few ostracodes and trilobites); 2) an intermediate- to high-diversity, mixed tabulate coral-stromatoporoid-dominated reef-core community; 3) a slightly lower diversity stromatoporoid-tabulate coral-dominated climax community with laminar coenitids and alveolitids, and, 4) in a few localities, a capping, low-diversity tabulate coral-dominated (alveolitid and coenitid), and stromatoporoid-bearing community comprising laminar forms. Amelioration of Early Silurian climates, following Late Ordovician glaciation, allowed gradual reestablishment of extensive shallow-water reef growth, by mainly new and increasingly diverse genera and species of metazoans. Reef development within the Chicotte

Formation coincided with global, widespread development of latest Llandovery and earliest Wenlock reefs in subtropical to tropical areas. Chicotte reefs have broad characteristics, in terms of overall biotic composition, vertical successions recognized, and paleogeographic setting, similar to those of equivalent and slightly younger age from intracratonic settings in Baltica (Gotland, Sweden and Estonia) and central and northern Laurentia (Midcontinent, U.S.A.; Hudson Bay, Canada; and North Greenland, Denmark). </ABSTRACT>

25449 <TITLE>Facies and evolution of a Silurian coral microbialite reef complex, Maumee, Ohio, USA.</TITLE>

25450 <SOURCE>J. sediment. Res. A, 64, 4: 711-725.</SOURCE>

25451 <ABSTRACT>Silurian dolomite that crops out in a quarry at Maumee, Ohio, USA, forms a thick reef complex roughly 600m in diameter and about 68m thick. It is composed, in ascending stratigraphic order, of the Lockport Dolomite and the Greenfield Dolomite. The Lockport Dolomite at Maumee contains multistory stromatolite, thrombolite, and coral-microbialite reefs. Such reefs have never been reported previously in this unit in Ohio and Indiana. Thrombolite and stromatolite reefs are interpreted to have formed in a subtidal setting, possibly within a hypersaline lagoon. Wave stress affected the coral-microbialite reefs by limiting the number of metazoans and promoting the formation of fibrous cement inferred to have been marine precipitates originally in the form of magnesian calcite. Thrombolites and stromatolites form 20-60% by volume of coral-microbialite reefs, and they contributed substantially to the syndepositional stabilization of these reefs by serving as binders and encrusters of metazoans, especially branching corals. Such stabilization sharply limited the amount of sediment available for the formation of flank beds next to coral-microbialite reefs. Evolution of the Maumee reef complex (MRC) involved two shallowing upward sequences, each of which was terminated by subaerial exposure. The older interval of subaerial exposure is represented by an intraformational unconformity within the Lockport Dolomite. The younger unconformity at the top of the Lockport Dolomite is correlated with the base of the A-1 evaporite in the Michigan Basin. Parts or all of patterns shown by coral-microbialite reefs and microbialite reefs in the MRC may provide an analogue for better understanding the nature and evolution of pinnacle reefs and patch reefs in the Michigan Basin region and other reefs elsewhere.</ABSTRACT>

25463 <SOURCE>Neues Jb. Geol. Palaeont. Abh. 144, 3: 342-372.</SOURCE>

25464 <ABSTRACT>Analysis of petrology and fossil contents, preservation and diagenesis of Middle Silurian Mississinewa Shale in northern Indiana

suggests interpretation of the depositional history of this lithostrome. Autochthonous dendroid graptolites, sponges, inarticulate brachiopods and algal structures are considered pioneering communities which were cyclically buried by storm or turbidite induced sudden deposition of ultrafine grained carbonate-clastic muds in interreef microbasins. The degree of bioturbation and carbonate removal through early diagenesis under reducing conditions permits reconstitution of individual stages of maturity reached by each biosere prior to subsequent burial. These stages of bioseral resettlement locally determined the development of interreef (Mississinewa), patch reef (Liston Creek) or biohermal (Huntington) facies within the Wabash Formation.

25488 <TITLE>Reef-capping laminites in the Upper Silurian carbonate-to-evaporite transition, Michigan Basin, south-western Ontario.</TITLE>
25489 <SOURCE>Sedimentology 51, 3: 653-668.</SOURCE>
25490 <ABSTRACT>Silurian pinnacle reefs in the subsurface of the south-western Ontario portion of the Michigan Basin display a variety of laminated carbonates (laminites) within predominantly muddy reef-capping facies in the upper part of the Guelph Formation and the overlying A-1 Carbonate of the Salina Group. Laminites, which are limestone, dolomite or partially dolomitized limestones, have a range of morphologies, from simple planar to a variety of wavy and serrated forms. Individual laminae are composed mainly of micrite, microspar or replacive dolomite, and vary internally from isopachous and continuous over the diameter of the core to non-isopachous and often discontinuous. Clotted and peloidal micrite, sometimes defining small knobs and chambers, is interpreted as being microbial in origin and occurs within all types of laminites. Fibrous cement locally comprises laminite clasts in breccias or coats clasts in breccias, and also occurs as spherulites in the interparticle spaces in breccias. Although

similar laminites have been described from elsewhere in the Michigan Basin and interpreted as caliche, travertine and abiotic subtidal stromatolites, the laminites in south-western Ontario are most realistically regarded as microbial. The causes for the variations in morphology and characteristics of the constituent laminae are uncertain, although fluctuations in local microenvironmental conditions would have been important, set against a backdrop of an increasingly restricted overall setting. Caliche or travertine origins for these laminites are unlikely in general, except perhaps locally at the subaerial exposure surface at the tops of pinnacle reefs. [original abstract]

25527 <TITLE>Silurian and Early Devonian Graptolite, Brachiopod and Coral faunas from the Northwestern and Arctic Canada.</TITLE>
25528 <SOURCE>Geological Association of Canada, Special Paper 17: 1-71.</SOURCE>
25529 <ABSTRACT>Emphasis of this paper is biostratigraphic, and illustrations (Pls. 1-4, graptolites; 5-14, brachiopods and two trilobites; 15-44, rugose corals) arranged by faunas and regions, not zoological affinities. Age estimations primarily are based on graptolites and conodonts in Pragian and earlier strata, and on conodonts and a goniatite occurrence in later strata. Ages are argued as much as

possible in terms of the European Hercynian magnafacies stages. Twelve formally defined graptolite zones are recognized in shale facies: nilssoni, leintwardinensis primus Zones (Ludlovian), formosus, bugensius, chelmiensis, bouceki, transgrediens, angustidens Zones (Pridolian), uniformis uniformis, hercynicus Zones (Lochkovian), thomasi and yukonensis Zones (Pragian). The zone of Monograptus thomasi is new. Corals figured are referred to 11 units, which take their names either from associated conodonts, or from their stratigraphic occurrence between conodont or graptolite faunas. In ascending order with approximate stage assignments these are: index associates (early Pridolian), post bugensius and pre transgrediens praecipuus Fauna, and confluens δ associates (middle Pridolian), post index and pre hesperius Fauna (late Pridolian), hesperius associates (early Lochkovian), post hesperius and pre pesavis Fauna (middle Lochkovian), pesavis associates (late Lochkovian), late sulcatus associates (late Pragian), dehiscens associates (early Zlichovian), aff. perbonus associates (late Zlichovian) and serotinus associates (Daleján). In Prongs and Royal Creeks areas, where the best dated coral faunas are mostly allochthonous in debris flows, migrations caused by minor transgressive / recessive cycles considerably affected the composition of the coral faunas. Several forms present have no known ancestors or descendants in other local faunas. Halysitids are not known in Pridolian or later faunas and Lower Devonian heliolitids are extremely rare in the region. Coral provinciality was most marked in Pridolian time, when Yukon faunas were still entirely Silurian, while arctic faunas included obvious Devonian forerunners, and in late Pragian to early Zlichovian time, when the Yukon and arctic faunas continued to be of Old World Faunal Realm aspect, while contemporaneous faunas in Nevada appear to have included forms developed from Eastern North America Realm species. The following taxa are described: Ogilvilasma discors gen. & sp.n., Werneckelasma multiseptata gen. & sp. n., Spongonaria guttata sp.n., and Windelasma werneckensis gen. & sp. n. [extracted from original summary]

- 25554 </TITLE>
<SOURCE>Canadadian Journal of Earth Sciences 17, 6: 788-796.</SOURCE>
25555 <ABSTRACT>Halysitid tabulate corals occur in the Silurian and Devonian rocks of northeastern Gaspé Peninsula, Quebec. Silurian specimens from the Dartmouth River and Madelaine River areas are referred to Cystihalysites. A specimen from a possibly Early Devonian level in the Gascons Formation in the Dartmouth River area is assigned to Cystihalysites. Two specimens from different levels in the Early Devonian part of the West Point Formation in the Madelaine River area are assigned questionably to Quepora. The latter occurrences in the West Point Formation demonstrate that this group of tabulate corals lingered into the Devonian.</ABSTRACT>

25566 <TITLE>Corals from the Turkey Creek Limestone (Lower Devonian), Southern Oklahoma.</TITLE>
25567 <SOURCE>Oklahoma Geological Survey Bulletin 145: 137-159.</SOURCE>
25568 <ABSTRACT>The Turkey Creek Limestone is known from one small outcrop in Marshall County, Oklahoma. This report describes the Turkey Creek corals and puts them into the stratigraphic, ecologic, and biogeographic context established by earlier studies of the brachiopod, trilobite, and conodont elements of the fauna. The corals are compatible with a middle Early Devonian, Pragian age suggested by the conodonts and trilobites, and give some support to a paleogeographic position within the Eastern Americas Realm (EAR) between the Appohimchi and Great Basin provinces on the southern margin of the North American plate. The corals belong to "basinal" genera, but this term is inappropriate for several EAR assemblages of this kind; the term laccophyllid assemblage is recommended for use in discussing Silurian-Devonian faunas. Neaxon amsdeni n.sp., "Stereolasma" sp, and Favosites sp. 1 are described.</ABSTRACT>

25631 <TITLE>Conodonts and corals in kimberlite xenoliths confirm a Devonian seaway in central Ontario and Quebec.</TITLE>
25632 <SOURCE>Canadian Journal of Earth Sciences 37: 1651-1663.</SOURCE>
25633 <ABSTRACT>Eighteen samples containing sedimentary rock xenoliths were obtained from cores drilled into eight Mesozoic kimberlite pipes in the Kirkland Lake area, Ontario and in Ontario and Quebec near Lake Timiskaming. Nine samples from five pipes contained fossils that were used for age determinations. These fossils are Middle or Late Ordovician graptolites, inarticulate brachiopods and conodonts; Silurian and (or) Devonian conodonts; Early Devonian colonial corals; a Devonian stromatoporoid; Early and Middle Devonian conodonts. These fossils provide the first physical evidence for a connection between a Lake Temiskaming "basin" and other Ontario Basins during at least

- part of the Devonian. These strata persisted at least until the Mesozoic before they were removed by erosion. The stromatoporoid is illustrated in longitudinal section and described as [#34](#); The Late Silurian or Devonian multilayered stromatoporoid *Densastroma* sp. This form has short, thick pillars that are highly replaced. [#34](#); </ABSTRACT>

- 25672 <ABSTRACT>A fauna of eight taxa of demosponges and hexactinellid sponges has been collected from the Lower Devonian (Lochkovian) Ross Formation, largely out of the upper Birdsong Shale Member in Benton Decatur, and Perry Counties in west-central Tennessee. The Upper Birdsong Shale ([#34](#); bryozoan zone [#34](#);) in which the sponges are most common appears to have been deposited below normal wave base in a quiet marine environment, and represents a terrigenous clastic sediment influx onto a carbonate shelf that had existed in the area from at least the middle Silurian. Benton Quarry in Benton County was the most productive locality for fossil sponges. The new demosponge genera and species *Ginkgospongia foliata* and *Coniculospongia radiata* occur with the new species *Haplition lobatum* and skeletal mats of fine spicules,

- along with moderately rare specimens of *Hindia sphaeroidalis* Duncan. The new hexactinellid genus and species *Stiodermiella amanita* and *Stiodermiella tetragona* are characterized by peculiar ornamented papillose, swollen spicules that produce a massive, armored layer on the upper part of the sponge. The latter are associated with the new hexactinellid species *Twenhofelella bulbulus*, which has relatively normal-appearing hexactines, and with an indeterminate hexactinellid genus, which has spinose hexactines in irregular orientation in a small, platelike fragment. Root tufts of probable hexactine origin also occur. Swollen spicules in *Stiodermiella* are reminiscent of swollen spicules in the family *Stiodermatidae* Finks, largely from the Permian of western Texas, but elements of the family are also known from Lower Carboniferous to Permian rocks in Europe and North America. </ABSTRACT>

- 25684 <SOURCE>Journal of Paleontology 64, 1: 31-39.</SOURCE>
- 25685 <ABSTRACT>Three remarkable fossil medusoid hydrozoans (*Plectodiscus latinutilus* n.sp.) with disc, topsail, and pendant tentacular appendages were recovered from the latest Late Devonian beds of the Sappington Member of the Three Forks Formation in the Gallatin Range, southwest Montana. This is the first velellid reported from a Paleozoic beach paleoenvironment. Top and underside patterns of these chondrophorine velellids display well-preserved casts and mold imprints in fine siltstone. Outlines of the circular disc and the profile of the wide sail and tentacular structures embedded in soft tissue can be recognized. These floating colonial animals were moved along the southeast shores of the Sappington Basin during a time of eustatic sea level lowering and regression in a tropical setting. Colonies were washed up on the upper beach where they were stranded in the bubbling swash left behind by the surf. The foreshore was constructed of tabular, planar cross-bedded, seaward-dipping, foreset accretionary beds which contain parallel laminations and lime-coated grains. Bedding is inclined 17 to 24 seaward.</ABSTRACT>

- 25696 <TITLE>Biostratigraphy of Frasnian (Upper Devonian) Strata in western Canada, based on conodonts and rugose corals.</TITLE>
- 25697 <SOURCE>002 Bulletin of Canadian Petroleum Geology 46, 4: 515-563.georef/1999022410</SOURCE>
- 25698 <ABSTRACT>A total of 13 conodont zones and 11 rugose coral faunal assemblages currently provides a subdivision of the Frasnian of the Western Canada Sedimentary Basin. The conodont zonation adopted is that first developed in the Montagne Noire area of southern France and subsequently found to have widespread applicability, especially when

supplemented through the use of graphic correlation. The rugose coral faunal scheme is based on the overlapping ranges of species with wide geographic distribution, but with relatively short stratigraphic duration. Integration of these faunal schemes allows for more precise biostratigraphic control and provides a basis for refined correlation of the sequences of basin fill. * As all fossil groups have varying degrees of facies control on their distribution, we do not have conodont and coral biostratigraphic data for all units in the basin. Significant conodont data have been obtained mainly from the margins of the larger bank and reef complexes, rather than their relatively shallow water interiors, and from the basinal strata enclosing them. These data generally support a reciprocal process of reef and off-reef sedimentation throughout the Frasnian. Rugose corals are most commonly developed within the reef and bank complexes (especially the Winterburn Group and equivalents), and particularly near their margins. They are rarer and of less biostratigraphic value in basinal strata. * Some of the more significant formational time spans, expressed in terms of Montagne Noire (MN) Frasnian conodont zones, are summarized as follows. The Beaverhill Lake Group of Alberta ranges from the norrisi Zone of the latest Middle Devonian to lower Zone 5. The succeeding Cooking Lake-Majeau Lake interval is in Zone 5 to possibly lower Zone 6, and the overlying Duvernay Formation extends into Zone 10. The Perdrix Formation in outcrop of the Rockies is largely equivalent in age to the Cooking Lake-Majeau Lake-Duvernay, but locally at least ranges into lower Zone 11. The black/grey shale facies of District of Mackenzie and northeast British Columbia (Canol Formation, Horn River Group) ranges at least as high as Zone 6 and locally as high as Zone 10. The Ireton, Leduc, Peechee, lower Mount Hawk interval of Alberta extends through Zone 11, while most of the Nisku, Arcs/Grotto and upper Mount Hawk lie within Zone 12. The z-marker; within the clastic basin fill of subsurface Alberta lies approximately at the boundary of Zones 11 and 12. In the southern District of Mackenzie and northeast British Columbia, the Jean-Marie Member and equivalents are in Zone 12. Finally, the Blue Ridge, Simla, Kakisa and equivalents lie primarily within Zone 13. [original abstract]

 25722 <TITLE>A new Zlichovian (Early Devonian) species of the rugose coral genus Zelolasma from the Eids Formation of Ellesmere Island, Northwest Territories.</TITLE>

- 25723 <SOURCE>Current Research B, Geological Survey of Canada 83-1B: 195-200.
</SOURCE>
- 25724 <ABSTRACT>Zelolasma sensu stricto, is known from the Pragian of Tadjikistan, late Pragian or early Zlichovian of New South Wales, early Zlichovian of Ellesmere Island, and Dalejan of Taymyr. Reported occurrences in the late Lochkovian of Salair and the Dalejan or Eifelian of Gansu have yet to be substantiated. Forms resembling Zelolasma, but differing from it by lacking discrete adaxial septal fragments, are known from the Ludlow Series of New South Wales and the Upper Silurian (Ludlow or Pridolian equivalent) of the southern Urals. Zelolasma apsidiferum sp.n. is described from high strata of the Eids Formation, 20.5 km west of the head of Sor Fiord, southwestern Ellesmere Island. The type horizon of the new coral is in the Polygnathus dehiscens Zone, which spans the Pragian/Zlichovian boundary. However, the age of the type stratum is judged to be early Zlichovian, rather than late Pragian, because it overlies probable Zlichovian brachiopods, as well as spores dated approximately as middle Emsian (equivalent to late Zlichovian).</ABSTRACT>

- 25737 <ABSTRACT>The family Columnariidae Nicholson 1879, is revised, so that it comprises the subfamilies Columnariidae Nicholson 1879, Hexagonariinae Bulvanker 1958, Paradisphyllinae Jell 1969, Utaratuinae Spasskiy, Kravtsov and Tsyganko 1975, Spongonariinae Crickmay 1962, and Tropicodiphyllinae subfam.n. Stereophyllum Schlueter 1889, is likely to be a synonym of Digonophyllum Wedekind 1923. However, Digonophyllum, which is a widely used generic name, is retained on the grounds that Stereophyllum appears to be a nomen oblitum. Aulacophyllum Milne-Edwards & Haime 1850, and its probable synonym Pinnatophyllum Grabau 1922, are discussed because of similarities between them and a new genus Thoulelasma. Digonophyllum primitivum confertum subsp.n. (Family Cystiphyllidae) and Thoulelasma loewei. gen. et sp.n. (Family Halliidae) are described from high in the inversus Zone in the Sor Fiord section. Paraspongonaria delicata gen. et sp.n. (Family Columnariidae) is described from the same horizon and locality, as well as from the overlying serotinus Zone near Vendom Fiord. Newly prepared type material of Paraspongonaria sverdrupi (Loewe 1913) is figured from the Zlichovian (Early Devonian) Db Series of Schei (1903; 1904) in the vicinity of Goose Fiord.</ABSTRACT>

- 25750 <ABSTRACT>The Bird Fiord Formation, between Blubber Point and the area north of Muscox Fiord, is divided into four lithological units, informally designated units 1 to 4. Unit 3 contains a rich benthic, marine fauna, including the corals described in this paper. Its age is deduced to be probably late Dalejan (late Early Devonian), on the basis of conodonts, brachiopods and corals. The genera Spongophylloides, Actinocystis, Grypophyllum, Dubrovia, Salairophyllum, Tonkinaria and Neogrypophyllum are discussed in preparation for the proposal of a new ptenophyllid genus named Ellesmerelasma. Four new species and a new subspecies are introduced. They are Lekanophyllum foliatum, Ellesmerelasma pumile, Mansuophyllum uyenoii, M. versicularium and M. comsolum.</ABSTRACT>

- 25763 <ABSTRACT>Protocorallite ontogeny, corallite increase and colony development in Phillipsastrea nevadensis Stumm 1940 are described from serial section of four complete colonies from the Late Devonian of northern Canada. The protocorallite shows characteristic rugosan septal insertion, with serial insertion of minor septa. Increase is almost exclusively marginal, non-parricidal. Offset development displays subtle distinctions between peripherally and more centrally located offsets. In both, most septa are inherited from the parent and no regular pattern of insertion can be detected. All corallites have the potential to offset repeatedly. Increase shows a weak to strong periodicity, interpreted as seasonal, from which linear growth rates of 4-10 mm yr⁻¹ can be calculated. The balance between peripherally and centrally located offsets, and the pattern of distribution of corallites at the colony surface are the results of space competition and simple geometric constraints operating during growth. These factors, and different corallite growth rates are responsible for the range of colony form. The most important variable in the environment imposing space competition during growth is probably rate of soft sediment accumulation around the colonies, with the suspension and resedimentation of calcareous mud by seasonal storms causing corallite or colony mortality. 25840 <SOURCE>Curr. Res., C, Geol. Surv. Canada, Pap. 82-1C: 71-82.</SOURCE>

25841 <ABSTRACT>The genera *Taimyrophyllum*, *Cavanophyllum* and *Radiastrea* are reviewed. A lectotype is chosen for *Phillipsastrea scheii* Loewe, 1913, to make it a junior objective synonym of *Iowaphyllum alpenense* (Rominger, 1877). This allows *Taimyrophyllum nolani* Merriam, 1974, which would otherwise be a junior subjective synonym of *Phillipsastrea scheii*, to stand. *T. nolani beumannense* subsp. n., *Cavanophyllum uyenoii* sp. n. and *Radiastrea pulchra* sp. n. are described from the early Zlichovian part of the dehiscens Zone, at localities close to the outcrop known as the Sor Fiord section, on southwest Ellesmere Island, arctic Canada. *Cavanophyllum uyenoii* sp. n. also occurs in the slightly younger Zlichovian Polygnathus aff. *perbonus* conodont unit in the Sor Fiord section.</ABSTRACT>

25879 <SOURCE>Bulletin U.S. geol. Surv. 1690: D1-D9.</SOURCE>
25880 <ABSTRACT>Two rugose coral faunules from a single well in Coles County, Ill., are of contrasting origins. A Lingle Limestone faunule is of Centerfield age (Givetian). It is dominated by characteristic Eastern Americas Realm corals, but includes three specimens of Old world Realm ptenophyllids. An upper Grand Tower Limestone faunule is derived from the Michigan Basin Anderdon Limestone of late Onondaga age (Eifelian). This contains only two species of rugose corals, both having Old world Realm affinities. The Old World corals of both faunules are thought to have entered the Michigan Basin from the west and to have migrated from there into the Illinois Basin. An analogous superposition of Old world and Eastern Americas corals is known in the Logansport, Ind., area on the Kankakee Arch that separates the Michigan and Illinois basins.</ABSTRACT>

25917 <TITLE>Geochemical signature of incremental growth and diagenesis of skeletal structure in Tabulophyllum traversensis (Winchell 1866).</TITLE>
25918 <SOURCE>Boletín de la Real Sociedad Española de Historia Natural, Sección Geológica 92, 1/4: 77-86.</SOURCE>
25919 <ABSTRACT>Understanding biogenic structures within fossil corals, and diagenetic changes in skeletal material is basic to taxonomy in the Rugosa and Tabulata. Incremental growth has long been known in living and fossil scleractinian corals, and likewise recognized in Paleozoic rugose and tabulate corals. Study of very well-preserved rugose corals from Devonian rocks of Michigan reveals skeletal growth banding within fibrous septotheca, shown by variation in the trace element magnesium. Modern electron microprobes (superprobes) allow detailed mapping of minor element distribution on a less than 1µm scale, with material studied here of Tabulophyllum traversensis from Traverse Group strata (Givetian) of Michigan. Element mapping of magnesium distribution clearly shows incremental skeletal banding within fibrous walls that marks growth, with alternating bands of magnesium-rich (maximum concentrations of 0.5%) and magnesium-free carbonate. Such a geochemical marker of growth provides the opportunity to evaluate diagenesis of corals and possibly recognize precursors of secondary structures in skeletal carbonates of fossil corals.</ABSTRACT>

25930 <TITLE>Frasnian (Upper Devonian) rugose corals from the Lime Creek and Shell Rock Formation of Iowa.</TITLE>
25931 <SOURCE>Bulletins of American Paleontology 113, 355: 1-159.</SOURCE>
25932 <ABSTRACT>Rugose corals from Frasnian Lime Creek ("Hackberry") and Shell Rock strata are known largely from the works of Fenton and Fenton (1924) and Belanski (1927, 1928), each of which described outcrop stratigraphy and major parts of the fauna. The Shell Rock Formation includes three members, two of which contain rugosans, the basal Mason City and the uppermost, or Nora Member. The overlying Lime Creek Formation contains the Juniper Hill Member, lacking corals, overlain by the very fossiliferous Cerro Gordo Member, source of much of the famous "Hackberry" coral fauna described by Fenton and Fenton in 1924. The uppermost, Owen Member, also contains abundant Rugosa. […] Based on the brachiopod and conodont zonation, the Shell Rock and Lime Creek coral faunas are medial and late, but not latest Frasnian. [excerpts from extensive summary]</ABSTRACT>

25944 <SOURCE>Journal of Paleontology 47, 5: 915-918.</SOURCE>
25945 <ABSTRACT>Lithostrotion *stokesi* Milne Edwards and Haime, 1851, is assignable to *Acinophyllum* Mc Laren, 1959. The species originally was said to come from Carboniferous rocks at Lake Winnipeg, Manitoba, Canada, but the type specimen is probably from Lower Devonian strata and not from Lake Winnipeg unless it was collected from glacial drift. The name *L. stokesi* is a senior subjective synonym of *Acinophyllum davisii* Stumm, 1965.</ABSTRACT>

25956 <TITLE>Lower and Lower Middle Devonian rugose corals of the Central Great Basin.</TITLE>
25957 <SOURCE>U.S. Geological Survey Prof. Paper 805: 83 pp., 25 pls.</SOURCE>
25958 <ABSTRACT>Rugose corals of the Great Basin Devonian seaways underwent three major bursts of evolutionary activity: (1) in late Early to early Middle Devonian (early Eifelian) time; (2) in the medial Middle Devonian (late Eifelian); (3) in Late Devonian (Frasnian) time. No Rugosa are known in the highest Devonian (Famennian) of this province. The product of the first of these bursts of evolution is part of the subject of this paper. * Devonian rocks of the central Great Basin occur in three north-south facies belts of which the Antelope-Roberts Mountains belt is the more important in terms of Early and Middle Devonian coral distribution. No Rugosa were found in Early and early Middle Devonian rocks of this age of the Diamond Mountains facies belt on the east, where strata of this age are barren dolomite and siliceous sandstone. Within the Monitor-Simpson Park facies belt on the west, only the earliest Devonian Rabbit Hill Limestone coral fauna is known. * Nine successive coral zones are defined in the Nevada Formation and overlying Devils Gate Limestone of the Antelope-Roberts Mountains belt. These zones have been designated A through I in ascending stratigraphic order. Described and illustrated herein are Rugosa and Early Devonian coral zones A, B, and C and those of coral zone D, which is Early and early Middle Devonian. Rugosa of coral zone A are best known in the westerly Monitor-Simpson Park belt, where they characterize the Syringaxon facies of the Helderbergian Rabbit Hill Limestone.[part of extensive summary]</ABSTRACT>

26047 <TITLE>Frasnian (Upper Devonian) colonial disphyllid corals from Western Canada.</TITLE>
26048 <SOURCE>NRC Research Press, Ottawa, Ontario; 189 pp.</SOURCE>
26049 <ABSTRACT>Colonial rugose corals of the Family Disphyllidae occur abundantly in Frasnian (lower Upper Devonian) strata in western Canada. The branching genus Disphyllum is the most diverse, being represented by D. fasciculum (Meek), D. rugosum (Wedekind), D. catenatum Smith, D. iowense Sorauf, D. fumosum n.sp., and D. sp. cf. D. major Jia. The other branching genus recognized is Pantophyllum, and the species P. camelli (Smith) and P. oliveri n.sp. are described. The remainder of the described fauna are massive forms. Argutastrea is represented by a single species, A. bompassi (Smith). Four species of Hexagonaria are included: H. davidsoni (Edwards and Haime), H. magna (Webster and Fenton), H. oweni (Belanski), and H. arietina n.sp. The new genus Whittakeria comprises the type species, W. schucherti (Smith), together with W. caurus (Smith), while a single species of Kuangxiastraea is described, K. mirabilis n.sp. Biostratigraphic distribution of this assemblage is reviewed and related to the rugose coral faunal sequence and Montagne Noire conodont zonation previously applied in western Canada. Contrary to some earlier opinions, the Disphyllidae is shown to be unrelated to the Columnariidae, following new study of the holotype of the type species of Columnaria, C. sulcata Goldfuss. [original abstract]</ABSTRACT>

26062 <ABSTRACT>Representatives of the family Kyphophyllidae form a diverse and geographically widespread group in Frasnian (lower Upper Devonian) strata of Canada. From early to late Frasnian strata in western Canada the species *Tabulophyllum athabascense* (Whiteaves), *T. mcconnelli* (Whiteaves), *T. magnum* Fenton and Fenton, *T. mineatum* n.sp., *T. whiteavesi* n.sp., *T. asymmetricum* n.sp., and *T. vesiculosum* n.sp. are described, while a further species of *Tabulophyllum* is left in open nomenclature. *T. telfordi* n.sp. is described from the early Frasnian of eastern Canada. Other described species are from the late Frasnian of western Canada and comprise *Mictrophyllum nobile* Lang and Smith, *M. nobile* large variety, *M. semidilatatum* Smith and *M. betulinum* n.sp., with the new genus *Plectrophyllum* being represented by *P. kindlei* (Smith), *P. whittakeri* (Smith) and *P. pilatum* n.gen. et n.sp. Biostratigraphy of these taxa is discussed, together with that of previously described western Canadian representatives of the kyphophyllid genera *Smithiphyllum*, *Tarphyphyllum*, *Mikkwaphyllum*, *Parasmithiphyllum*, *Bouvieriphyllum*, *wapitiphyllum* and *Kakisaphyllum*. The biostratigraphic distribution of these species is related to the Montagne Noire conodont zonation previously recognized in the Frasnian of western Canada, and modified western Canadian rugose coral faunal assemblage</ABSTRACT>

26074 <SOURCE>National Research Council of Canada Monograph. NRC Research Press, Ottawa, 109 pp.</SOURCE>
26075 <ABSTRACT>Rugose corals of the Family Phillipsastreidae are abundant, diverse, and geographically widespread in the Frasnian (lower Upper Devonian) of western Canada. Species of the solitary genus *Macgeea* described here comprise *M. parva* Webster, 1889, *M. proteus* Smith, 1945, *M. telopea* Crickmay, 1962, *M. soraufi* n.sp., and *M. pustulosa* n.sp. *Thamnophyllum* and *Peneckiella* are branching forms, with *Thamnophyllum* represented by the species *T. colemanense* (Warren, 1928), *T. tructense* (McLaren, 1959), *T. pedderi* n.sp., *T. cordense* n.sp. and *T. julli* n.sp., while *Peneckiella* includes *P. floydensis* (Belanski, 1928), *P. metalinae* sorauf, 1972, *P. gracilis* n.sp. and *P. haultainensis* n.sp. Biostratigraphic distribution of these species is reviewed, together with that of previously described Canadian massive phillipsastreid species belonging to the genera *Phillipsastrea*, *Chuanbeiphyllum*, *Pachyphyllum*, *Smithicyathus*, and *Frechastrea*. The coral biostratigraphy is expressed in terms of the Montagne Noire conodont

- zonation and modified western Canada rugose coral faunal assemblages.

- 26100 <SOURCE>Palaeontographica A230: 39-76.</SOURCE>
26101 <ABSTRACT>Rugose corals of the family Phillipsastreidae with a primarily massive corallum are common in Lower Upper Devonian (Frasnian) strata of western Canada. In Part A of this work, the type genus Phillipsastrea is reviewed and the species *P. woodmani* (White 1870), *P. nevadensis* Stumm 1940, *P. irregularis* (Webster & Fenton 1924), *P. disrupta* n.sp. and *P. variabilis* (Sorauf 1988) are described. Also discussed in this part is the genus *Chuanbeiphyllum*, with species *C. mikkwaense* n.sp., *C. impensum* n.sp. and *C. vesiculosum* (Smith 1945). The following Part B deals with western Canadian representatives of *Pachyphyllum*, *Smithicyathus* and *Frechastraea*. Stratigraphic information for the full massive phillipsastreid fauna may be found in Part A, while the Locality Register and reference list of cited literature is in Part B.</ABSTRACT>

- 26179 <ABSTRACT>Five species of Stromatoporella are described of which one (S. megastrophorhizifera) is new. The new genus Syringodictyon with type species Stromatopora tuberculata Nicholson 1873 is established for stromatoporoids with ordinicellular laminae and columns of superposed upwardly inflected cones filled with skeletal material with a central lumen. Other pillars are rare but cyst plates are common. The new genus is close to Tubuliporella khalfina but differs in not having ring pillars between the columns and the near absence of solid pillars.</ABSTRACT>

26218 <ABSTRACT>The stratigraphy, sedimentary petrology and paleoecology of stromatoporoid-bearing dolostones of the Lake Erie area are examined. The stromatoporoid bioherm shows a vertical zonation of intraspecific and interspecific growth forms from laminar at the base to progressively more erect forms culminating in fasciculate forms at the top. Twelve species of stromatoporoid are illustrated and briefly described (Syringostroma, 4 species; Habrostroma, 3 species; Anostylostroma, 2 species; Pseudoactinodictyon, 2 species; Clathrodactyon, 1 species. None are new). Environmental conditions affecting skeletal shape are fully discussed.</ABSTRACT>

26256 <SOURCE>Journal of Paleontology 75, 1: 9-23.</SOURCE>
26257 <ABSTRACT>Through a review of older type collections and identifications of undescribed collections, using a broad species definition, the Devonian succession is divided into 10 assemblages. The names of many species are revised. With the exception of the Pragian, all stages of the system are represented by one or more assemblages. The ranges of important taxa are plotted and shown to be relatively short and diagnostic of the 10 intervals. In the absence of conodonts in the reef facies, stromatoporoids offer a supplementary method of correlation. Many species occurring in Canada can be recognized in the stromatoporoid faunas of the former Soviet Union, China, Europe and Australia.</ABSTRACT>

26270 <ABSTRACT>This study is the result of many years of research on the Emsian and Eifelian stromatoporoids of Ontario, Michigan and Ohio. The new genus Habrostroma (type species H. formosensis) and three new species (H. formosensis, H. beachvillensis, Pseudoactinodictyon stearni) are proposed. In addition 23 other species are described belonging to 7 genera. The monograph includes extensive discussions of species groups, genus groups, Syrinostroma and throughout emphasizes the use of statistics in establishing the limits of variation in species.</ABSTRACT>

26359 <TITLE>Stromatoporoids from the allochthonous reef facies of the Stuart Bay Formation (Lower Devonian), Bathurst Island, Arctic Canada.</TITLE>
26360 <SOURCE>Journal of Paleontology 64: 493-510.</SOURCE>
26361 <ABSTRACT>The fauna is a mixture of genera that characterize Ludlovian-Gedinnian rocks (Actinodictyon, Parallelostroma, Syringostromella) and those that characterize Emsian-Eifelian rocks (Atopostroma, Anostylostroma, Habrostroma, Syringostroma). The new genus Belemnostroma (type species B. hastatum) is established for stromatoporoids with the basic structure of Anostylostroma but penetrated by large rodlike mega-pillars. New species of Geronostroma (G. franklinense. G. nivale) Actinodictyon (A. venustum), and Syringostroma (S. praecox) are described. Species with long coenosteles are excluded from Stromatopora on the basis that they are not cogenetic with the type species and many species assigned to Ferestromatopora should be reassigned to Stromatopora.</ABSTRACT>

26372 <TITLE>Devonian (Givetian-Frasnian) stromatoporoids from the subsurface of Saskatchewan, Canada.</TITLE>
26373 <SOURCE>Canadian Journal of Earth Sciences 27: 1746-1756.</SOURCE>
26374 <ABSTRACT>The lower Duperow beds (Frasnian) contain 11 species most of which occur in the upper Cairn and Peechee units of Alberta. The Souris River Formation contains 2 species and the underlying Dawson Bay Formation (Givetian) contains 7 species. No new species are named but the generic assignments of several species are changed and widening of species concepts places the following species in synonymy: Anostylostroma intermedium Klován, Hammatostroma nodosum Klován, Hermatostroma maillieuxi (Lecompte) of Fischbuch, Parallelopora cf. P. dartingtonensis (Carter) of Stearn, Trupetostroma cervimontanum Stearn, Clathrocoilona abeona Yavorsky of Fischbuch, Stromatopora mikkwaensis Stearn, Ferestromatopora dubia (Lecompte) of Klován, Arctostroma ignotum Yavorsky, These revisions greatly reduce the apparent endemism of western Canadian stromatoporoid faunas and indicate the wide distribution of species of the Cairn-Flume interval from the Northwest Territories to Iowa.</ABSTRACT>

26385 <TITLE>The Detroit River Group is Middle Devonian: Discussion on "
Early Devonian age of the Detroit River Group, inferred from Arctic
stromatoporoids". </TITLE>
26386 <SOURCE>Canadian Journal of Earth Sciences 32: 1070-1073. </SOURCE>
26387 <ABSTRACT>In their paper on the age of the Detroit River Group, the
authors, Prosh E. G. and Stearn C. W., suggest that the occurrence of
two to four species of stromatoporoids in the Detroit River, which are
also known to occur in well-dated Lower Devonian Arctic formations,
outweighs the evidence of conodonts and goniatites that is currently
used to date the Detroit River as mostly, or entirely, Middle Devonian.
The conodont and goniatite evidence is much stronger than indicated by
the authors and too strong to be set aside in response to their new
data. Correlation difficulties are attributable to the known endemism
of the eastern North American Early and Middle Devonian faunas and to
environmental differences. </ABSTRACT>

26398 <TITLE>Stromatoporoids from the Emsian (Lower Devonian) of Arctic
Canada. </TITLE>
26399 <SOURCE>Bulletins of American Paleontology 109, 349: 66 pp. </SOURCE>
26400 <ABSTRACT>Early Devonian limestones of Ellesmere, Bathurst and smaller
islands between them in the Canadian Arctic Archipelago contain a
diverse fauna of stromatoporoid sponges. This fauna provides the best
evidence in North America of the early recovery phase of this
reef-building group from a diversity low at the Silurian/Devonian
boundary, a recovery that led to its diversity peak in Givetian time.
Stromatoporoids from the lower member of the Blue Fiord Formation
locally form large reefal masses. Well preserved stromatoporoids also
occur less abundantly: 1. in the top of the underlying Bids Formation,
2. in the upper member of the Blue Fiord Formation, 3. in the
Disappointment Bay Formation, which is correlative of the upper Blue
Fiord, and 4. in the overlying Bird Fiord Formation and a correlative
unnamed formation both of which span the Lower/Middle Devonian
boundary. The stratigraphic distribution of these stromatoporoids can
be accurately determined according to conodont biostratigraphy as
spanning the dehiscens to partitus (Emsian to basal Eifelian) conodont
zones. Common occurrences of Stromatoporella perannulata, Stictostroma
gorriense, Habrostroma proxilaminatum, and Parallelopora campbelli in
the arctic fauna and southern Ontario and the adjacent United States,
indicate that the Detroit River Group is of similar Emsian age, and
that the Eastern Americas realm was open to migration from the Arctic.
Similarity of species with the Emsian faunas of Russia, Australia and
China suggests the cosmopolitan and equatorial distribution of
stromatoporoids in Emsian time and opens possibilities for using the
group in correlation. The fauna is therefore important in establishing

both the evolution of the order and also its geographic distribution in Early Devonian time. Twenty-five species (assigned to 22 genera) are described. The species concept used is a broad one and the range of variations in each taxon is documented. New species described are: *Gerronostroma septentrionalis*, *Anostylostroma anfractum*, *Pseudoactinodictyon conglutinatum*, *Stictostroma? nunavutense*, *Clathrocoilona vexata*, *Stromatopora hensoni*. The morphologic limits of the following genera are considered in the description of species: *Plectostroma*, *Aculatostroma* and *Atelodictyon*, *Clathrocoilona*, *Salairella* and *Syringostromella*. The range of *Trupetostroma* is extended downward into Emsian strata. </ABSTRACT>

26411 <TITLE>Stromatoporoids from the Devonian (Eifelian to lowest Frasnian) of Manitoba, Canada.</TITLE>

26412 <SOURCE>Journal of Paleontology 70: 196-217.</SOURCE>

26413 <ABSTRACT>Twenty-two taxa of stromatoporoids are described from the outcrop belt of the Elm Point, Winnipegosis, Dawson Bay and Souris River formations in Manitoba. The Elm Point Formation contains a fauna of stromatoporellids of Eifelian age that is characterized by the new species, *Stromatoporella manitobaensis*. The Winnipegosis stromatoporoids are dolomitized but the widespread species *Actinostroma tyrrelli*, *Taleastroma logansportense* and the new species *Trupetostroma imbrex* can be recognized in this Givetian assemblage. The Dawson Bay fauna is characterized by the appearance of the dendroid forms, *Stachyodes* and *Dendrostroma* and species of *Hermatostroma*, *Trupetostroma* and *Parallelopora*. A species of *Actinostroma* comparable to *A. filitextum* is the most abundant stromatoporoid in the Dawson Bay Formation. The Souris River fauna, referred to as the *Arctostroma contextum* assemblage, is widespread at the Givetian-Frasnian boundary. Elements occur elsewhere in western Canada in the Beaverhill Lake, Waterways, lower Duperow and lower Fairholme units. Stromatoporoids in these four assemblages are relatively restricted in their stratigraphic occurrence and sufficiently widespread in their distribution to be useful in correlation.</ABSTRACT>

26424 <TITLE>Reply: Early Devonian age of the Detroit River Group, inferred from Arctic stromatoporoids.</TITLE>

26425 <SOURCE>Canadian Journal of Earth Sciences 32: 1073-1077.</SOURCE>

26426 <ABSTRACT>The biostratigraphic review of G. Klapper and W. A. Oliver jr, discussers, will assist interested readers in weighing the evidence between their Eifelian date and the older Emsian age proposed for the Detroit River Group by C. W. Stearn and myself in our original paper. Two important points emerge from their review: Detroit River - Onondaga faunas are very endemic; the conodont data do not immediately relate to the standard zonation, so some interpretation is necessary. The Detroit

River Group of Ontario is mostly Lower Devonian. The Edgecliff and Nedrow members of the Onondaga Limestone of New York are also Lower Devonian. Stromatoporoids in common between the lower Detroit River Group and the Arctic Blue Fiord Formation provide the Early Devonian date.

26437 <TITLE>Biostratigraphy of the Devonian reef facies of western and arctic Canada based on stromatoporoids.</TITLE>
26438 <SOURCE>Boletín de la Real Sociedad Española de Historia Natural, Sección Geológica 92, 1/4: 339-348.</SOURCE>
26439 <ABSTRACT>Although stromatoporoids have been considered inadequate for biostratigraphy, in western and arctic Canada ten assemblages characterized by species with short ranges and wide geographic distribution can be distinguished in the Devonian System. Carbonate facies in the Arctic Islands and mainland of the Northwest Territories contain stromatoporoids of Early Devonian and early Middle Devonian ages. The reef facies of the Western Canada Sedimentary Basin contains assemblages ranging from late Eifelian to middle Famennian in age. (1) The earliest Devonian rocks in the Arctic are characterized by species of *Parallelostroma*, (2) The lower Blue Fiord fauna of *dehiscens* to *grombergi* zone stromatoporoids is distinguished by new species of *Gerronostroma* and *Stictostroma*, and *Stromatoporella perannulata*. (3) The upper Blue Fiord assemblage of *inversus* to *partitus* age has *Plectostroma salairicum* and new species of *Stromatopora* and *Anostylostroma*. (4) the late Eifelian assemblage of the Elm Point Limestone in Manitoba is characterized by a new species of *Stromatoporella* and *Stictostroma* cf *S. foraminosum*. (5) The early Givetian (lower *varcus* Zone) assemblage is widespread in western Canada and easily recognized by the presence of *Neosyringostroma logansportense* and *Actinostroma tyrrelli*. (6) The middle Givetian assemblage is a transitional fauna present in the Dawson Bay Formation of: Manitoba. (7) Rocks of late Givetian and earliest Frasnian age contain the *Arctostroma contextum* assemblage, widespread in the Beaverhill Lake Group. (8) The mid-Frasnian fauna is characterized by *Ferestromatopora parksii*. (9) Late Frasnian faunas found in the Rocky Mountains and the Great Slave Lake areas can be characterized as the *Trupetostroma saintjeani* assemblage. (10) The youngest assemblage is found in mid-Famennian reefs and is identified by the presence of *Labechia palliseri* and *Stylodictyon sinense*. Nearly all these ten assemblages contain species that are valuable for correlation within North America and assemblages 1, 2, 3, 5, 7, and 10 have species that have potential for intercontinental correlation of the reefal facies across the equatorial belt of Devonian time inhabited by stromatoporoids.</ABSTRACT>

- 26452 <ABSTRACT>Sixty-five specimens belonging to 13 genera and 22 species were collected to determine if their shapes were the result of environmental or genetic factors. Many were collected from a single bedding plane and are assumed to have been exposed to the same environmental conditions. Domical and bulbous shapes predominate. Some species exhibit a wide range of shapes; others, a narrow range. Stromatoporoids from the same bedding plane did not grow to the same shape. The relative importance of genetic disposition and environmental factors in determining growth form cannot be determined from this study. [condensed from abstract by C. W. Stearn]</ABSTRACT>

- 26464 <SOURCE>Canadian Journal of Earth Sciences 35: 16-22.</SOURCE>
- 26465 <ABSTRACT>The reservoir reef carbonates at the Bent Horn Field have been referred to as the Blue Fiord Formation but they are younger than the type Blue Fiord of Ellesmere Island. The top of these carbonates, from which the Stromatoporoid fauna is described, is dated by conodonts as of Eifelian age. They are the same unit that has also been called the Unnamed Formation. Fourteen taxa of stromatoporoids, none of them described as new, are identified from cores. Five species are common to the fauna of the Unnamed Formation of surface exposures on Bathurst and Truro islands. The ranges of the three species from the fauna of the typical Blue Fiord of Emsian age are extended into the Unnamed Formation. A synthesis of the paleontological evidence suggests that the top of the reservoir is basal Eifelian age. The recognition of Pseudoactinodictyon, cf. P. stearni and Simplexodictyon vermiforme at Bent Horn suggests paleogeographic connections to the Great Lakes and Yukon stromatoporoid faunas of this age.</ABSTRACT>

- 26478 <ABSTRACT>The group has traditionally been considered mostly or entirely of Middle Devonian age but much of the fauna is endemic. Four Detroit River Group stromatoporoid species are recognized in the fauna of the Emsian Blue Fiord Formation in Ellesmere Island and two other species show close relationships. The Emsian faunas of the Arctic are accurately dated by conodonts and indicate a serotinus age for the Amherstburg Formation and a serotinus to patulus age for the Lucas Formation. This is the first direct species-level correlation of a

- Detroit River Group "endemic" to a globally dateable level and the first regional application of stromatoporoid biostratigraphy in North America.</ABSTRACT>

26528 <TITLE>Distribution of Devonian stromatoporoid buildups in the eastern Basin and Range.</TITLE>

26529 <SOURCE>Utah Geological Association Publication 38 [B. Tripp, K. Krahulec & L. Jordan (eds.): Geology and Geologic Resources and Issues in western Utah]: 43-53, 2 appendices, 8 plates.</SOURCE>

26530 <ABSTRACT>Devonian carbonates in the Basin and Range Province of western Utah and eastern Nevada form part of a large, carbonate-dominated depositional complex that occupied the western margin of the mid-Paleozoic North American craton. These Devonian carbonates are generally continuous with and coeval with hydrocarbon reservoirs in the Alberta foreland basin of Canada. This stratigraphic association and the production of modest amounts of oil from the Devonian in Nevada raise the possibility that the carbonate-reef play concepts that have been successful in Canada could be applied to the Devonian of the Basin and Range. For this review paper, we collected descriptions of more than 100 measured outcrop sections in the literature and oil-industry data from about 45 wells, and integrated the descriptions with published sequence stratigraphic frameworks for the Middle and Upper Devonian. We assigned the carbonates to eight depositional environments, ranging from supratidal to deep subtidal, and correlated the measured sections across four cross sections. Paleogeographic maps based on limited age control suggest that two populations of stromatoporoid buildups occur: a shelf-edge group that is probably not prospective for hydrocarbons, and a middle-shelf group that may be prospective. However, the Basin and Range buildups are smaller and less numerous than those in Canada, lack structural control and internal biofacies zonation, and are mud supported. From the hydrocarbon exploration perspective, carbonate buildup distribution is probably less important than timing and development of fracture porosity. [original abstract]</ABSTRACT>

26567 <TITLE>Structure et microstructure de Favosites cylindrica Michelin 1847, espece-type de Ohiopora n.gen. (Tabulata, Devonien).</TITLE>
26568 <SOURCE>Canadian Journal of Earth Sciences 24: 1465-1477.</SOURCE>
26569 <ABSTRACT>The holotype of Favosites cylindrica Michelin 1847 is a fragment of a corallum completely silicified and poorly preserved. Some specimens, regarded as topotypic (Falls of the Ohio), allow a detailed study of internal characters, wall, pores, and tabulae. Development of horizontal ridges results from folding of the wall. The abundance of these ridges is generally associated with the final stage of growth of the corallum. In ultra-thin sections with polished faces (LFP thin sections), parts of the skeleton not affected by silification show the microstructural features of the wall. The median "dark line" is composed of granules, sometimes elongated; the stereozone is made of lamellae approximately parallel to the intramural coenozoone. A biometric study of the so-called "topotypic" specimens and of the holotype of F. cylindrica shows the conspecificity of all this material. A new genus, Ohiopora, is proposed for F. cylindrica. The new genus is very close to Michelinia sensu stricto, from which it probably derived but from which it may be distinguished by the presence of horizontal ridges, which form an original feature within the Tabulata.

Several old species may be assigned to the new genus, and probably all are synonymous with *O. cylindrica*. Occurrence: Emsian?, lower and middle Emsian; Eifelian. *Ohiopora* is endemic of eastern North American Province.

26581 <SOURCE>Geologica et Palaeontologica 27: pp?</SOURCE>
26582 <ABSTRACT>The auloporid genus *Bainbridgia* Ball 1933 is revised on the base of its type species *B. typicalis* Ball 1933. This species, until now supposed to be of Ludlovian age (Bainbridge Limestone), is probably coming from the Lower Devonian (Lochkovian) of Missouri in the United States. The genus is characterized by slender cylindrical corallites, disposed in two opposite and alternate rows. Scarce tabulae and rare mural pores are present. The microstructure of the walls shows a granular median lamina covered by two thin micro-lamellar layers, followed by two thick layers of grondules. The morphological and microstructural characters show that the genus is close to the genus *Cladochonus* McCoy 1847 and to the family Pyrgiidae De Fromental 1861.</ABSTRACT>

26634 <ABSTRACT>The upper Peechee Member of the Ancient wall reef complex that is well exposed on the southeast margin of Mount Haultain represents the end of the first main depositional cycle of this complex. The uppermost part forms a 15-30m thick carbonate sequence that extends basin-ward over deeper water fore-reef detritus and is divisible into three distinct layers: the lower two consist mainly of stromatopoid and coral bioherms and biostromes and associated calcarenites and calcilutites; the uppermost consists of five small micrite and wacke-stone bioherms 7,5 - 22 m long and 4 - 6 m high; three of these grew around and on top of a 30 m wide stromato-poroid-coral biostrome. Frame-building organisms include laminar and hemispherical colonies of Phillipsastrea, renalcid algae (often associated with small fenestral cavities), encrusting calcareous algae (Sphaerocodium). and laminar stromatoporoids. Renalcid encrustations of micrites and wackestones on the vertical sides and undersides of bioherms indicate that early submarine cementation was also significant in forming these rigid structures. The bioherms formed during deepening water conditions with agitation and bioerosion too gentle to apron them with detritus but sufficient to fragment and disorient fragile skeletal elements. The sharp contacts and the lack of inter-fingering with basin strata indicate that the bioherms were drowned before burial by basin calcareous shales. (Original summary)</ABSTRACT>

26658 <TITLE>The allochthonous origin of the reefal facies of the Stuart Bay
Formation, Early Devonian, Bathurst Island, arctic Canada.</TITLE>
26659 <SOURCE>Canadian Journal of Earth Sciences 21, 6: 657-668.</SOURCE>
26660 <ABSTRACT>Blocks of limestone and dolomite up to tens of metres across
occur near the base of the Lower Devonian (Siegenian-Emsian) Stuart Bay
Formation at six sites on eastern Bathurst Island. These blocks occur
of up to 30. At the two localities with the greatest number of blocks
they are disposed in two or three roughly linear groups reflecting
their occurrence on bedding planes. The blocks are mostly wacke- and
floatstones and they contain abundant fossils of the reefal biofacies of
which stromatoporoids and corals are most prominent. The blocks have
weathered from a matrix of finely laminated deep-water siltstone. Most
of the blocks are unbedded but where bedding attitudes can be measured
they are discordant with that of the siltstone and those of
neighbouring blocks. Although they have been described as bioherms that
grew in place, the evidence indicates that they are allochthonous
blocks derived when several catastrophic events such as earthquakes
disturbed a Devonian reef tract developed on the western flank of the
Cornwallis Fold Belt.</ABSTRACT>

26671 <TITLE>Microbial carbonate as indicator of environmental change and
biotic crises in carbonate systems: examples from the Late Devonian,
Alberta Basin, Canada.</TITLE>
26672 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 181, 1-3:
127-151.</SOURCE>
26673 <ABSTRACT>Microbial precipitation of calcium carbonate has played a
vital role in the development of carbonate platforms since their
initiation in the Proterozoic. We report here the varied roles that
microbial carbonates played in Late Devonian carbonate platforms in the
Alberta basin, Canada. We recognize microbial carbonates as important
contributors within the carbonate system during times of major
environmental change including transgressive events in platform
environments and the recovery interval following the Frasnian-Famennian
mass extinction. Detailed sequence stratigraphic analysis of two
isolated platforms in the Canadian Rockies was used to document their
evolution from a regional ramp to isolated platforms with phases of

progradation, aggradation and backstepping, and renewed progradation related to rates of second-order and third-order sea-level change and basin infill. The carbonate system was reorganized following annihilation of many carbonate-producing biota during the Frasnian-Famennian mass extinction. Microbial carbonates figure prominently in both Frasnian platform development and the Famennian recovery of the carbonate system following the Frasnian-Famennian mass extinction. [...] Microbial carbonates occur at important sequence stratigraphic and paleoecologic horizons indicating changes in sea level, nutrient supply, and biotic assemblages. These examples indicate that microbial carbonates can be important indicators of environmental and ecological change within carbonate systems. [first and last part of extensive abstract]

26685 <SOURCE>Canadian Journal of Earth Sciences 23: 2047-2056.</SOURCE>
26686 <ABSTRACT>Early and Middle Devonian fossils from the Sainte-Helene Island diatreme breccias are critically reviewed and analyzed stratigraphically. They include marine benthic faunas of Helderberg, Oriskany, Schoharie, Onondaga, and Hamilton ages. Brachiopods are the most abundant fossils; significant corals are also present and are discussed for the first time. These diatreme faunas from the Montreal region significantly augment the lithofacies - paleogeographic data known for the first part of North America. For the first time, attention is paid to the lithologies in which the Sainte-Helene Island faunas are embedded, as clues to the regional relations of these rock types. The absence of Silurian specimens is ascribed to nondeposition similar to that known in the Albany, New York, region to the south. The presence of marine, Hamilton age rocks and fossils at Montreal shows that the Acadian Orogeny and uplift into the nonmarine environment did not affect the area until at least some time in the Hamilton.</ABSTRACT>

26764 <ABSTRACT>Most Devonian reef and platform carbonates in the western Canada Sedimentary Basin (WCSB) are pervasively replaced by grey matrix dolomite. The following parameters of these dolomites have been investigated: textures, spatial relationships to facies and structure, relationships to limestone diagenesis and stylolitization, stable isotopes, trace elements, 87Sr/86Sr-ratios, associated sulfates, recrystallization, fluid inclusions. The data presently available suggest that most grey matrix dolomites in the WCSB are "burial dolomites" that formed during burial at depths of about 300 to 1500m. Pervasive matrix dolomitization appears to have been a basin-wide phenomenon, and the dolomitizing solutions probably were diagenetically altered Devonian seawater. The "mechanisms" and directions of dolomitizing fluid flows are presently unknown and under further investigation.</ABSTRACT>

26801 <TITLE>Cyclostratigraphy of Middle Devonian carbonates of the eastern Great Basin.</TITLE>
26802 <SOURCE>Journal of Sedimentary Research B65, 1: 61-79.</SOURCE>
26803 <ABSTRACT>Middle Devonian carbonates (250-430m thick) of the eastern Great Basin were deposited along a low energy, westward-thickening, distally steepened ramp. Four third-order sequences can be correlated across the ramp-to-basin transition and are composed of meter-scale, upward-shallowing carbonate cycles (or parasequences). Peritidal cycles (shallow subtidal facies capped by tidal-flat laminites) constitute 90% of all measured cycles and are present across the entire ramp. The peritidal cycles are regressive- and transgressive-prone (upward-deepening followed by upward-shallowing facies trends). Approximately 80% of the peritidal cycle caps show evidence of prolonged subaerial exposure including sediment-filled dissolution cavities, horizontal to vertical desiccation cracks, rubble and karst breccias, and pedogenic alteration; locally these features are present down to 2 m below the cycle caps. Subtidal cycles (capped by shallow subtidal facies) are present along the middle-outer ramp and ramp margin and indicate incomplete shallowing. Submerged subtidal cycles (64% of all subtidal cycles) are composed of deeper subtidal facies overlain by shallow subtidal facies. Exposed subtidal cycles are composed of deeper subtidal facies overlain by shallow subtidal facies that are capped by features indicative of prolonged subaerial exposure (dissolution cavities and brecciation). Average peritidal and subtidal cycle durations are between approximately 50 and 130 k.y. (fourth- to fifth-order). [part of extensive summary]</ABSTRACT>

26814 <TITLE>Development of Western Canadian Devonian reefs and comparison with Holocene Analogues.</TITLE>
26815 <SOURCE>Bulletin of the American Association of Petroleum Geologists 58, 5: 787-799.</SOURCE>
26816 <ABSTRACT>The complex interplay of basin geometry and tectonic history, subsidence rate, weather conditions, and postdepositional history is the factor determining the ultimate morphology of a reef tract, individual reefs comprising the tract, and the lithologic variations within the reefs. Although the effects of these influences usually can be documented in studies of recent reefs, their determination in fossil settings is commonly obscure. This may preclude the use of recent reefs as explicit analogues of ancient ones. The applicability and limitations of such comparisons with references to some Devonian reefs of western Canada and various Holocene structures indicate that the variety of reef tracts available for study allows the various causal influences to be isolated to a first order of approximation.</ABSTRACT>

- 26828 <SOURCE>Proceedings of the VIth World Petroleum Congress: 733-763.</SOURCE>
- 26829 <ABSTRACT>At least three separate pulses of reef growth occurred in northwestern Canada during Middle Devonian time. These are, in order of decreasing age, Keg River (Rainbow Member), Sulphur Point and Slave Point reefs. Isopachous and facies maps illustrate that in the western part of the region, in northeastern British Columbia, the distribution of Keg River (Rainbow Member) reefs determined to a considerable degree, the extent and configuration of younger (Sulphur Point and Slave Point) reefs. In the eastern part, no direct relationship is apparent. Examples illustrate that seismic exploration for reefs must be adapted to specific geologic conditions obtaining in the particular part of the basin being explored. * During the two years ending March 31, 1967, exploratory and development drilling has confirmed recoverable reserves of more than a billion barrels of oil in Rainbow reefs of northwestern Alberta. Substantial reserves of gas have been discovered in Middle Devonian reefs in British Columbia. The new system of proration to market demand adopted by Alberta has allowed this substantial reserve to be developed with only those wells needed to broadly define the reserves in each pool. Continuous year-round exploitation has been carried out in a remote environment by employing extensive stock-piling during winter months and by placing heavy reliance on air support. Rainbow crude started to market on March 18, 1966, approximately one year after discovery. Mathematical model studies of the discovery reservoir confirm that primary recovery will be 57 per cent of the oil-in-place. Maximum recovery of 96 per cent should be achieved by using a downward-moving miscible blanket. A processing plant is under construction to recover L.P.G., sweetened solution gas and compress these fluids for injection for pressure maintenance.</ABSTRACT>

- 26855 <ABSTRACT>Following the collapse of the ~2000km long Givetian (Middle Devonian) Inuitian/Ellesmere carbonate platform factory in arctic Canada, within the 0° to 10° equatorial palaeolatitudes north, the only Frasnian reefs in high arctic Canada retreated westwards, confined to northeastern Banks Island. These reefs, numbering well over 130, and dominated by corals and stromatoporoid sponges, were spread over c. 5000 km², within the 220m thick Mercy Bay Formation. Reefs were developed at four different stratigraphic levels (termed the A, B, C and D levels) during early and middle Frasnian time, periodically smothered by intervening siliciclastics during sea-level lowstands, and were finally buried by thick siliciclastic sands, silts and muds derived from the east during the late Frasnian. - 26867 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 154, 3: 275-292.</SOURCE>
- 26868 <ABSTRACT>Major and trace metal results from three Great Basin stratigraphic sections with strong conodont biostratigraphy identify a distinct anoxic interval that precedes, but ends approximately 100 kyr before, the Frasnian-Famennian (F-F, mid-Late Devonian) boundary mass extinction horizon. This horizon corresponds to the final and most severe step of a more protracted extinction period. These results are inconsistent with data reported by others from the upper Kellwasser horizon in Europe, which show anoxia persisting up to the F-F boundary in most sections. Conditions returned to fully oxygenated prior to the F-F boundary in the study area. These data indicate that the worst part of the F-F extinction was not related directly to oceanic anoxia in this region and potentially globally. [original abstract]</ABSTRACT>

26931 <TITLE>Coral zonation of the Mississippian system in the Western Interior Province of North America.</TITLE>
26932 <SOURCE>U.S. Geological Survey Professional Paper 1334: 1-61</SOURCE>
26933 <ABSTRACT>Analysis of the distribution of coral taxa, principally genera and subgenera, in the Mississippian of the Western Interior Province of Canada and the conterminous United States permits recognition of a system of coral zones and subzones useful for correlating stratigraphic units throughout an area extending from the southwestern District of Mackenzie in the Northwest Territories of Canada to southern California in the United States. The zonation comprises six OppeI Zones, four of which are divided into locally useful subzones. Coral Zone I corresponds approximately to the Kinderhookian Provincial Series and is divided into Subzones A, B, and C. Coral Zone II corresponds approximately to the Osagean Provincial Series and is divided into Subzones A and B. The Tournaisian Stage of western Europe is represented by Coral Zones I and II. Coral Zone III corresponds approximately to the lower and middle parts of the Meramecian Provincial Series and is divided into Subzones A, B, C, and

D. Coral Zone IV corresponds approximately to the upper part of the Meramecian and is not divided. Coral Zone V corresponds approximately to the lower and middle parts of the Chesterian Provincial Series and is divided into Subzones A and B. Coral Zone VI corresponds approximately to the upper part of the Chesterian and is not divided. The Visean Stage of western Europe is represented by Coral Zones III and IV and Subzone VA. The lower part of the Namurian Stage of western Europe is represented by Coral Subzone VB and Zone VI. Deep-water and shallow-water coral biofacies are discussed and integrated into the zonation system.</ABSTRACT>

26971 <SOURCE>Journal of Paleontology 67, 2: 179-193.</SOURCE>
26972 <ABSTRACT>The Chesterian Imo Formation of northern Arkansas represents the highest Mississippian strata present on the Ozark platform and contains a unique, although sparse, coral fauna that is transitional between Mississippian and Pennsylvanian assemblages. Of four most abundant genera represented, Lophophyllidium, Bradyphyllum, and Tectamichelinia are characteristic of Pennsylvanian assemblages and only Amplexizaphrentis is a typical Mississippian form. The fauna is interpreted as part of a shallow-water, muddy bottom community. Of the

11 rugosans and single tabulate coral described, the following are new: Bradyphyllum lesliense n.sp., Amplexizaphrentis maneri n.sp., Lophyphyllidium imoense n.sp., and Tectamichelinia mangeri n.gen. et n.sp.

26983 <TITLE>Mississippian coral latitudinal diversity gradients (western interior United States): Testing the limits of high resolution diversity data.</TITLE>
26984 <SOURCE>Journal of Paleontology 71, 5: 780-791.</SOURCE>
26985 <ABSTRACT>Analysis of high resolution diversity data for Mississippian corals in the eastern interior United States yielded mild latitudinal diversity gradients despite the small geographic area covered by samples and a large influence on diversity patterns by geographic sampling intensity (sample bias). Three competing plate tectonic reconstructions were tested using the diversity patterns. Although none could be forcefully rejected, one reconstruction proved less consistent with diversity patterns than the other two and additional coral diversity data from farther north in Canada would better discriminate the two equivalent reconstructions. Despite the relatively high sampling intensity represented by the analyzed database, diversity patterns were greatly affected by sample abundance and distribution. Hence, some effort at recognizing and accounting for sample bias should be undertaken in any study of latitudinal diversity gradients. Small-scale geographic lumping of sample localities had only small effects on geographic diversity patterns. However, large-scale (e.g., regional) geographic lumping of diversity data may not yield latitudinally sensitive diversity patterns. Temporal changes in coral diversity in this region reflect changes in eustasy, local tectonism, and terrigenous sediment flux, far more than they do shifting latitude. Highest regional diversity occurred during the interval when the studied region occupied the highest latitude. Therefore, diversity data from different regions may not be comparable, in terms of latitudinal inference. Small-scale stratigraphic lumping of the data caused a nearly complete loss of the latitudinal diversity patterns apparent prior to lumping. Hence, the narrowest possible stratigraphic resolution should be maintained in analyzing latitudinal diversity gradients.</ABSTRACT>

26997 <SOURCE>Proceed. Iowa Acad. Sci. 81, 2: 43-50. [key words: Pennsylvanian Corals, Missourian Corals, Fossil Corals]</SOURCE>
26998 <ABSTRACT>As in Kansas, where distinct zonation of corals has been recognized, the dissepimental Rugosa Dibunophyllum, Neokoninckophyllum and Geyerophyllum are invariably associated with limestones and thin calcareous shale interbeds within limestone units. In both states, the

- nondissepimental rugose genera *Lophamplexus* and *Stereostylus* have been collected from both limestones and thick intervening shale units. The tabulate genera *Syringopora* and *Cladochonus* are restricted to limestones in both areas. Although the vertical distribution of Iowa and Kansas dissepimental corals is similar, Iowa rocks contain fewer and generally smaller corals than correlative Kansas units. Elements of the informal dissepimental coral zones 1, 5 and 4 established by Cocke (1970, 1972) in Kansas are presently known in Iowa. </ABSTRACT>

27036 <SOURCE>US Geol. Survey Prof. Paper 848-C: C1-C31.</SOURCE>
27037 <ABSTRACT>The coelenterate faunas of the Amsden Formation of Wyoming consist of 14 species that represent 11 genera distributed among the

- chaetetid hydrozoans and the rugose and tabulate corals. Five new species and one new genus are described in this paper. Coelenterates are rare or absent in the Darwin Sandstone, Horseshoe Shale, and Ranchester Limestone Members of the Amsden, but they form a significant part of the invertebrate fauna of the Moffat Trail Limestone Member. Although both Mississippian and Pennsylvanian forms are present in the Amsden, the Moffat Trail fauna, which is of Late Mississippian (Chesterian) age, is the only coelenterate assemblage that is significant for correlation with other strata of similar age. </ABSTRACT>

27088 <SOURCE>Journal of Paleontology 68, 4: 734-746.</SOURCE>
27089 <ABSTRACT>Silicified and well-preserved specimens of the new orchocladine anthaspidellid genus and species, Virgaspongia ichnata, the rhizomorine haplistiid, Haplistion sphaericum Finks 1960, and various root tufts, and the new hexactinellid species Steioderma hadra are reported from the Brentwood Member of the Morrowan Bloyd Formation from the Sulphur City quadrangle, in the Ozark Mountains of northwestern Arkansas. Virgaspongia is a subcylindrical branched or unbranched sponge that lacks a spongocoel and has a dendroclone-based skeleton in which trabs diverge upward and outward from an axial region. It is abundant here but is one of only a few anthaspidellid genera known from the Pennsylvanian. This is the first record of Haplistion from Pennsylvanian rocks of Arkansas, although the genus is widespread in upper Paleozoic rocks. The new hexactinellid species, Steioderma hadra, also documents the first occurrence of that genus from Arkansas and in Morrowan rocks. Only fragments were recovered but the swollen grotesque spicules, of several sizes, that make the fused dermal layer and outer sponge wall are distinctive, particularly where combined with an inner layer(?) or root tuft of monaxons of various sizes. Two different root tufts and one demosponge wall fragment(?) also occur in the collection.</ABSTRACT>

27126 <TITLE>The coral fauna of the Pitkin Formation (Chesterian), northeastern Oklahoma and northwestern Arkansas.</TITLE>
27127 <SOURCE>Journal of Paleontology 61, 3: 462-493.</SOURCE>
27128 <ABSTRACT>The Upper Chesterian Pitkin Formation of the Ozark Dome region contains a large and diverse, yet highly endemic, coral fauna consisting of 10 genera of rugose corals and three of tabulate corals. Coral distribution within the formation is affected by stratigraphic, paleoecologic, and possibly paleogeographic controls. Although it is impossible at this time to fully evaluate the importance of stratigraphic controls on the coral distribution, the occurrence of two types of carbonate bioherms within the formation provides substantial paleoecologic control on the distribution of certain corals. Despite the high endemism and facies restriction, the coral fauna has proven to be biostratigraphically sensitive, correlating with middle and upper Chesterian coral zones in the Western Interior Province of North America. Among the Pitkin corals herein described are the new genera: Lesliella n.gen. (*L. amplexa* n.sp., type species) and Parvaxon n.gen. (*P. minutum* n.sp., type species). Other newly described species are: *Amplexizaphrentis browni* n.sp., *Barytichisma clubinei* n.sp., *B. ozarkana* n.sp., and *Leonardophyllum arkansanum* n.sp., which represents the first reported occurrence of the genus in strata below the Pennsylvanian boundary.</ABSTRACT>

27153 <SOURCE>Boletín de la Real Sociedad Española de Historia Natural, Sección Geológica 91, 1/4: 117-126.</SOURCE>
27154 <ABSTRACT>A new species of the genus *Petalaxis* occurs in strata of early Pennsylvanian Morrowan age in northeastern Oklahoma, in the *Branneroceras branneri* ammonoid zone, which correlate with the lower G2 interval in western Europe. It occurs in a quiet, offshore carbonate mudstone environment in which the colonies are all in growth positions. Large colonies are grouped into widely separated clusters in and on the

top surface of a widely distributed carbonate mudstone interval. with the slow influx of mud new spats of *Petalaxis* settled immediately on muddy surfaces partly covering the large *Petalaxis* n.sp. A colonies. In this adverse environment the new colonies survived for varying spans of time. They range in size from less than 2cm up to 16cm. Those over 5cm in diameter can be identified with certainly as being the same species as the large underlying colonies. Even those less than 2cm in diameter must be the same species in that no corals are found in the extensive barren spaces separating the underlying clusters of *Petalaxis* colonies. If a shale containing tiny *Petalaxis* colonies occurred at the same horizon in a locality separated even a short distance from a limestone containing large colonies of *Petalaxis* then the two groups of specimens would almost certainly be classified as different species. Such a conclusion would not necessarily be justified. </ABSTRACT>

 27180 <ABSTRACT>Dibunophyllum hansonii C. & H. n.sp. and Neokoninckophyllum tushanense (Chi 1931) occur throughout the Pennsylvanian (Missourian) Lost City Limestone Member of the Hogshooter Formation in northeastern Oklahoma. The former most closely resembles dibunophyllid species from the Upper Pennsylvanian Hertha, Swope and Dennis Limestones of Kansas. The latter is common in those limestones and also in Upper Carboniferous rocks of China. Neokoninckophyllum acolumnatum Cocke 1970 has been collected from one Lost City locality as well as in the Lower and Upper Missourian rocks of Kansas.</ABSTRACT>

- 27193 <ABSTRACT>Three species of dissepimental corals are described from a single limestone lentil in the upper Wann Formation, of northeastern Oklahoma. One species, *Neokoninckophyllum strimplei* Cocke & Molinary n.sp. is similar to *N. variabile* of the Kansas Wyandotte and Plattsburg Limestones and to *N. heckeli* of the Kansas Stanton Formation. Another dissepimental coral, *Dibunophyllum dibolium* represents the higher part of the Kansas *D. parvum* - *D. dibolium* lineage and suggests correlation of the upper Wann with the Stanton Limestone of Kansas. The third Wann species, *D. valeriae* Newell (1935) is widespread in the Wyandotte, Plattsburg and Stanton Limestones of Kansas. *Caninia torquia* and *D. parvum* occur in other Wann limestone lentils but are not described here.</ABSTRACT>

- 27218 <SOURCE>Palaeoworld 19, 3-4: 325-332.</SOURCE>
- 27219 <ABSTRACT>Little is known about predation on rugose corals or the repair of damage to rugose coral skeletons. Here we describe a population of the solitary rugose coral *Amplexizaphrentis spinulosa* (Milne-Edwards and Haime, 1851) from the Late Mississippian Pella Formation in Keokuk County, Iowa, USA wherein ~30% of 135 specimens experienced sublethal damage resulting from compression apparently inflicted by fish or other large predators. Many corals were able to repair severe damage and re-establish a relatively normal morphology despite the loss of parts of the wall. Healed damage includes: (1) chips to the edge of the calice, (2) punctures in the wall, (3) lost sections of wall, (4) re-cemented sections of wall, some at odd angles, (5) changes in growth direction, and (6) rejuvenescence. Multiple episodes of damage and repair occurred in 5% of samples. More severe damage on the cardinal side in almost one-half of damaged samples may reflect structural weakness at the cardinal fossula relative to the counter side, but septa were broken in all positions in many samples. The pattern of alignment and preservation of broken plates in the calice suggests that soft tissues were better attached to the skeleton in a band relatively far above the calice floor. Better musculature also may have occurred in the same band. Where parts of the wall were broken free from septa that remained fixed at their axial ends, new wall was deposited as stereoplasm against and enveloping the adaxial ends of the original septa. Lost lengths of septa were replaced by adaxial growth. New septa were commonly contorted, presumably owing to

deformation of surviving soft tissues that had lost structural support. Broken septa were generally healed, commonly with poor alignment. The high survival rate, even following multiple attacks, suggests that the soft tissues of the coral polyps were robust. The rarity of changes in growth direction following attacks suggests that the corals may have been more capable of righting themselves and re-establishing an optimum growth orientation than has commonly been suggested for solitary Rugosa. 27230 <TITLE>Diagenesis and microstructure of a rugose coral (Lophophyllidium sp.) from the Buckhorn Asphalt (Upper Carboniferous), south-central Oklahoma.</TITLE>
27231 <SOURCE>Bulletin of the Tohoku University Museum 1 [Proceedings of the 8th International Symposium on Fossil Cnidaria and Porifera]: 236-244.</SOURCE>
27232 <ABSTRACT>A rugose coral (Lophophyllidium sp.) from the Buckhorn Asphalt of Oklahoma provides new information on the mineralogy and microstructure of rugose corals. The Buckhorn Asphalt is an asphalt impregnated interval of mixed marine carbonate and siliciclastic sediments in the Deese Group (Upper Carboniferous) of central Oklahoma, USA. Buckhorn strata are renowned for their well preserved aragonite molluscan fauna. The Lophophyllidium specimen is slightly compressed and interseptal spaces contain little cement. X ray diffraction indicates that the coral is calcite. Septa contain medial "dark lines" flanked by stereoplasm that contains prominent laminae, possibly growth laminae, that have been diagenetically enhanced and form part of the chevron structure of secondary zigzag microstructure. Dissolution zones occur along septal margins. Microprobe minor element maps (Mg, Sr, Fe, and S) demonstrate highly variable Mg values in the dissolution zones, as much as 2-3 times Mg enriched, as compared to the rest of the coral, which has a relatively uniform, lower Mg content. Magnesium is mostly present in secondary microdolomite crystals, which disrupt the primary fibrous microstructure, but which are aligned along lineations defined by zigzag alteration. Strontium levels are low and uniform; Fe and S are largely confined to asphalt. Partial dissolution and occurrence of microdolomite crystals suggests that the skeleton was originally metastable low intermediate Mg calcite. Magnesium in the microdolomite was apparently derived from the coral itself by a process of microdissolution reprecipitation in a relatively closed system. Zigzag microstructure presumably formed during this very early neomorphism and may be directly related to the mobilization of Mg from the unstable precursor Mg calcite. 27295 <TITLE>Skeletal microstructure and the mode of attachment in Palaeacis species (Anthozoa: Tabulata) from the Mississippian and Pennsylvanian of northeastern Oklahoma and northwestern Arkansas.</TITLE>

- 27296 <SOURCE>Journal of Paleontology 67, 2: 167-178.</SOURCE>
- 27297 <ABSTRACT>Three species of Paleozoic coral Palaeacis are described from northeastern Oklahoma and northwestern Arkansas. Included are the Chesterian species *P. carinata* Girty and *P. snideri* nom. nov., a replacement name for the junior homonym *P. cuneata* Snider, and the Desmoinesian? species *P. erecta* n.sp. Coralla of each species exhibit two types of microstructure that characterize two skeletal zones. The outer skeletal zone is composed of numerous parallel trabeculae, mostly between 0,2 and 0,3mm in diameter, that lie perpendicular to, and have their accretionary surfaces on, the exterior surface of the corallum. Trabeculae are closely spaced laterally and are not organized into rows except uncommonly on the distal portion of some coralla. where trabeculae coalesce into parallel rows, ornamentation on the corallum exterior consists of parallel ridges or rows of small nodes. where trabeculae are irregularly arranged, external ornamentation consists of irregularly disposed nodes. The inner skeletal zone consists of radially fibrous stereoplasm arranged into discrete septal spines that coalesce into irregularly developed septal ridges in each calice. In *P. erecta*, septal spines merge into continuous [zone] of fibro-normal stereoplasm in some places. On the basis of microstructure, corallum morphology, and external ornamentation *P. carinata* and *P. snideri* can be allied with *P. axinoides* Smyth and *P. robusta* Webb. *P. erecta* falls within the same group on the basis of microstructure and ornament, but has a unique corallum morphology. Two distinct types of skeletal attachment occur in these Palaeacis species. Palaeacis *carinata* and *P. snideri* exhibit an encrusting attachment surface that results in a prostrate growth habit wherein smaller substrates were entirely engulfed, producing free-living coralla. Palaeacis *erecta* exhibits a small, circular attachment surface and an erect growth habit wherein most skeletal accretion occurs perpendicular to, and away from, the substrate. The substrate is not engulfed and the corallum remains attached and sessile throughout ontogeny. Palaeacis *erecta*, to date, the only Palaeacis species known to possess this erects, sessile growth form.</ABSTRACT>

- 27308 <TITLE>A Lower Pennsylvanian encrusting tabulate coral from a rocky shore environment developed on the Mississippian-Pennsylvanian unconformity surface in northwestern Arkansas.</TITLE>
- 27309 <SOURCE>Journal of Paleontology 67, 6: 1064-1068.</SOURCE>
- 27310 <ABSTRACT>Paleozoic corals are very rare in rocky shore settings. The only Paleozoic encrusting coral so far reported from this environment is Favosites sp. from Ordovician rocky shore deposits in Manitoba, Canada (Johnson and Baarli 1987). Reading and Poole (1961) reported corals and brachiopods that occur between, and coating, boulders from a Silurian rocky shore in England, but it appears that the corals and brachiopods only occur in the sediment enveloping the boulders, not as encrusters on the surfaces of the boulders. One reason for the sparse record of Paleozoic corals in rocky shore settings is the scarcity of described Paleozoic rocky shore deposits themselves. Johnson (1988) found only 20 examples of Paleozoic rocky shores in a compilation of references on ancient rocky shores from the literature. The paucity of described ancient rocky shores has been attributed to the prevalence in the past of epicontinental seas with little relict upon which to develop rocky shores and with higher wave attenuation

farther from shore (Boucot 1981; Harland and Pickerill 1984). Johnson (1988) concluded that the major reason for the rarity of ancient rocky shores in the literature is the difficulty with which they are recognized and studied, owing to the relatively poor exposure of most unconformity surfaces. The rocky shore environment was also probably hostile to many Paleozoic coral genera. Recent scleractinian corals may serve as analogues because they are also not very abundant in rocky shore settings despite their great abundance in similar shallow-water, high-wave-energy reefal environments. Turbidity and relative substrate stability may be important limiting factors for corals in rocky shore environments. Many corals are known to be highly sensitive to sediment in the water column. Substrate stability (Wilson 1987) and the scouring effects of sand in high-energy environments (Palmer and Palmer 1977) also have been shown to affect the abundance and diversity of organisms encrusting cobbles and boulders. The purpose of this note is to describe a Lower Pennsylvanian encrusting coral, possibly *Michelinia scopulosa* Moore and Jeffords 1945, from transgressive rocky shore deposits at the base of the Cane Hill Member of the Morrowan Hale Formation in northwestern Arkansas. Illustrated specimens are deposited in the Oklahoma Museum of Natural History (OU).</ABSTRACT>

27321 <TITLE>Benthic auto-mobility in discoid Palaeacis from the Pennsylvanian of the Ardmore Basin, Oklahoma? </TITLE>
27322 <SOURCE>Journal of Paleontology 68, 2: 223-233.</SOURCE>
27323 <ABSTRACT>The enigmatic tabulate genus Palaeacis is composed primarily of species with wedge-shaped coralla. Palaeacis walcotti Moore and Jeffords 1945, P. kingi Jeffords 1955, and P. cf. P. walcotti, described below from the Morrowan (Pennsylvanian) Golf Course Formation of the Ardmore Basin, south-central Oklahoma, represent a distinctive morphogroup characterized by a discoid corallum. Discoid Palaeacis ranges from the Morrowan to the Missourian and, so far, is known only from the mid-continent region of North America. The discoid shape, combined with concentric skeletal accretion, large corallite diameters, complex calice floors, and porous skeleton suggest, based on comparisons with the functional morphology of recent scleractinians, that these corals were well suited to an auto-mobile (vagile) life strategy, much as are many Recent fungiid corals. Discoid Palaeacis inhabited environments with muddy or sandy, unconsolidated substrates and was associated with low-diversity, non-encrusting faunas. This association is consistent with an auto-mobile life strategy. Auto-mobility in Palaeacis would represent the first such reported occurrence in the Tabulata, and the first in Paleozoic colonial corals of all types.</ABSTRACT>

27334 <TITLE>First record and a new species of Palaeacis Haime 1857, from the

- Mississippian of western Canada.</TITLE>
27335 <SOURCE>Journal of Paleontology 57, 1: 42-47.</SOURCE>
27336 <ABSTRACT>A single elongate and structurally advanced specimen of the rare and problematical supposedly tabulate coral genus Palaeacis Haime 1857, in Milne-Edwards 1860, emended Conkin, Bratcher and Conkin 1976, was collected in 1980 by Mr. H. J. Negrich (submitted by Dr. M. Wilson) from the Kananaskis Valley, Alberta, in beds high in the Mississippian Rundle Group. The specimen is referred to Palaeacis elongata n.sp. The taxonomic status of Palaeacis is problematical, as it lacks septa and tabulae, and has a porous sponge-like wall rarely found in coelenterates, although the alternating biserial arrangement of eighteen calyces appears coral-like. The origin of interwoven submicroscopic fibers lining the calyces is unknown. The recorded species. P. bifida (Kinderhookian and Osage), P. cavernosa. P. obi usa (Osage), P. cuneiformis (Meramecian) P. carinata (Chesterian), P. walcotti P. testate, P. kingi (Pennsylvanian), may demonstrate restricted stratigraphic ranges, although symbiotic and sedimentological controls may also be involved. Palaeacis has been recorded from the Carboniferous of the British Isles, Morocco, the Soviet Union, the United States, Australia, and from the Permian of Timor. [original abstract]</ABSTRACT>

27349 <ABSTRACT>The Pennsylvanian Missourian Hogshooter formation of Northeastern Oklahoma locally contains abundant Tabulate Corals, Crinoids, and rare Blastoids in calcarenites and calcareous shales. These organisms are most abundant in reef associated beds at a single locality. None were collected from the phylloid algal mound complex which comprises most of the Hogshooter outcrop belt in Oklahoma. Species of four Tabulate coral genera are described from reef flank beds. They are Sutherlandia cf. S. irregularis Cocke and Bowsher, 1968, Striatopora kolmani n.sp., Michelinia adibilus n.sp., Cladochonus conus n.sp.</ABSTRACT>

27465 <SOURCE>Ra pp. Groenlands geol. Unders. 161: 39-44.</SOURCE>
27466 <ABSTRACT>Three types of carbonate-buildups occur in the mid-Carboniferous - ?early Permian (Moscovian-?Asselian) succession at Kap Jungersen, southern Arndrup Land, North Greenland: (1) Palaeoaplysina-dominated build-ups; (2) Algae-dominated build-ups; and (3) Bryozoan-dominated build-ups. The build-ups are less than 15m thick

and up to a few hundred metres wide. They often coalesce to form laterally widespread, build-up dominated units and are locally stacked to form up to 100m thick build-up dominated sections along platform margins.

27477 <TITLE>Guadalupian (Middle Permian) solitary rugose corals from the Degerbøls and Trolld Fiord formations, Ellesmere and Melville Islands, Canadian Arctic Archipelago.</TITLE>
27478 <SOURCE>Acta Geologica Polonica 51, 1: 31-79.</SOURCE>
27479 <ABSTRACT>The sparse, Wordian rugose coral fauna of the Degerbøls and Trolld Fiord formations consists exclusively of nondissepimental, solitary taxa and includes the youngest Permian corals in the Sverdrup Basin. Similar, approximately coeval, Guadalupian coral assemblages are widespread in the youngest coral-bearing deposits of the Calophyllum Province in the northern Cordilleran-Arctic-Uralian Realm. The described Sverdrup Basin fauna includes eight species (four new) belonging in the genera Allotropiochisma, Calophyllum, Euryphyllum, Lytvolasma, Soshkineophyllum and Ufimia. Revision of several previously described corals from East Greenland clarifies their taxonomy and emphasizes the similarity between that fauna and others in the Calophyllum Province. The distribution and relative abundance of solitary species in Svalbard, East Greenland and the Sverdrup Basin confirms the geographic proximity of those areas and open marine communication between them during Guadalupian time. Contrasting, low diversity in the Central European Basin and East European Platform indicates scarcity of favourable marine habitats and a low level of faunal exchange with the remainder of the Calophyllum Province.</ABSTRACT>

27491 <SOURCE>Canadian Society of Petroleum Geologists, Memoir 19: 427-436.</SOURCE>
27492 <ABSTRACT>The sparse rugose coral fauna of the Degerbøls and Trolld Fiord formations consists exclusively of nondissepimental, solitary taxa and includes the youngest Permian corals in the Sverdrup Basin. Similar faunas occur in the youngest coral-bearing deposits elsewhere in the northern parts of the Cordilleran-Arctic-Uralian (CAU) Realm - in Alaska, East Greenland, the Svalbard Archipelago, the Central European Basin and the East European Platform. These assemblages occupy a separate biogeographic province, here named the Calophyllum Province. In comparison to the CAU faunas, Guadalupian faunas in the Tethys Realm are much richer and contain abundant, diversified colonial taxa as well. The solitary, nondissepimental corals of the Tethys Realm show much greater diversity than those in the CAU Realm and survived almost until the end of the Permian. On the family and genus level, there is a

fairly close relationship between the nondissepimental solitary corals of the two realms. This did not result, however, from direct faunal exchange during the Permian, but reflects common roots for these corals and widespread faunal dispersion prior to Permian establishment of the realms.</ABSTRACT>

27503 <TITLE>Early Permian buildups (Tolkien reefs) associated with subaqueous evaporites, Canadian Arctic: a record of syn-tectonic to post-tectonic reciprocal uplift and subsidence.</TITLE>
27504 <SOURCE>SEPM Special Publication 78 (Permo-Carboniferous carbonate platforms and reefs): 133-153.</SOURCE>
27505 <ABSTRACT>Twenty-six reef-mounds of Early Permian (Middle or Late Asselian) age crop out along the north shore of Greely Fiord on west-central Ellesmere Island, Canadian Arctic Archipelago. Each reef was attributed the name of a character from J.R.R. Tolkien's <#34;The Lord of the Rings<#34;. The reefs interfinger with evaporites in the upper part of the Mount Bayley Formation, immediately below the Tanquary Formation. The reefs grew at the northern margin of a large depression of the Sverdrup Basin referred to as the Fosheim-Hamilton sub-basin, which is separated from the main Sverdrup Basin by the Elmerston high, an elongated structure of probable compressional origin. The Tolkien reefs range from 50m to over 130m in thickness and between 50m and 500m in width and length. The buildups have a massive core around which are wrapped a series of well-defined, variably steep beds (flanks), many of which display a sharp erosional base. Facies of the core and inner flank comprise: bryozoan-Tubiphytes-stromatactoid (sponge) boundstone; bryozoan cementstone; bryozoan mudstone-wackestone; and bryozoan (fusulinacean) packstone-grainstone. Facies of the outer flank include: algal boundstone; and fusulinid-algal grainstone-rudstone. Facies that occur both in the inner and outer flanks include carbonate breccia and moldic dolomicrite. The Tolkien Reefs of west-central Ellesmere Island recorded the transition from an evaporite-dominated succession (Mount Bayley Formation) to an evaporite-free succession (Tanquary Formation). The reefs grew south of a major structural element - the Elmerston high - through the complex interplay between high-order to low-order relative sea-level fluctuations driven by tectonics, glacio-eustasy, and evaporative drawdown. The Tolkien Reefs recorded the rapid transition between a long episode of differential, and in part fault-controlled, syntectonic subsidence and a long period of slower, regional post-tectonic passive subsidence. While the former can be associated with a pulse of compressional tectonics that affected many areas of the Sverdrup Basin, the latter represents a phase of tectonic quiescence. - 27544 <ABSTRACT>A cavity-dwelling fauna from the Middle Jurassic of the Western Interior shows a succession controlled by increasing restriction of the cavities, most likely by sediment infilling. The succession proceeds from large and ubiquitous bivalves to smaller serpulids, cyclostome bryozoans, and thecideidine brachiopods; there is a concurrent decrease in biomass and percent cover. This Jurassic fauna demonstrates that marine cavity-dwelling faunas were specifically adapted to their environments at least 160 m.y. ago.</ABSTRACT>

27568 <TITLE>A new hexactinellid sponge from the Cretaceous of Devon Island, Canadian High Arctic.</TITLE>
27569 <SOURCE>Canadian Journal of Earth Sciences 44: 1235-1242.</SOURCE>
27570 <ABSTRACT>Over 20 specimens of the new genus and species Nunavutospongia irregulara, an irregular stump-like to columnar, or fan- to blade-shaped, hexactinosid hexactinellid sponge, have been recovered from exposures of the Upper Cretaceous upper Kanguk Formation on Devon Island, Nunavut Territory, in the Canadian High Arctic. The species and genus are characterized by dermal surfaces with prominent radial, irregularly vertical, rib-like flanges that have a single linear series of separated oscula perforating their rounded crests. The thin, but persistent dermal layer of fused hexactine-based spicules has rays thicker than those of the similarly fused endosomal, quadrangularly arranged, hexactines of the principal skeleton. Ostia of coarse exhalant canals, and finer inhalant canals, are extensively and uniformly developed, but irregularly placed, in the dermal layer. A thin, less prominent, gastral layer of thickened spicules lines the short, internally tapered spongocoel openings. The skeleton exposed in the commonly upward-arcuate base of each sponge has a radiate structure that does not have significant ostia. The new genus is tentatively included in the Family Cribrospongiidae Roemer, 1864, within the Order Hexactinosa Schrammen, 1903. The specimens were found in unconsolidated fine-grained glauconitic sediments along with other fossils such as fish teeth, bird bones, lingulids, coprolites, and wood. The sedimentology, stratigraphic context, and co-occurrence with fossil wood suggest that these sponges inhabited the neritic zone. As such, they would have been subject to polar light regimes, because paleogeographic reconstructions indicate that Devon Island was above the Arctic Circle during the Late Cretaceous. The distribution of the specimens suggests that they were solitary sponges that used their arcuate bases to colonize sandy substrates or biotic debris.</ABSTRACT>

27581 <TITLE>A new hydroid from the Upper Cretaceous of Mississippi.</TITLE>
27582 <SOURCE>Paläontologische Zeitschrift 67, 3-4: 253-259.</SOURCE>
27583 <ABSTRACT>A new fossil hydroid is reported as an organic impression on a calcareous gastropod steinkern from the Prairie Bluff Chalk (Maastrichtian), Oktibbeha County, Mississippi. This is the first such hydroid reported from the Upper Cretaceous of the Atlantic Coastal Plain. The fossil organism consists of anastomosing hydrorhizae forming a holdfast, a fascicled hydrocaulus, and elongated, crenulated and ribbed hydrothecae. The fossil is unlike other Mesozoic hydroids that have been reported from Europe and North America; it is described as Mesodendrium oktibbehaensis gen. et sp.nov. and tentatively referred to an extant family, the Campanulariidae (Calyptoblastina). The complete preservation of the holdfast, hydrocaulus and hydrothecae suggests that this hydroid lived inside gastropod shells. In analogy with Recent symbiotic hydroids inhabiting mollusc shells, the new specimen described here possibly represents the oldest known example of a

- 27584 symbiotic relationship between hydroids and hermit crabs.</ABSTRACT>

27607 <TITLE>Scleractinian Corals from the Upper Cretaceous and Lower
Tertiary of Nugsuaq, West Greenland.</TITLE>
27608 <SOURCE>Meddr. Groenland. 196, 1; 132 pp.</SOURCE>
27609 <ABSTRACT>Localities and deposits in north-west Nugsuaq yielding
fossil corals of the order Scleractinia are described. The age of the
corals is Campanian?, Maastrichtian and Lower Paleocene (Danian), on
the basis of other marine fossils. 22 species are considered; 7 are
described as new and are indigenous, 2 are possibly North American
forms, 3 are known from Europe, and 10 are identifiable only to generic
level. The following genera and subgenera are represented:
Haimesiastraea (Haimesiastraea), H. (Peruviastrea)?, Astrangia
(Coenangia)?, Oculina, Caryophyllia, Trochocyathus, Paracyathus,
Stephanocyathus (Stephanocyathus), Desmophyllum?, Lophelia?,
Parasmilia, Flabellum, Balanophyllia, and Dendrophyllia. In addition,
two new genera are described: Kangiliacyathus and Faksephyllia. Certain
Danian corals from Scandinavia are also revised. In a survey of
habitats, the lithology of the coral localities is considered together
with bathymetric and thermal ranges known for scleractinian genera and
species from other parts of the world. Depth and temperature of the
Campanian and Maastrichtian seas in Greenland cannot be estimated with
any accuracy. The Lower and UpperDanian seas were generally rather
shallow. There is little evidence on which to judge the Danian climate.
Two species were perhaps hermatypic (no reef structures have been
found). The remaining scleractinians are presumed to have been
ahermatypic. A non-reef coral association has been found. Lower Danian
rather sparsely populated polytypic coral thickets show signs of
continual disturbance from water turbulence. The approximate depth of
formation of these thickets appears to have been 80m. or shallower,
which appears to be less than is usual for coral structures of this
type. Some Lower Paleocene species provide conclusive evidence of a
direct connection between the Danian seas of west Greenland and of
Scandinavia.</ABSTRACT>

27621 <SOURCE>Journal of Paleontology 66, 4: 594-602.</SOURCE>
27622 <ABSTRACT>An assemblage of well-preserved octocoral holdfasts and sclerites has been collected from the Red Bluff Formation at the Chickasawhay River, Wayne County, Mississippi. Seven families were identified, utilizing a collection of approximately 1,000 sclerites. Families represented are Telestidae, Nephtheidae, Anthothelidae, Paramuriceidae, Plexauridae, Virgulariidae, and Gorgoniidae. These families, with exception of the Gorgoniidae, are here reported for the first time as fossils from the Gulf Coast region. The collection represents one of the most diverse fossil octocoral assemblages known from a single location.</ABSTRACT>

27646 <TITLE>Uranium-series dating of fossil corals from marine sediments of southeastern United States Atlantic Coastal Plains.</TITLE>
27647 <SOURCE>Bulletin Geological Society of America 96: 398-406.</SOURCE>
27648 <ABSTRACT>Extensive low-lying marine deposits border the southeastern United States Atlantic Coastal Plain. Some units are fossiliferous and contain corals as isolated fragments in sediments of a detrital character. These corals are subject to alteration processes such that suites of related samples must be examined to determine the suitability of these coral samples for reliable uranium-series dating. With the exception of those from one location, most samples appear to have remained closed systems with respect to the isotopes of uranium and thorium throughout their geologic history. Extraneous ²³⁰Th has been detected in some of the corals due to incorporation of some detrital materials into their skeletons. For these samples, different methods are applied to correct for the initial ²³⁰Th contamination. Continued sampling and analyses have resulted in 55 individual uranium-thorium determinations.</ABSTRACT>

27685 <TITLE>Ecological stratification in the Pleistocene coral reefs of the Kenya coast.</TITLE>
27686 <SOURCE>Palaeontology 24, 3: 609-646.</SOURCE>
27687 <ABSTRACT>Ecological succession on small patch reef structures can be studied by employing the concept of ecological stratification. The component coral of a patch are divided into two basic categories, the B or C horizons (or strata). The former category represents the initial colonizers (or pioneers) on a soft substrate, and the latter the subsequent colonizers. The potential exists for studying the later stages of successions by finely subdividing the C horizon. Detailed mapping of vertical sections through patch reefs in the Pleistocene reef limestones of the Kenya coast provided stratification analyses in a variety of back-reef environments. Massive Porites proved to be the commonest B horizon coral throughout the region studied, and clearly was of fundamental importance in patch reef formation. Massive faviids and mussids were less frequent early colonizers. The most important C horizon corals were encrusting Montipora (in more open water areas), encrusting Cyphastrea (in quieter, deeper water areas), and tiny domes and patches of massive Favia. Many coral may be much more specialized in their habitat requirements than has previously been recognized. The principal coral type within the back-reef patches of the Kenya Pleistocene reef consistently adopt distinctive three-dimensional growth forms within either B or C horizons, and it is argued that they must have partitioned at least part of the available habitat space. Ecological stratification is a useful tool for determining the nature

- and extent of habitat resource partitioning by scleractinian corals.

27712 <SOURCE>Canadian Journal of Zoology 71: 665-682.</SOURCE>
27713 <ABSTRACT>During a recent survey of the freshwater sponges of eastern Canada (from Ontario to Newfoundland). 15 species were recorded, representing approximately 50% of the total number of species known from North America. Radiospongilla crateriformis, Spongilla aspinosa, and Trochospongilla horrida are reported from Canada for the first time. Two problematic species, Corvospongilla novaeterrae and Spongilla johanseni, are reviewed and their status is revised. Detailed notes on taxonomy, morphology, distribution, and ecology are given. New limits of tolerance with respect to pH, water temperature, and calcium and magnesium concentrations are established for several species. A taxonomic key to the freshwater sponges of eastern Canada is presented.

27815 <TITLE>A model for the origin and petrogenesis of the red stromatactis limestone of Paleozoic carbonate mounds.</TITLE>
27816 <SOURCE>Journal of Sedimentary Petrology 63, 4: 607-619.</SOURCE>
27817 <ABSTRACT>From study of the Devonian "écifs rouges" of Belgium and the Silurian mounds of the Quebec Appalachians, we propose that deposition of the red stromatactis limestone facies of Cambrian-Devonian carbonate mounds was controlled by sponges and that the red color and stromatactis result from early diagenesis within a few meters below the substrate-water interface in the deep-marine environment. The common presence of sponge body fossils, as well as various stages of sponge preservation, ranging from easily delineated to indiscernible bodies, in the Belgian "écifs rouges" support the conclusion that a large part of the red finely crystalline limestone originated from early cementation of sponge communities or spicule-rich organic mats derived from degradation of sponge communities. The role of bacteria and other microbes, although widely advocated as the main primary builders of carbonate mounds, is difficult to assess. Microbial communities may have contributed to mound accretion as primary builders and/or mud producers, but their presence cannot be documented. We suggest that they may have acted as agents for concurrent sponge petrefaction and early cementation (biodiagenesis) during the sulfate-reduction phase under alkaline pH and anoxic conditions. We interpret stromatactis as a spar body that resulted from early marine cementation of a cavity network created by excavation of uncemented material in partly indurated, decaying sponges and spicule-rich organic mats derived from degradation of sponge communities through circulation of interstitial water in the uppermost

few meters of the sediments. This cavity network was connected to sea floor and flushed by oxic waters that changed the diagenetic environment from anoxic to oxic, converting amorphous iron sulfide to hematite and giving the facies its red color. Recognition of the dominant role of sponge communities in the construction of red stromatolite limestone mounds of the Cambrian-Devonian time interval has important implications for the geological record. This community was the main deep-water mound-building community during this time, but it is difficult to recognize because of its variable but often poor preservation.

 27828 <TITLE>Die tabulate Korallen-*genus*; *Emmonsia* Milne-Edwards *genus*; Haime 1851 - ein verwirrt-Beispiel *genus*; palaeontologische Systematik.</TITLE>
 27829 <SOURCE>Sonderveröffentlichungen, Geologisches Institut der Universität zu Köln 114 (Festschrift Eugen K. Kempf): 325-357.</SOURCE>
 27830 <ABSTRACT>*Emmonsia* Milne-Edwards *genus*; Haime 1851 is a characteristic *genus*; of the American Middle Devonian, but also occurs in Europe. During the last 140 years *Emmonsia* became a perfect example for the difficulties and problems of taxonomic work. This concerns the *genus*; and its typology as well. In the dawn of systematic work the history of the *genus*; *Emmonsia* began with the groping for detailed description. In the following interpretation, new naming and the *genus*; *Emmonsia* of scientists took care for the rest. The uncertainty concerning the functional significance and taxonomic value of the squamulae - here tabulae, their septa - confused even more. This paper tries to answer this palaeontological law case (International Code for Zoological Nomenclature) by circumstantial evidence and witness.</ABSTRACT>

 27842 <SOURCE>Journal of Paleontology 49, 1: 163-186.</SOURCE>
 27843 <ABSTRACT>The limestones of the Chazy Group contain a record of the spread of the mid-Paleozoic reef community dominated by the stromatoporoids. The oldest stromatoporoid in this community, *Pseudostylodictyon lamottense* (Seely), occurs in the Day Point Formation, the lowest in the group. Just above the base of the succeeding Crown Point Formation three species of *Labechia* [*L. eatoni* (Seely), *L. cf. L. pustulosa* (Safford) and *L. prima* n.sp.] and one species of *Pachystylostroma* (*P. goodsellense* n.sp.) appear. By late Crown Point time the fauna has attained a diversity of nine species including a new species of *Labechia* (*L. valcourensis*) and three new species of *Pachystylostroma* (*P. vallum*, *P. pollicellum*, and *P. champlainensis*). * The first stromatoporoids had denticled laminae and

large irregular cysts. This genus (Pseudostyiodictyon) appears to have given rise to forms with clearly differentiated laminae and cysts and superposed denticles (Pachystylostroma) and to forms which combine cysts and round pillars (Labechia). Solid pillars were formed by the superposition of denticles and hollow pillars through the superposition of erupted denticles. However the state of preservation may also determine whether pillars are expressed as solid rods, hollow tubes or columns of spar without walls.</ABSTRACT>

27854 <TITLE>An annotated list of New York Silurian corals.</TITLE>

27855 <SOURCE>FC&P 12, 1: 4-11.</SOURCE>

27856 <ABSTRACT>Following is a list of the coral species known or supposed to occur in the Silurian rocks of New York. It represents part of a paper discussing the status of New York Silurian coral biostratigraphy, to be included in the field guides for the Fourth International Symposium on Fossil Cnidaria. The full paper will include the stratigraphic distributions of each species. This list is offered here in the hope that it may prove useful to specialists who do not obtain the field guide. * The name next to each marginal number is that which seems most correct or useful in light of our current knowledge of the available specimens. Indented beneath each name are citations of references to New York Silurian material believed to pertain to that species. For brevity, only the first page of each reference, and no indication of illustrations, is given. As indicated, many of the reports are tentative identifications kindly provided by William A. Oliver, Jr. (U.S. Geological Survey, Washington, D.C.), based upon his own as-yet unpublished work. * where known, the catalogue numbers of the specimens on which each reference was based are given following each citation. The prefixes attached to these catalogue numbers indicate the following repository institutions: * AMNH American Museum of Natural History, New York, New York; * NYSM New York State Museum, Albany, New York; * USNM United States National Museum of Natural History, Washington, D.C.; * YPM Peabody Museum of Natural History, Yale University, New Haven, Connecticut. 27920 <SOURCE>Bulletins of American Paleontology 67, 287: 407-422.</SOURCE>
27921 <ABSTRACT>Upper Devonian strata in western Steuben County, New York State, have yielded new fossil material of the genus Plumalina provisionally assigned herein to the species P. densa Hall 1878. The specimen occurs with the sponge Clathrosporgia? sp. in a thin sandstone bed virtually devoid of other fauna. The occurrence of macroscopic surface features, referred to as papillae, are reported from specimens of P. plumaria Hall and P. densa Hall. The papillae are suggested to be

- poorly preserved polyp bases. The history of Plumalina (Octocorallia) is reviewed and its possible affinities explored. </ABSTRACT>

- 27934 <ABSTRACT>Rugose corals are of little value for intercontinental correlations but are useful for correlation within basins or biogeographic provinces. In Devonian rocks of the northern Appalachian Basin (New York and adjacent areas), 12 stratigraphically useful rugose coral assemblages are recognized. These assemblages vary in the degree to which they are controlled by facies and in the amount of time that they represent (resolving power), but some are widespread and are more useful stratigraphically than other fossils for correlations within the basin or province.</ABSTRACT>

- 27946 <SOURCE>Journal of Paleontology 75, 1: 24-33.</SOURCE>
- 27947 <ABSTRACT>Heliophyllum halli contains variable, mostly solitary rugose corals. Specimens reported here come from shaly beds of the Middle Devonian Hamilton Group in New York State. Early recognition of morphotype variation led James Hall to establish numerous species in the H. halli group that were later interpreted by John Wells in terms of varying life history. Life on unstable and/or soft substrates was facilitated for these corals by talons, root-like structures that allowed larval settling and post-larval development on hard particles such as echinoderm or shell debris. Variation in subsequent growth history is reflected in corallum shape and change in diameter. Straight growth axes reflect partial burial accompanied by vertical growth, while growth axis curvature resulted from unequal settling into substrate or alternatively, life at the surface of substrate, with sharp bends (geniculations) reflecting major changes in growth orientation. Decrease in diameter resulted from environmental stress, with greatest effects on the peripheral portion of the calice. Other major reactions to increased burial rate (through sinking or increased sedimentation) are epithelial secretion to form an outer wall for isolation of itself from surrounding sediment or decrease in polyp size as shown by terminal shrinking of the corallum diameter, at times nearly to zero. Yonge's (1940) summary of observations on living coral polyps suggests that the living H. halli was nonzooxanthellate, with an efficient system of feeding that utilized its multitude of

tentacles without the help of cilia, which thus were able to generate currents to promote efficient sediment cleansing. Sediment shedding would also have been aided by polypal distension (swelling) above a reflexed calical margin.</ABSTRACT>

27959 <SOURCE>Bulletin Biological Society of Washington 10: 233-241.</SOURCE>
27960 <ABSTRACT>A hand sized specimen of a colonial rugose coral, Prismaticophyllum foetidum, new species, was collected from black shale of the Middle Devonian Union Springs Formation in Onandagan County, New York. The coral could not have grown in the black, fetid, mud environment indicated by the shale and it most likely originated in the Seneca Member of the Onandaga Limestone that unconformably underlies the Union Springs. If so, it is only the second specimen of colonial rugosan known from the Seneca. The new specimen is congeneric, but clearly not conspecific with the previously known specimen.</ABSTRACT>

27971 <TITLE>The genus Heliophyllum (Anthozoa, Rugosa) in the Upper Middle Devonian (Givetian) of New York.</TITLE>
27972 <SOURCE>Bulletins of American Paleontology 362: 1-72.</SOURCE>
27973 <ABSTRACT>Specimens of the genus Heliophyllum are among the most common components of the upper Middle Devonian coral fauna (Givetian; Hamilton Group and Tully Limestone) in New York State. Although these corals are abundant and widespread, examination of large numbers of specimens indicate that most of them belong in a single, variable species, H. halli Milne-Edwards and Haime, including both solitary and colonial forms. This study has resulted in the recognition of four subspecies of H. halli, the solitary H. halli halli, and three colonial subspecies, H. halli confluens (Hall), H. halli bellonense n. subsp., and H. halli joshuense n. subsp. The three colonial subspecies occur in restricted stratigraphic positions, each in a coral bed in which it is associated and intergrades with solitary H. halli halli. Two additional species of Heliophyllum are recognized in the Hamilton, the small solitary H. cribellum n.sp. and the dendroid branching H. delicatum Oliver and Sorauf. The former has been found only in the Centerfield Limestone, lower Ludlowville Formation; the latter is limited to the lower Deep Run Shale, Moscow Formation. Heliophyllum halli flourished in muddy but well-oxygenated parts of the Hamilton sea floor because basal, rootlike structures (talons) and shape adaptations helped keep the living polyp from being overwhelmed by the mud. Septal carinae are thought to have helped anchor the polyps in their calices, perhaps making it easier for them to remove any sediments that accumulated on the oral surface. Heliophyllum cribellum is common in the Centerfield Limestone, which represents a more calcareous, relatively stable sea floor, while

H. delicatum seems to have adapted to a more muddy, subsiding sea floor by fast upward growth. However, both species were associated with solitary H. halli halli, a further indication of the great adaptability of the species.

27998 <SOURCE>Journal of Paleontology 61, 4: 676-689.</SOURCE>
27999 <ABSTRACT>West Falls Group strata (Chemung facies) of Upper Devonian (Frasnian) age in New York State reflect sedimentation on a storm dominated sandy shelf. Rugose corals occur in storm deposited coquinites rich in bioclastic debris and are abundant locally, although representing only three species, Tabulophyllum orientale (Stumm), Macgeea ponderosa Stumm, and Disphyllum caespitosum (Goldfuss). The Tabulophyllum and Macgeea species are both characterized by large amounts of stereome (biogenic calcite) in the apical part of the corallite, perhaps useful in stabilizing corallites in the sediment.</ABSTRACT>

28024 <SOURCE>Bulletin U.S. Geol. Surv., 1860: D1-D6.</SOURCE>
28025 <ABSTRACT>The rugose coral Bowenelasma Scrutton was originally described from early Eifelian (?) specimens in northwestern Venezuela. It is here described from New York on the basis of specimens from the Bois Blanc Formation (early? Emsian) and the Edgecliff Member of the Onondaga Limestone (early Eifelian(?)). The Bois Blanc Bowenelasma are beautifully silicified, so that morphologic details of both exterior and interior can be described. Bowenelasma is limited to the Eastern Americas Realm and to rocks of late Early and early Middle Devonian age.</ABSTRACT>

28037 <SOURCE>Boletín de la Real Sociedad Española de Historia Natural, Sección Geológica 91, 1/4: 053-060.</SOURCE>
28038 <ABSTRACT>Heliophyllum halli Milne-Edwards & Haime is common to abundant in many Lower and Middle Devonian stratigraphic units in New York. Most Heliophyllum are solitary, but both branching and massive colonies are known. Four "populations" of colonial Heliophyllum in the Givetian part of the sequence are distinct, as is a fifth form that occurs through the section. Each of the colonial forms is interpreted as an independent derivative of solitary forms of H. halli. The relationships appear to range from infrasubspecific to specific, and it is suggested that the complex should be recognized as the Heliophyllum halli species group.</ABSTRACT>

28049 <TITLE>Branching Heliophyllum (Devonian Rugose corals) from New York and Ohio.</TITLE>
28050 <SOURCE>Journal of Paleontology 68, 6: 1183-1201.</SOURCE>
28051 <ABSTRACT>Solitary species of Heliophyllum are the most common form of the genus but branching and massive colonies do occur, especially in Middle Devonian strata of eastern North America. Heliophyllum delicatum n.sp. offsets laterally and has a dendroid, broad bushy growth form. The species is known only from western and west-central New York and appears to be limited to the lower part of the Deep Run Shale Member of the Moscow Formation (middle Givetian); specimens are common within this restricted geographic and stratigraphic range. The skeleton of H. delicatum was poorly designed for the common coral environments of the Devonian, but seems to have been well adapted to muddy, carbonate-poor conditions where its thin skeletal elements required less calcium

carbonate and its unsupported branches were not subject to vigorous water movement. *Heliophyllum stewarti* n.sp. is based on a single specimen from the Tenmile Creek Dolomite (middle Givetian) in northwestern Ohio. The colony is phaceloid but each branch is an astreoid cluster without walls between individual corallites. In addition, the apparent protocorallite is turbinate with a larger diameter than any of the ceratoid offsets although offset lengths are several times that of the protocorallite. </ABSTRACT>

28127 <TITLE>A multivariate analysis of two contemporaneous species of the stromatoporoid Habrostroma from the Lower Devonian of New York.</TITLE>

28128 <SOURCE>Bulletin of the Tohoku University Museum 1 [Proceedings of the 8th International Symposium on Fossil Cnidaria and Porifera]: 279-284.</SOURCE>

28129 <ABSTRACT>Two species of Habrostroma dominate the stromatoporoid fauna of the Manlius and Coeymans Formations (Lower Devonian, Lochkovian) of New York. In the past, Stock has discriminated between these two species on the basis of localized, cystlike microlaminae within the skeleton. Those with more than 37% of the skeleton containing the cystlike microlaminae were placed in Habrostroma microporum, whereas those with less than 34% of the skeleton containing the cystlike microlaminae were placed in H. centrotum. All other skeletal structures typically used in stromatoporoid species identification failed to yield consistent differences among species examined. However, Stock was uncomfortable with this classification, so a statistical analysis was

carried out to confirm the earlier decisions. Measurements of nine morphologies from 103 specimens of *Habrostroma* were subjected to a hierarchical cluster analysis. Using the average linkage between groups, two distinct clusters were revealed. Group assignments made from the cluster analysis were saved and entered into a canonical discriminant analysis along with the nine morphological variables. An overall Wilks' lambda was calculated, and is statistically significant at $\alpha = 0.001$. The hit rate for classifying group one was 95.5%, while that of group two was 98%, and the total hit rate was 97.09%. The morphological variable contributing the most to the classification of the two groups was the percentage of the skeleton occupied by cystlike microlaminae, the criterion regarded most important in Stock's earlier studies; the second-best classifier was laminar thickness. Both morphological variables were statistically significant at $\alpha = 0.01$. The statistics confirm that there are two species, *H. centrotum*, and *H. consimile*.

28166 <TITLE>Lower Devonian (Lochkovian) Stromatoporoidea from the Coeymans Formation of central New York.</TITLE>
28167 <SOURCE>Journal of Paleontology 71, 4: 539-553.

- <http://www.jstor.org/pss/1306575>
- 28168 <ABSTRACT>Stromatoporoids are found in the Daysville and Deansboro members of the Coeymans Formation in central New York where they are common to rare. The most common species present are Habrostroma centrotum (Girty), and H. microporum (Girty). Present in lesser numbers are Parallelostroma foveolatum (Girty), Atopostroma sp. 1, A. sp. 2, Coenostroma cf. C. monticuliferum (Winchell), Coenostroma sp., Habrostroma cf. H. centrotum (Girty), and Coenostelodictyon cf. C. krekovi (Yavorsky). Although previously reported from the Coeymans, Coenostelodictyon jewetti (Girty) was not found. Species identifications were based on qualitative traditional methods, supplemented by statistics. The assemblage bears affinities with Lochkovian faunas in Virginia and the Canadian Arctic.</ABSTRACT>

- 28180 <SOURCE>Lethaia 15: 247-262.</SOURCE>
- 28181 <ABSTRACT>The tabulate coral Pleurodictyum americanum Roemer has been cited as an example of a host-specific organism occurring exclusively on the shells of gastropods, particularly Palaeozygopleura hamiltoniae (Hall). Examination of over 1600 specimens of P. americanum from the Middle Devonian Hamilton Group of western New York reveals additional complexities which require reinterpretation. While substrate selectivity for Palaeozygopleura shells is evident in all 42 subsamples, a variety of other substrates were also utilized by Pleurodictyum including corals, brachiopods, other molluscs and pebbles. Recent scleractinian corals inhabiting soft bottoms show similar substrate preference, selecting for the tubes of live serpulids, or gastropod shells (invariably with a secondary sipunculid host), but also occasionally settling on unoccupied shells or pebbles. Shell surfaces of P. hamiltoniae, preserved as external molds on the Pleurodictyum epitheca, exhibit encrustations by worm tubes and bryozoans as well as borings and mechanical shell damage, suggesting that these were not the shells of live gastropods. However, the invariant aperture-downward orientation and the high degree of selectivity of P. americanum strongly suggests that the shells were occupied by secondary hosts.</ABSTRACT>

- 28192 <TITLE>Mutvei's solution: an ideal agent for resolving microgrowth structures of biogenic carbonates.</TITLE>
- 28193 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 228, 1-2: 149-166.</SOURCE>
- 28194 <ABSTRACT>Accretionary hard parts of many organisms provide excellent archives of past climate and environmental conditions or life history traits. Variable growth rates function as environmental and

physiological proxies, and growth increments as calendars. Recognition of growth structures is thus a prime necessity for sclerochronological studies. Here we present a new, handy, easy-to-use and time-efficient technique that resolves annual and sub-annual growth structures in skeletons of a wide range of different organisms. Mutvei's solution simultaneously etches biogenic carbonates and calcium phosphates, fixates the soluble and insoluble organic matrices and fibers, and stains mucopolysaccharides. It produces a filigreed three-dimensional relief of etch-resistant ridges (growth lines) and etched depressions (growth increments) and stains skeletal growth structures in shadings of blue. Growth lines stand out as crisp, darker-blue stained lines. Reflected optical light microscopy (axial and oblique illumination) and scanning electron microscopy can be used to analyze the microgrowth structures. We demonstrate the use of the technique on hard tissues of various marine and freshwater bivalves, a coral, a sclerosponge, a barnacle, gastropods, a cephalopod, a fish otolith and a whale's ear bone. This technique may be of interest for paleoclimatologists, geochemists and biologists. It can significantly expand the use of biogenic hard parts as environmental and physiological indicators because it reveals microgrowth structures of biogenic skeletons that potentially form on a periodic basis and thus function as calendars.

28206 <SOURCE>Geobios 21, 4: 515-521.</SOURCE>

28207 <ABSTRACT>The wall of *Thamnoptychia* consists of a granular median lamina flanked by thick margins of cupular microlamellae in which are inserted fibrous spines. Ramose Tabulate Corals, with a considerable peripheral microlamellar thickening, are here united in the family *Thamnoptychiidae* nov. This name substitutes *Dendroporidae* De Fromentel 1861, since *Dendropora* owns a microstructure which differs it from all other Tabulate Corals. [original abstract]</ABSTRACT>

28218 <TITLE>Well-preserved favositid corals in the Oriskany Sands (Lower Devonian) of New York.</TITLE>

28219 <SOURCE>Bulletin New York State Museum 481: 265-287.</SOURCE>

28220 <ABSTRACT>Corals are rare in quartz sandstones of any age, and are particularly rare in the medium - to coarse grained quartz sandstone facies of Pragian age in the Appalachians. The occurrence of well-preserved specimens of *Favosites* (*Emmonsia*) spp. in the Oriskany Sandstone in a local area of central New York provides the opportunity to re-analyze the Oriskany depositional environment and comment on the meaning of *Emmonsia*; The preservation and details of occurrence of the corals suggest that they essentially grew

where found. They were moved and, in many cases, overturned, but lived in the turbulent, nearshore depositional environment of the sandstone. It is concluded herein that *Emmonsia* is a morphologic stage in the development of many lineages of Favosites. However, the near-restriction of the morphology to the biogeographic Eastern Americas Realm indicates a more complex history. Either Eastern American and Old World Favosites were genetically different, or intrinsic or extrinsic factors caused the *Emmonsia* morphology to be preferentially expressed in the American biogeographic area. Favosites (*Emmonsia*) *alternata* n.sp. with two morphologic variants (forms A and B) and F. (*E.*) *congesta* n.sp. are described.

28232 <SOURCE>Journal of Paleontology 68, 4: 727-734.</SOURCE>
28233 <ABSTRACT>Part and counterpart of a well-preserved specimen of *Gondekia* landfer (Reimann 1945a), and a well-preserved specimen of *Pseudohydroceras erraticum* Reimann 1935, are described from the wanakah Member of the Middle Devonian, Givetian, Ludlowville Formation, of western New York State. The specimen of *Gondekia* is only the second articulated specimen known and is more complete than the holotype. It has an intact skeleton of felted sexiradiates of three orders of spicules; the largest has rays approximately 2mm long. The specimen of *Pseudohydroceras* has preserved hexactine-based spicules in a dictyid skeleton, described for the species for the first time.</ABSTRACT>

- 28271 <SOURCE>Canadian Journal of Zoology 70: 352-354.</SOURCE>
- 28272 <ABSTRACT>A freshwater sponge classified as Spongilla heterosclerifera Smith 1918 and reported only from Oneida Lake, New York, was considered to be an endangered species. Examination of the holotype specimen reveals that it is actually an interspecific mixture of two widely distributed sponges, Ephydatia muelleri (Lieberkuehn) and Eunapius fragilis (Leidy). Spongilla heterosclerifera is therefore a junior synonym, in part, of both of these distinct species. Similar erroneous taxonomic interpretations of species mixtures have been documented and illustrate the importance of recognizing the possibility of species mixing when identifying freshwater sponge taxa.</ABSTRACT>

28349 <SOURCE>NRC Research Press, Ottawa, Canada, 231 pp. ISBN 0-660-19664-6</SOURCE>
28350 <ABSTRACT>The Pangaeian landmass separated Cisuralian (Early Permian) colonial rugose coral faunas into the Tethyan Realm, characterized by

the exclusive development of Kepingophyllidae Wu and Zhou, 1982, and Waagenophyllidae Wang, 1950, and the Cordilleran-Arctic-Uralian (CAU) Realm, characterized by Durhaminidae Minato and Kato, 1965, and Kleopatrinidae fam. nov. Both realms also contain Lithostrotionidae d 'Orbigny, 1852, and Petalaxidae Fomichev, 1953. Within the four families in the CAU Realm we recognize 20 genera, of which four are new (Sandolasma, Cordillerastraea, Iskutella, and Shastalasma), and 156 species, of which 14 are new (Sandolasma elegans, S.? cooperi, S. stonei, Pararachnastraea lyallensis, P. wilsoni, Cordillerastraea complexa, Iskutella gunningi, I. stikinensis, Heintzella borealis, Protowentzelella columellata, Kleopatrina grinnellensis, Permastraea buttensis, Tschussovskenia dilata, and Lytvophyllum sustutense). Twenty-three previously described corals are unassigned because of insufficient data. [first part of extensive summary] </ABSTRACT>

28361 <TITLE>New occurrences of Permian corals from the McCloud Belt in western North America.</TITLE>

28362 <SOURCE>Palaeontologia Electronica 12, 2: 6A: 16./palaeo-electronica.org/2009_2/175/index.html</SOURCE>

28363 <ABSTRACT>Previously unreported Permian rugose corals from several terranes considered part of the McCloud Belt are herein described and figured. These include two species from the Eastern Klamath terrane, one of which is described as new; four species from the Central Belt of the Northern Sierra Nevada, with two additional species thought to have been derived from that terrane; four species from the Bilk Creek terrane; and two species from the Harper Ranch subterrane of the Quesnel terrane, one of which is described as new. * Permian species of Lytvophyllum? and Cystolonsdaleia are now reported from almost all parts of the dispersed McCloud Belt, and Heterocaninia? is now known from the Bilk Creek terrane in addition to the Eastern Klamath terrane. These newly reported occurrences strengthen the interpretation that these terranes were closely associated during Early Permian time. None of these genera, however, occur anywhere along the Pangaeian margin of North America. * Conversely, Protowentzelella and Tschussovskenia, which are abundantly represented in Lower Permian rocks all along the western and northern margins of cratonal North America, are rare in rocks of the McCloud Belt. These faunal differences suggest that the terranes of the McCloud Belt lay far out in the Paleopacific Ocean, far west of cratonal North America during the Early Permian so that faunal exchange was minimal.</ABSTRACT>

28375 <SOURCE>Journal of Paleontology 84, 3: 529-537.</SOURCE>

28376 <ABSTRACT>Five new species of Early Permian (late Sakmarian to

Kungurian) colonial corals from eastern Nevada and southeastern California, one assigned to a new genus, are described and illustrated. These include *Heintzella playfordi* n.sp. from the Arcturus Formation in Nevada and the Darwin Canyon Formation in California, *Paraheritschioides fergusonensis* n.sp. from the Ferguson Mountain and Bird Spring formations in Nevada, and *Wendoverella arca* n.gen. and n.sp., *Permastraea nevadensis* n.sp., and *Pararachnastraea moormanensis* n.sp. from the Pequop Formation in eastern Nevada. These new taxa are distinct from all previously described species, but most are related to other species in the North American miogeocline. *Wendoverella arca* n.sp., however, is unlike any other species described from North America but is quite similar to a Russian species, indicating faunal communication between the Ural Mountains and the Cordilleran miogeocline at least into Artinskian time. 28400 <TITLE>Distribution of three key Early Permian fossil groups in western USA and northern Mexico and their relevance to interpretation of paleotectonic features along the southwestern margin of Laurentia.</TITLE>

28401 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 288, 1-4: 103-107.</SOURCE>

28402 <ABSTRACT>Three species groups, including two groups of corals and one of fusulinids, delineate the zone of favorable marine environments for these animals along the shelves bordering southwestern Laurentia during the Cisuralian (Early Permian). The three species groups are: the coral *Protowentzelella* group of late Asselian to early Sakmarian age, the fusulinid *Eoparafusulina linearis* group of late Sakmarian age, and the coral *Pararachnastraea illipahensis* group of late Artinskian to Kungurian age. Occurrences of these three species groups clearly outline most of the major paleotectonic features that were present along the southwestern margin of the Laurentian shelf at that time. The paucity of data in Mexico, however, leaves open the question of large-scale displacement on the Mojave-Sonora megashear, a feature proposed to cut across northern Mexico and southwestern USA, although the data presented here could be construed to suggest lack of significant displacement in post-Pennsylvanian time.</ABSTRACT>

28426 <TITLE>Taxonomic affinities and paleogeography of Stromatomorpha Smith, a distinctive Upper Triassic reef-adapted demosponge.</TITLE>
28427 <SOURCE>Journal of Paleontology 83, 5: 783-793.</SOURCE>
28428 <ABSTRACT>Stromatomorpha californica Smith is a massive, calcified, tropical to subtropical organism of the Late Triassic that produced small biostromes and contributed in building some reefs. It comes from the displaced terranes of Cordilleran North America (Eastern Klamath terrane, Alexander terrane, and Wrangellia). This shallow-water organism formed small laminar masses and sometimes patch reefs. It was first referred to the order Spongiomorpha but was considered to be a coral. Other affinities that have been proposed include hydrozoan, stomatoporoid, sclerosponge, and chambered sponge. Part of the problem was diagenesis that resulted in dissolution of the siliceous spicules and/or replaced them with calcite. Well-preserved dendroclone spicules found during study of newly discovered specimens necessitate an assignment of Stromatomorpha californica to the demosponge order Orchocladina Rauff. Restudy of examples from the Northern Calcareous Alps extends the distribution of this species to the Tethys, where it was an important secondary framework builder in Upper Triassic (Norian-Rhaetian) reef complexes. Revisions of Stromatomorpha californica produce much wider pantropical distribution, mirroring paleogeographic patterns revealed for other tropical Triassic taxa. Review of Liassic material from the Jurassic of Morocco, previously assigned to Stromatomorpha californica Smith var. columnaris Le Maitre, cannot be sustained. Species previously included in Stromatomorpha are: S. stylifera Frech (type species, Rhaetian), S. actinostromoides Boiko (Norian), S. californica Smith (Norian), S. oncescui Balters (Ladinian-Carnian), S. pamirica Boiko (Norian), S. rhaetica Kuhn (Rhaetian), S. stomatoporoides Frech, and S. tenuiramosa Boiko (Norian). Stromatomorpha rhaetica Kuhn described from the Rhaetian of Vorarlberg, Austria shows no major difference from S. californica. An example described as S. oncescui Balters from the Ladinian-Carnian of the Rarau Mountains, Romania, is very similar to S. californica in exhibiting similar spicule types. However, because of the greater distance between individual pillars, horizontal layers, and the older age, S. oncescui is retained as a separate species. The net-like and regular skeleton of Spongiomorpha sanpozanensis Yabe and Sugiyama, from the Upper Triassic of Sambosan (Tosa, Japan), suggests a closer alliance with Stromatomorpha, and this taxon possibly could be the same as S. californica.</ABSTRACT>

28479 <SOURCE>Journal of Paleontology 59, 5: 1158-1172.</SOURCE>
28480 <ABSTRACT>Microcavities within allochthonous Cambrian Epiphyton algal mounds in the upper Shady Dolomite (Shady Formation) of southwestern Virginia contain a preserved coelobiontic (cavity-dwelling) biota of probable late Early Cambrian age. The microcavities (range from 0.3mm to 15.0mm across (mean, 2.0mm) and are constructed by overgrowth of Epiphyton fronds. Epiphyton dominates the coelobiontic biota, although other algae occur on the cavity roof and walls, including spherical micro-algae (?), crust-forming Girvanella and Cavifera, a probable endolithic alga found only in the fringe cements within microcavities.

- 28481 Globular Foraminifera (?) or foraminifer-like microorganisms, possible
28482 brachiopods, and cylindrical borings also occur on or in the roofs and
28483 walls. [first part of an extensive abstract] </ABSTRACT>

28524 <TITLE>Paleoecology of the Day Point Formation (lower Chazy Group,
28525 Middle-Upper Ordovician) and its bryozoan reef mounds, northwest
28526 Vermont and adjacent New York.</TITLE>
28527 <SOURCE>Northeastern Geology and Environmental Sciences 25, 4: 313-329.
28528 </SOURCE>
28529 <ABSTRACT>The stratigraphy of the Day Point Formation (Middle-Upper
28530 Ordovician Chazy Group) is complex, and shows lateral changes in
28531 lithology that produce sequences that are unique at different
28532 localities around the Champlain valley. This unit contains bryozoan
28533 mounds or reefs built by Batostoma and Champlainopora species. In the
28534 lower portion of the formation, the bryozoan mounds and non-mound
28535 layers are often found on top of quartzose sand beds, or within the
28536 sand. In contrast, no sand is found in the upper Day Point, yet the
28537 bryozoan mounds also flourish. The Day Point Formation bryozoan reefs,
28538 especially the one exposed on Garden Island, NY are the geologically
28539 oldest in North America. They were built mostly by encrusting Batostoma
28540 chazyensis and branching Champlainopora chazyensis, in differing
28541 vertical and lateral relationships, that had frame-building,
28542 sediment-binding, and sediment-forming roles. Nine additional bryozoan
28543 species which are taxonomically updated herein, functioned as minor

accessories in the sedimentology of these build-ups. Six lithofacies that represent various lagoonal, bar / shoal, and subtidal environments are recognized in the Day Point. These include: (1) highly bioturbated sandstone with symmetrical and bifurcating ripples; (2) bioturbated, brachiopod-rich wackestone; (3) planar crossbedded, interlayered sandstone and sandy packstone; (4) interlayered sandstone and shale grading into sand and limestone layers; (5) grainstone, which at some localities, contains bryozoan mounds, and at other localities, thin non-mound sheet-like layers, and planar-laminated and cross-bedded packstone; (6) fine-grained calcareous sandstone with planar and herringbone cross-bedding, which in places contains small bryozoan mounds. This study has revealed more laterally discontinuous sand units in the lower portion of the Day Point Formation than noted by previous studies. There are repeated sequences of sandstone units succeeded by deeper water (subtidal, open shelf) carbonates in the Day Point, which we interpret to be a series of transgressive cycles. We hypothesize that sedimentation of the sand stopped as a result of a rise in sea level within each cycle. The deeper water induced the accumulation of carbonate sediments, causing the water depth to decrease and allowed sand to accumulate again. Hydraulic variations may explain both the lithologic sequences and the faunal relationships observed in mounds within the Day Point Formation. The Day Point mounds are significantly different from Middle Ordovician bryozoan reefs described elsewhere in the Appalachians. They are older, contain a less diverse bryozoan fauna, and are smaller than bryozoan reefs in the Holston, Rockdell, and Carters Limestones. They are more similar in structure and composition to Middle Ordovician bryozoan mounds in Pennsylvania, Virginia, and Oklahoma, and indeed also resemble living Bahamian bryozoan reefs. 28543 <TITLE>Diagenetic calcite from the Chazy Group (Vermont): an example of aragonite alteration in a greenhouse ocean.</TITLE>

28544 <SOURCE>Sedimentary Geology 121: 277-288.</SOURCE>

28545 <ABSTRACT>Marine diagenetic calcite with both a calcitic (low-to-intermediate Mg) and aragonitic origin was examined from the middle Ordovician buildups of the Chazy Group in Vermont. All marine phases have elevated Sr (up to 1800 ppm) compared with that observed from marine precipitates in other middle Ordovician units. Stromatoporoids (labechiids) which were originally aragonitic, have

higher Sr values than phases with an original calcite mineralogy (trilobites, marine cement). Additional evidence supporting precursor mineralogy interpretations includes elevated Mg values (up to 3.6 mole% MgCO₃) and the presence of microdolomite in interpreted calcitic phases. Originally aragonitic precipitates have lower Mg values and most significantly lack microdolomite. This study demonstrates the presence of elevated Sr values in marine precipitates that formed during a period when calcite, not aragonite, was the dominant physiochemically precipitated calcium carbonate mineralogy that formed from sea water. Elevated Sr is attributable to at least a partially open system diagenetic stabilization of biogenic aragonite. </ABSTRACT>

28556 <TITLE>Paleoecology of Middle Ordovician Stromatoporoid mounds in Vermont.</TITLE>

28557 <SOURCE>Lethaia 8: 195-207.</SOURCE>

28558 <ABSTRACT>Fossiliferous mounds of carbonate muds are a distinctive facies in middle Chazy Group (Crown Point Formation) at Isle La Motte, Lake Champlain. The mounds are surrounded by bedded calcarenite of spar cemented pelmatozoan debris. Channels which cut into the mounds during mound growth are filled with the same calcarenite. The mud free intermound rocks and the mound biota suggest agitated, normal marine shallow-water environments. The principal lime-secreting organisms within the mounds are stromatoporoids, calcareous algae, tabulate corals, sponges and bryozoans. Each mound is dominated in terms of biomass by one of three groups: stromatoporoids, calcareous algae and bryozoans. Most of the mound biota first appear at the base of the Crown Point Formation. In the lower Crown Point Formation, the organisms increase in number and species. Both changes in the biota are related to periods of shallowing of the Chazy Sea which are also reflected in the character of the carbonate sands.</ABSTRACT>

28597 <ABSTRACT>This paper reviews the lithofacies, stratigraphy, and
paleoenvironments of the Keyser Formation (Silurian, Pridoli) and
describes the place of stromatoporoids in various lithofacies. The
paleoecological roles of stromatoporoids are described with reference
to patch reefs exposed at Altoona (Eldorado quarry), the Altoona Bible
Church, near Jersey Shore, and at Mustoe (Virginia). The only species
of stromatoporoid mentioned is "Stromatopora" constellata.

28635 <SOURCE>Paleocommunities: A Case Study from the Silurian and Lower Devonian [Boucot A. J. & Lawson J. D. (eds); Cambridge University Press]: 800-805.</SOURCE>
28636 <ABSTRACT>Several rugose coral assemblages of Pridolian and Lochkovian age in eastern North America have been studied in enough detail to permit discussion of them as "communities". The assemblages are best known in New York and in the Appalachian belt from Virginia to southeastern Québec and the Maritime Provinces. They are unknown or poorly studied in other parts of the east which is biogeographically defined as that part of the Silurian-Devonian North American Plate east of the Transcontinental Arch and south of the central Canadian Shield (Oliver, 1977). Older (Ludlovian) assemblages are not well enough known to discuss as "communities", but are briefly characterized in the next section. Some younger Early Devonian assemblages, beyond the scope of this volume, are also briefly reviewed. It is notable that the Pridolian-Lochkovian rugose coral assemblages or communities do not show strong connections with either preceding or succeeding assemblages of the same geographical area. Names given to the coral assemblages or communities are informal and are not considered to be potentially useful outside of eastern North America.</ABSTRACT>

28673 <TITLE>The origin of "Spongophylloides" in eastern North America.</TITLE>
28674 <SOURCE>Bulletin of the Tohoku University Museum 1 [Proceedings of the 8th International Symposium on Fossil Cnidaria and Porifera]: 77-85.</SOURCE>
28675 <ABSTRACT>A morphologic sequence of ptenophyllid corals in Upper Silurian (Pridolian) and Lower Devonian (Lochkovian) strata in New York and the central Appalachian Mountains poses problems in the recognition, definition and naming of genera. Ptenophyllids occur in the fine-grained, stromatoporoidal limestone facies that crosses the system boundary. Specimens of Embolophyllum are especially common in the Pridolian but morphologically similar forms occur in the Lochkovian. Embolophyllum generally has complete septa but, near the Pridolian-Lochkovian boundary, ptenophyllids with peripherally incomplete septa are common and, above the boundary, many specimens have a broad dissepimentarium that entirely lacks septa. Using conventional morphological criteria, the transitional morphotype might be referred to Dubrovia and the younger form to Spongophylloides. I consider it more likely that, in the Appalachians, the three forms bear ancestor-descendant relationship, and that biologically, the younger two should not be assigned to the established genera they resemble. However, naming new genera that can only be recognized locally is equally unsatisfactory and there seems to be no way to suggest the postulated relationship in Linnéan terms. The overall pattern is similar to what might be expected from reticulate evolution.</ABSTRACT>

28687 <SOURCE>Coral Research Bulletin 05: 203-209.</SOURCE>
28688 <ABSTRACT>Rugose corals of the Family Ptenophyllidae are widely distributed in rocks of Late Silurian to Middle Devonian age. However, in eastern North America, they are not known to occur in rocks of Pragian to early Eifelian age and later Eifelian to Frasnian occurrences are limited to western parts of the area. At each of three Middle and one Upper Devonian (Frasnian) stratigraphic levels, individual Ptenophyllids are rare and only one, two or three species are present. Each occurrence is related to a separate incursion of elements of the Old world fauna into the eastern North American Michigan and Illinois Basins from western or northwestern North America; no Middle or Upper Devonian ptenophyllids are known from the more easterly Appalachian Basin.</ABSTRACT>

28740 <ABSTRACT>Analysis of the world distribution of rugose coral genera that occur in the eastern half of North America in rocks of latest Silurian and Devonian age helps to delineate palaeobiological provinces

of this time and to outline their history. For this purpose, eastern North America (ENA) endemic genera are defined as those known only from ENA, northern South America, north-western Africa, and Spain (?).

28765 <SOURCE>Lethaia 23: 167-178.</SOURCE>

28766 <ABSTRACT>Detailed plotting of the stratigraphic ranges of Devonian rugose coral genera within the Eastern Americas Realm reveals new information about the extinctions and migrations of this largely endemic fauna. There were significant faunal turnovers in the Lochkovian, middle Eifelian and late Givetian, as well as in the often discussed late Frasnian. The late Givetian turnover was nearly as great as the Frasnian one. Inward migration was principally from western North America, and the greatest influxes were during the early Givetian and Frasnian. It seems likely that there were several separate incursions and that some genera were introduced to the east two, or even three times.</ABSTRACT>

28777 <TITLE>A unique occurrence of Endophyllum (rugose coral; Devonian) in Eastern North America: an ecological and biogeographical puzzle.</TITLE>

28778 <SOURCE>Journal of Paleontology 70, 1: 46-56.</SOURCE>

- 28779 <ABSTRACT>Endophyllum is described for the first time from North America. The occurrence of a single, large colony in Middle Devonian strata in New York is both biogeographically and environmentally anomalous: it belongs to an Old World Realm genus but was found in the Eastern Americas Realm, and it occurred in a gray, ambocoeliid-bearing mudstone, a facies in which morphologically complex corals are otherwise unknown. Available evidence suggests that the coral lived not far from where it was found, possibly on a hardground or bank a few km north of the outcrop. Endophyllum ciurcai new species is described.

- 28792 <ABSTRACT>Several families of rugosans, endemic to the Devonian Eastern Americas Realm, are well enough known to justify an analysis of both family- and genus-level relationships. Cladistic methods are used to test ideas on evolution within three recently monographed families with varied results. The analyses are most valuable in providing justification for, or raising questions about, the results of earlier studies. Genera of the Zaphrentidae and Craspedophyllidae are analyzed both separately and as one unit because the families are considered to be closely related. Several outgroups were tried; most successful was the genus Phaulactis which has been mentioned elsewhere as a possible zaphrentid ancestor. Results of the analyses are compatible with earlier studies based on conventional, "Simpsonian" methods, and support a near relationship between the two EAR families. Cladistic analysis of the Siphonophrentidae is less satisfactory. No outgroup is evident so a hypothetical "primitive" siphonophrentid, based on conventional ideas of morphologic trends, is substituted. The value of the analysis is in the questions raised about the importance of some of the characters used. A discussion of family relationships is based on comparative morphology, known stratigraphic ranges, and apparent trends. Cladistic analysis at this level is impractical because of the paucity of data and the lack of any general agreement on rugosan classification at the family level.</ABSTRACT>

28817 <SOURCE>US Geological Survey Bulletin 2024-B: I-IV + B1-B32.</SOURCE>
28818 <ABSTRACT>Rugose corals belonging to the Family Siphonophrentidae Merriam 1974, are morphologically simple and extremely variable. They are widely distributed in Lower and Middle Devonian strata in areas that were formerly parts of the Devonian Eastern Americas Biogeographic Realm. The family, its constituent genera, and all type species are reviewed or redescribed. In addition, all previously named species and some additional species from New York are described. Two new genera are Metaxyphrentis, type species M. prolifica (Billings), 1858, and Enallophrentis, type species E. simplex (Hall), 1843. New species are Briantelasma boucoti (Lochkovian) and Enallophrentis broweri, Breviphrentis cista, and B. pumilla (all Givetian). Heterophrentis Billings 1874 (and Heterophrentidae Kullmann 1965), and Trilophyllum Simpson 1900, are restricted to the type specimens of their type species because they are unrecognizable.</ABSTRACT>

28831 <ABSTRACT>Several models showing possible evolutionary relationships of the genera of two small families of Early and Middle Devonian rugose corals are analyzed. Cladograms based on parsimonious character transpositions disagree with what is evident in the paleontologic record and are rejected. Those based on the record, using character state polarization where the record is not clear, are more satisfactory even though much less parsimonious. The apparent failure of cladistic methods in this analysis reflects the low number of available morphologic characters and the number of these characters that are convergent. This is a common problem in fossil invertebrates, and it is suggested that the principal value of cladistics in such groups is to force a more rigorous consideration of the characters on which taxa are based.</ABSTRACT>

28882 <SOURCE>Canadian Society of Petroleum Geologists, Memoir 19: 580-587.</SOURCE>
28883 <ABSTRACT>The upper part of the Windsor Group, Nova Scotia, includes limestone members which are of great value for local lithostratigraphic correlation. Three of them, the Ryan Brook, the Herbert River and the Kennetcook Limestone, contain rugose corals. The Ryan Brook Limestone Member has yielded only one species of Siphonodendron, suggesting a possible Upper Viséan age. The Herbert River Limestone Member marks the base of the upper part of the Windsor Group. It is locally rich in Rugosa and yielded species belonging to Siphonodendron, Nemistium, Lonsdaleia, Axophyllum, Dibunophyllum, Koninckophyllum, a colonial Koninckophyllum and Palastraea. Most of the corals were collected in boulders in the Mahone Bay area, SW Nova Scotia. These taxa indicate Brigantian age, as previously suggested by foraminifera, and are similar to those known in Ireland, suggesting close relations between

Nova Scotia and the Irish-North England basin. The Kennetcook Limestone Member is at the top of the Windsor Group. It contains only solitary corals belonging to *Amplexizaphrentis* and *Turbinatocaninia*. This fauna, rich in specimens but poorly diversified, is known in the Serpukhovian of the Russian platform.

28909 <ABSTRACT>A fauna of rugose corals is described from Upper Permian rocks in the Kap Scotsch area, Northeast Greenland. The fauna consists of 11 genera and subgenera. A new subgenus is established *Calophyllum* (*Groenlandophyllum*), which has no epitheca on the apex of the corallite. A faunal list is given in table 1. The age of the fauna is doubtful, although it is certainly older than latest Permian faunas of the Dzhulfian stage. It is possible that the East Greenland fauna is of the age of the Yabeina Zone as suggested by Dunbar et al. in 1960. It is, therefore to be suspected that at Kap Scotsch the Triassic rocks rest unconformably on Permian strata.</ABSTRACT>

28934 <SOURCE>Palaios 8: 3-17.</SOURCE>
28935 <ABSTRACT>A bed of Late Pliocene age from west central Florida is dominated by smoothed, bioeroded and broken colonies of the coral *Septastrea crassa* (Holmes). This bed appears to have formed as a result of the destruction of a coral thicket by one or more severe storms over a relatively short period of time. The coralla surfaces were sand-blasted; during the storm(s) and smoothed. The shattered thicket was then subjected to bioerosion for an estimated period of 25-30 years, before being buried relatively quickly by an influx of sediment, possibly by a migrating sand wave. The coral grew upon and was in turn grown upon by a variety of encrusting organisms including barnacles, bryozoans and oysters. The coral bed is continuous with both overlying and underlying assemblages allowing reconstruction of its paleoenvironmental setting and history. Fossil *Septastrea crassa* thickets preserved elsewhere display different patterns of physical wear and bioerosion, indicating that this coral bed experienced a different mode of formation.</ABSTRACT>

28946 <TITLE>Coral mounds on the West Florida slope: unanswered questions regarding the development of deep-water banks.</TITLE>
28947 <SOURCE>Palaios 02: 359-367.</SOURCE>
28948 <ABSTRACT>Late Pleistocene deep-water coral mounds of 10-15m relief occur in a 20km linear zone parallel to the 500m isobath along the west Florida carbonate-ramp slope. These relict mounds were constructed by the densely calcified, ahermatypic framework builder, *Lophelia prolifera*, and provided habitats for a host of associated invertebrates, including epizoans, epifaunal commensal organisms, nestlers and crevice dwellers, and macroendoliths. Scleractinian diversity and taxonomic composition are congruent with those of other *Lophelia* buildups in the North Atlantic, particularly buildups in the eastern Atlantic. The scleractinians also retain primary mineralogic, isotopic, and trace-element geochemical signatures, indicating relatively little diagenetic alteration, despite dead (>40,000 years b.p.) radiocarbon ages. The small but rapidly expanding global data base on deep-water coral mounds has magnified two key questions concerning the ecologic and environmental controls on mound nucleation, growth, and death. First, what are the principal ecologic controls on dominance within communities of deep-water framework builders? Second, why are there so many relict and so few living deep-water mounds in the modern ocean? Ecological and paleoecological investigation of these questions would elucidate much about the dynamics of deep-water mound growth.</ABSTRACT>

28961 <ABSTRACT>The objective of this paper is to describe the Corals of the
Tampa Formation (Lower Miocene) from three localities south and east of
the city of Tampa (Florida). 30 species are treated in the paper. 14
species are new. Collections in the Geological Department of Florida
State University, Florida Bureau of Geology and U.S. National Museum
(Washington). Included in the paper is the description of a new species
Goniopora aucillana from the Suwannee Limestone (Upper Oligocene) found
in Taylor County, Florida.</ABSTRACT>

28972 <TITLE>Colonial form, free-living corals, and macroborers from the
Pleistocene of South Florida.</TITLE>
28973 <SOURCE>Palaeoworld 19, 3-4: 426-434.</SOURCE>
28974 <ABSTRACT>Study of corallum shape in free-living colonies of Manicina,
Siderastrea and Solenastrea collected from the Pleistocene Bermont
formation in southern Florida indicates that they were mobile, either
self-righting (Manicina), or rotatory (Siderastrea and Solenastrea),
with colony forms that are the result of movement during growth. In
rotatory corals, growth of a radial and centrifugal nature away from
the corallum center indicates that rolling was frequent enough to
maintain the health of individual corallites along the skeleton's
entire spherical surface, as postulated previously by several authors.
Post mortem sponge boring and boring of sipunculid worms and the
bivalves Lithophaga and Gastrochaena during the life of these colonies
were common. Colonization by barnacles during the life of some colonies
also occurred, but they were generally overgrown. Boring of rotatory
coralla decreased the mass of the skeleton and probably increased the
ease and frequency of rolling of round colonies. The presence of these
rotatory coralla strongly suggests that the lower Bermont sediments
accumulated on and around shallow banks populated by numerous
free-living corals and some fixed corals such as branching Porites,
along with a diverse molluscan assemblage indicative of a Thalassia
(turtle grass) community. The Pleistocene Bermont Formation also
contains numerous well-preserved colonies of Manicina areolata,
indicative of deposition in shallow subtidal environments with abundant
sea grass. This species was well-suited to life in this environment,
and to overturning by current action, as it has the capacity to right
itself after overturning, either biologically or hydrodynamically or
both. The Bermont specimens of Manicina all (100%) possess a flat or
slightly concave base, typical of self-righting forms. Colonies
collected in the Bermont Formation show several types of macroborers,
sponges, sipunculid worms, but above all, the bivalve genera Lithophaga
and Gastrochaena as well as epibionts, bryozoans and serpulid worms.
Manicina is associated stratigraphically with rotatory colonies of

- Siderastrea radians, but the two have not been found within the same lamina. However, the two, taken together, provide strong indications of depositional environments on banks populated by sea grasses and associated fauna. [original abstract]

29039 <ABSTRACT>Fifty-two late Cenozoic species of fossil corals are described from the following formations of South Florida: Pinecrest, Caloosahatchee, Glades, Fort Thompson, and Key Largo Limestone / Miami Oolite. Fifty-one of the species are in the order Scleractinia and one in the order Milleporina. Five new species are proposed, and these are *Diploria sarasotana*, *Thysanus floridanus*, *Dichocoenia caloosahatcheensis*, *Dichocoenia eminens*, and *Isophyllia? desotoensis*. The salient characters of the several formations are depicted, and their ages, as determined by both biogeologic and radiometric dating, are analyzed and compared.</ABSTRACT>

29050 <TITLE>First documentation of tidal-channel sponge biostromes (upper Pleistocene, southeastern Florida).</TITLE>
29051 <SOURCE>Geology 35, 5: 475-478.</SOURCE>
29052 <ABSTRACT>Sponges are not a common principal component of Cenozoic reefs and are more typically dominant in deep-water and/or cold-water localities. Here we report the discovery of extensive upper Pleistocene shallow-marine, tropical sponge biostromes from the Miami Limestone of southeastern Florida built by a new ceractinomorph demosponge. These upright, barrel- to vase-shaped sponges occur in monospecific aggregations constructed within the tidal channels of an oolitic tidal-bar belt similar to modern examples on the Great Bahama Bank. The biostromes appear to have a ribbon-like geometry, with densely spaced sponges populating a paleochannel along a 3.5 km extent in the most lengthy biostrome. These are very large (as high as 2m and 1.8m in diameter), particularly well-preserved calcified sponges with walls as hard as concrete. Quartz grains are the most common particles agglutinated in the structure of the sponge walls. Where exposed, sediment fill between the sponges is commonly a highly burrowed or cross-bedded ooid-bearing grainstone and, locally, quartz sand. It is postulated that the dense, localized distribution of these particular sponges was due to a slight edge over competitors for food or energy supply and space in a stressed environment of tidal-influenced salinity and nutrient changes, strong currents, and frequently shifting submarine sand dunes. To our knowledge, this represents the first documentation of sponge biostromes composed of very large upright sponges within high-energy tidal channels between ooid shoals. The remarkably well-preserved accumulations provide an alternative example

- of sponge reefs for comparative paleoenvironmental studies.</ABSTRACT>

- 29064 <SOURCE>Palaios 18, 6: 495-509.</SOURCE>
- 29065 <ABSTRACT>In a companion study to earlier work in the Indo-Pacific [Pandolfi & Greenstein 1997], taphonomic alteration in reef-coral death assemblages was assessed in four distinct reef habitats ranging from 2-30m water depth in the Florida Keys reef tract. Physical and biological taphonomic attributes measured from coral specimens showed great variability with respect to reef environment. Physico-chemical degradation (abrasion and dissolution) was greatest in reef-crest and patch-reef environments. With the exception of encrusting foraminifera, coverage by epi- and endobionts was higher in deep-reef environments (20m and 30m). Variability in dissolution and abrasion is likely the result of the different energy regimes present in the reef habitats examined. Variability in biological attributes results from a combination of increased residence time of coral skeletons on substrates in deep-reef environments, higher overall coral skeletal densities of corals inhabiting deep reef environments, and increased nutrient availability in the deep reefs sampled. Clear gradients in the degree of taphonomic alteration of reef corals with reef habitat indicate the utility of corals as taphofacies indicators in ancient reef settings. In contrast to shallow-water reefs on the Great Barrier Reef, taphonomic alteration of corals in the Florida Keys was equitable across growth forms. [original abstract]</ABSTRACT>

- 29077 <SOURCE>Palaios 11: 362-375.</SOURCE>
- 29078 <ABSTRACT>This study reports on the δ180 and δ13C composition of the skeleton from a 240-year-old specimen of Montastraea faveolata growing in Biscayne National Park, South Florida. Annual variations in the δ180 of the skeleton deposited during the summer months show a bimodal correlation with summer rainfall. During wetter years, the δ180 of the coral skeleton and the amount of precipitation during the summer months are inversely correlated (r = - 0. 7) reflecting dilution of the seawater by meteoric water lower in δ180. During years in which summer rainfall is less than normal, increases in precipitation are positively correlated with skeletal δ180 (r = +0. 6) reflecting the input of freshwater from the Everglades higher in δ180. Based on this correlation the δ180 record of the coral skeleton suggests that the 19th and 18th centuries have been relatively dry compared to the 20th century. Carbon isotopic compositions of the

skeleton are positively correlated with $\delta^{18}\text{O}$ with the minimum in $\delta^{13}\text{C}$ occurring several months after the minimum in $\delta^{18}\text{O}$. Since the mid 1930s there has been a decrease in $\delta^{13}\text{C}$ of the skeleton. Explanations for this trend may be (1) it reflects the increased input of carbon derived from the destruction of terrestrial ecosystems, (2) it is part of a long-term decrease in $\delta^{13}\text{C}$ associated with increased addition of fossil fuel-derived CO_2 .

29089 <TITLE>Carbonate production of the coral *Diploria labyrinthiformis* in South Florida patch reefs.</TITLE>
29090 <SOURCE>Marine Geol. 45: 281-296.</SOURCE>
29091 <ABSTRACT>Average annual production of CaCO_3 (aragonite) by the hermatypic coral *Diploria labyrinthiformis* in the Florida reef tract is 11.8 ± 0.3 kg/m² of reef space occupied by the coral. Annual production was estimated from a population of 271 *Diploria* colonies measured in situ. The mass produced annually is the volume of annual growth times the skeletal density. Cores of 31 *Diploria* colonies were slabbed and X-rayed to reveal annual growth bands. The mean vertical growth rate is 0.35 - 0.06 cm/yr for skeletal density bands representing up to 24 years of growth. The annual volume of growth is approximated by a simple geometric shell whose thickness is determined by the horizontal and vertical growth rates of the colony. Horizontal growth rates are estimated from the ratio of the two lateral axes to the vertical axis. Bulk density determined by dry weight/volume of 9 cylindrical cores is 1.64 ± 0.13 g/cm³. Productivity of 11.8 kg/m²/yr for area occupied by the coral does not vary appreciably among a nearshore patch reef and two outer-shelf patch reefs. For comparison, production rates for 244 *Porites astreoides* near Key West, Florida, is 14 ± 3.3 kg/m²/yr for area occupied by the coral. The 271 colonies of *D. labyrinthiformis* potentially produce sediment which, if spread evenly, would accumulate at a rate of 0.026 m/103 yr for 9008 m³ of reef surveyed. Potential vertical accretion by all corals for the patch reef surveyed is estimated at 2.2 to 6.6 m/103 yr. [original summary]</ABSTRACT>

29102 <TITLE>Decelerating Holocene Sea-level Rise and its Influence on Southwest Florida Coastal Evolution: A Transgressive / Regressive Stratigraphy.</TITLE>
29103 <SOURCE>Journal of sedimentary Petrology 59, 6: 960-972.</SOURCE>
29104 <ABSTRACT>The Ten Thousand Islands (TTI) are a myriad of low-relief mangrove islands that lie along the low energy, subtropical southwest Florida coast. The region has been subjected to a relative rise in Holocene sea level, which has continuously decelerated to its present rate. Data derived from surface and subsurface sampling indicate that the Holocene sediment package of the TTI area consists of two sediment sequences. The lower sequence is transgressive and was generated as

coastal salt marsh and / or terrestrial environments [which] were submerged and replaced by a shallow coastal marine setting. The upper sediment sequence consists primarily of 1) biogenic shallowing upwards sequences or 2) thickened mangrove peat layers, reflecting island emergence and shoreline stabilization, respectively. Island emergence compartmentalized the area, further reducing wave and current energy and promoting the infilling of the protected bays through deposition of organic-rich shelly mudstone and wackestone. Based on coastal stratigraphy and 14C dates, the formation of this transgressive / regressive sediment sequence is directly related to changing rates of Holocene sea-level rise, reported to have occurred between 3,500 and 3,200 YBP. Continued regressive sedimentation could eventually generate a 5-10 m thick transgressive / regressive sediment couplet, with an aerial extent of over 300 km², in roughly 10,000 years. This externally forced sediment couplet compares remarkably well to individual small scale transgressive / regressive cycles which repeat tens to hundreds of times throughout the geologic record (see James 1984). The results of this study thus support the allocyclic mechanism as a viable working hypothesis for the generation of these small scale rock cycles.

29115 <TITLE>Early Holocene sea-level record from submerged fossil reefs on the southeast Florida margin.</TITLE>

29116 <SOURCE>Geology 26, 3: 255-258.</SOURCE>

29117 <ABSTRACT>Massive fossil (outlier) reefs are preserved seaward of the modern shelf and reef tract along the southeast Florida margin. Thermal ionization mass-spectrometric (TMS) U-Th dating of 16 pristine *Acropora palmata* and head corals cored from two transects document early Holocene reef growth from 8.9 to 5.0 ka, from approximately -13.5 to -7 m MSL (mean sea level). These samples fill a gap in the Florida Keys sea-level database and clarify the timing of a significant decrease in the rate of sea-level rise. A portion of this interval, represented by a gap in the Caribbean record of *A. palmata* reefs, has been interpreted as reef drowning during an inferred catastrophic sea-level rise event of >45 mm/yr, or 6.5 m rise between 7.6 and 7.2 ka, attributed to West Antarctic Ice Sheet instability and changes in marine ice extent between 8 and 7 ka. Continuous in situ shallow-water reef growth in Florida during this interval precludes the occurrence of exceedingly rapid rates of sea-level rise and is consistent with the North Atlantic record of deglaciation from 9 to 7 ka. Gaps in the early Holocene sea-level records for Florida and the Caribbean are thus more likely to be artifacts of limited sampling and/or core coverage, and not necessarily a result of drowning.</ABSTRACT>

29181 <SOURCE>Journal of Paleontology 58, 3: 703-708.</SOURCE>
29182 <ABSTRACT>A new skeletal organism, Rosellatana jamesi n.gen., n.sp., has been found in the Lower Cambrian (Bonnia-Olenellus Zone) Rosella Formation (Atan Group) exposed in the Cassiar Mountains of northern British Columbia. The organisms produced a compound cerioid skeleton comprising regular to rounded polygonal tubes without tabulae but with up to two septa-like partitions; these probably were used in axial bipartite division. The skeleton is similar in important respects to some Ordovician skeletal Zoantharia. As a result the fossil is assigned tentatively to the Zoantharia within the Anthozoa.</ABSTRACT>

29193 <TITLE>A new genus of Early Cambrian coral in Esmeralda County, southwestern Nevada.</TITLE>
29194 <SOURCE>Journal of Paleontology 80, 4: 609-615.</SOURCE>
29195 <ABSTRACT>Numerous Early Cambrian corals or coralomorphs, as they are often classified, are recorded from North America, Australia, and Siberia. A new Early Cambrian coral, Harklessia yuenglingensis n.gen. et sp., is found in conjunction with archaeocyathan-microbial reef in Esmeralda County, southwestern Nevada. The coral-bearing reefs are within quartzitic, trilobite-rich packstone beds in the upper portion of the Harkless Formation (Bonnia-Olenellus Zone). Coralla are constructed by subpolygonal to polygonal, cerioid, close-packed corallite tubes. Coralla average 12cm in height by 18cm in diameter with individual corallite tubes ranging from 1.2 to 3.2mm in diameter. Corallites are greater than 25mm in length. Septa and tabulae are not present. Many of the Early Cambrian corals previously described have attributes of the class Anthozoa and subclass Zoantharia, with some specific similarities to tabulate corals. Harklessia yuenglingensis is placed confidently within the class Anthozoa, subclass Zoantharia because its morphological characteristics indicate an affinity to true corals, but whether H. yuenglingensis is a tabulate coral remains uncertain.</ABSTRACT>

</TITLE>
- 29220 <SOURCE>Journal of Paleontology 57, 6: 1188-1211.</SOURCE>
- 29221 <ABSTRACT>A distinctive group of longitudinally septate, bilaterally
symmetrical, phosphatic, tubular microfossil, the Paiutiida n.ord.,
have been discovered to occur in archaeocyathid-bearing carbonate units
of the Lower Cambrian Campito and Poleta formations, White Mountains,
Inyo County, California. Possible anthozoan affinity is suggested for
the organisms that once occupied these coral-like microfossils. The
tubules are solitary, commonly cylindrical, and rarely exceed a maximum
of 1 mm in diameter, or 5 mm in length. A thin epitheca-like layer may
be present, and the exterior tubule surface is smooth or weakly
annulate. The tubule wall is 0.02-0.05 mm thick and composed of
fluorapatite. Tubules are characterized by the presence of Although
fundamental compositional and structural differences in skeletal
morphology exist among the several Cambrian coral-like groups, and
between the later evolved skeleton-secreting anthozoan orders, the
basic coral architectural plan is recognizable. It is suggested that
all of the groups stem from a common Precambrian ancestral form, but
that each arose iteratively from later evolved anemone stocks. Thus,
fossils assigned to the new order Paiutiida are included in the
subphylum Cnidaria, and questionably assigned to the class Anthozoa.
Subclass-level assignment remains uncertain due to the unique
compositional and morphological characteristics of the paiutiid
skeleton. Paiutitubulites variabilis n.gen., n.sp., and P. durhami n.sp.
are characterized by the presence of well-developed secondary
septa (secondary as defined herein); Cambrptubulites trisepta
n.gen., n.sp. and specimens assigned to the genus lack secondary
septa. These genera and forms questionably assigned to them are
characterized by the absence or weak development of septal grooves.,
which is a diagnostic feature of the Paiutitubulitidae n.fam. The
Paiutitubulitidae is defined to exclude problematical tubules:-
displaying a septal arrangement pattern that is convergent upon that of
cnidarian groups that appear to display tetrameral symmetry. These
problematical specimens are considered as a separate species, and
familial-level classification is uncertain pending further study,
although assignment to the Paiutiida is unquestioned. (Original summary)

29312 <ABSTRACT>A single specimen of *Ratcliffespongia wheeleri* n.sp. from the upper part of the Middle Cambrian Wheeler Shale in the Drum Mountains of western Utah shows two distinct skeletal layers in the limonite-replaced fragment. The probable inner layer has large, circular to elliptical parietal gaps, some of which are aligned horizontally(?); gaps are outlined by long rays of hexactine-based spicules in irregular orientation and spacing. The probable outer layer has several ranks of stauracts in regular reticulation and ranking, all at approximately 45 degrees to the probably horizontal direction. The specimen is part of a probably shallow turbidite-transported assemblage from the margin of the House Range embayment.</ABSTRACT>

29324 <SOURCE>Paläontologische Zeitschrift 69, 1-2: 7-17.</SOURCE>
29325 <ABSTRACT>We describe a new species of chondrophorine hydrozoan, *Palaelophacmaea valentinei* sp.nov., from the early Middle Cambrian part of the Cadiz Formation of the Marble Mountains of southeastern

California. This find extends the stratigraphic range of this genus into the early Middle Cambrian and its geographic range into the western United States. We review various chondrophorine-like fossils and present a tentative chondrophorine phylogeny in light of this find.

29336 <TITLE>Tabuloconus Handfield: microstructure and its implication in the taxonomy of primitive corals.</TITLE>

29337 <SOURCE>Journal of Paleontology 61, 1: 1-9.</SOURCE>

29338 <ABSTRACT>Numerous specimens of Tabuloconus Handfield. 1969, have been collected in carbonate buildups within the Adams Argillite (Early Cambrian, Tatonduk area, Alaska). The wall structure of this form has been investigated, along with contemporaneous archaeocyathids and algae, through the use of polished ultra-thin sections (2-3 μ m thick) and scanning electron microscopy. The results of this microstructural comparison indicate that despite diagenetic alteration Tabuloconus has a skeleton that is unlike any presently known and is quite distinct from associated algae and archaeocyathids. It is more elaborate than that found in the archaeocyathids but has not reached the stage of complexity seen in the primitive coral Cothonion Jell & Jell, 1976. The presence of some elongated units may represent an initial step towards the fibrous skeleton typical of Paleozoic corals. This study shows that even though diagenesis alters the original microstructure of calcareous skeletons, the resultant fabric and detailed structures can be useful in systematic descriptions. Tabuloconus is removed from the Gastroconidae Korda due to the presence of rudimentary septa and constitution of the tabularium. A number of species assigned to the genus Bacatocyathus Vologdin and included within the Archaeocyatha appear to be examples of Tabuloconus or very close relatives. An emended description of Tabuloconus kordae, the type species, is proposed.</ABSTRACT>

- 29442 <ABSTRACT>The Upper Ordovician (middle Edenian to upper Richmondian) Montoya Group of southern New Mexico and westernmost Texas comprises, in ascending order, the Second Value Dolomite, Aleman Formation, and Cutter Dolomite. Solitary rugose corals in the Second Value are *Grewingkia robusta* (Whiteaves, 1896), *Bighornia* sp. cf. *B. patella* (Wilson, 1926), *Streptelasma divaricans* (Nicholson, 1875), a new species of *Neotryplasma*, and *Salvadorea*? ssp. A and B. *Salvadorea kingae kingae* Nelson, 1981, *G. franklinensis* n.sp., and *G. crassa alemanensis* n. subsp. occur in the Aleman. Taxa found in the Cutter are *S. kingae cutterensis* n. subsp., *G. sp. cf. G. franklinensis*, and *B. sp. cf. B. patella*. (Extract from original summary)</ABSTRACT>

29466 <TITLE>Corals of the Advance Formation (upper Middle Ordovician), northern Rocky Mountains of British Columbia.</TITLE>
29467 <SOURCE>Geol. Surv. Canada Bull. 491: 78-93.</SOURCE>
29468 <ABSTRACT>All corals known from slope deposits of the Advance Formation are solitary rugosans. Paliphyllum norfordi n.sp., represented by a single specimen, and Grewingkia burdenetisis n.sp., which is more common, are the only identifiable species. Diversity and abundance are low compared with the taxonomically different coral fauna in approximately coeval shelf deposits of the Johnson Spring Formation, California. Grewingkia burdenensis is considered to be the ancestor of Grewingkia robusta, a Late Ordovician species that was widely distributed within the Red River-Stony Mountain Province of cratonic North America. Paliphyllum norfordi is the earliest paliphyllid worldwide, and the only rugosan with dissepiments known from the Middle Ordovician of North America. It appears to be most similar to some representatives of Paliphyllum in the Dolbor Formation (uppermost Caradoc-lowermost Ashgill), Siberian Platform. Coralla of G. burdenensis were subject to little current action or transportation. This species generally lived freely on soft substrates; sediment cohesion may have been low. In one stratigraphic interval, the presence of specimens with attachment structures suggests that the substrate may have been unfavourable for the coral's normal mode of life, or that more objects suitable for attachment were available than usual. The corallum of P. norfordi was subject to higher current energy and possibly transportation, and / or longer exposure before final burial. This coral was overturned, possibly due to current activity or substrate instability or both, and redirected its growth upward several times during life. It is the earliest North American solitary rugosan that had the ability to resume upward growth after being fully overturned.</ABSTRACT>

29544 <TITLE>Ordovician sponges from the Montgomery Limestone, Taylorsville area, northern Sierra Nevada, California.</TITLE>
29545 <SOURCE>Bulletin of Geosciences 83, 3: 299-310.</SOURCE>
29546 <ABSTRACT>The modest faunule of silicified fossil demosponges, documented here, was recovered from the Upper Ordovician Montgomery Limestone in the Taylorsville area, in the northern Sierra Nevada of northern California. Included are specimens of the ceractinomorph angullongioid *Amblysiphonelloidea tubulara* Rigby & Potter 1986, the girtyocoelliid *Girtyocoeliana epiporata* (Rigby & Potter 1986), the seburgasiid *Amblysiphonella* sp., and the cliefdenellids *Cliefdenella alaskaensis* Stock 1981, and *Rigbyetia obconica* (Rigby & Potter 1986). In addition, specimens of the vaceletiid *Corymbospongia adnata* Rigby & Potter 1986, are described and figured. The assemblage is closely related to faunules of sphinctozoan sponges earlier reported by Rigby & Potter (1986) from the eastern Klamath Mountains, to the west in northern California. 29583 <TITLE>Upper Ordovician to Lowermost Silurian solitary rugose corals from the Beaverfoot Formation, southern Rocky Mountains, British Columbia and Alberta.</TITLE>
29584 <SOURCE>Contr. Canad. Paleont., Geol. Surv. Canada 379: 47-91.</SOURCE>
29585 <ABSTRACT>Salvadorea distincta distincta (Wilson 1926), Salvadorea sp. 2 of Nelson 1981, Bighornia patella (Wilson 1926), B. cf. B. bottei Nelson 1963, Grewingkia haysii haysii (Meek 1865), and Deiracorallium prolongatum (Wilson 1926) are present within the Upper Ordovician Bighornia-Thaerodonta Zone of the Beaverfoot Formation. Bighornia wilsonae sp.nov., is recognized from the Montoya Group (Second Value Dolomite) of New Mexico and Texas, and the Red River Formation (Selkirk Member) of southern Manitoba. Paleoeological analyses suggest that Grewingkia haysii haysii and Deiracorallium prolongatum inhabited higher energy environments than Salvadorea distincta distincta and Bighornia patella, but all taxa probably lived in close proximity. The Beaverfoot Formation accumulated within the Red River - Stony Mountain Solitary Coral Province. Solitary rugosan species in the Bighornia-Thaerodonta Zone represent an "epicontinental" assemblage, and all occur in the Hudson Bay Basin. The absence of " continental margin" taxa could indicate that the formation was deposited some distance from the edge of the continent, or could reflect environmental factors or geographic barriers. The lowest occurrence of solitary Rugosa defines the base of the Bighornia-Thaerodonta Zone in the Beaverfoot Formation (Whisky Trail Member). Elsewhere such Salvadorea-dominated coral assemblages first appear in Maysvillian to middle Richmondian strata. The zone has been traced to 420 feet (128 m) above the base of the Beaverfoot at Akutlak Creek; its top is probably Richmondian but could be Gamachian. Solitary Rugosa in the thick, combined "poorly fossiliferous interval" and Eostropheodonta Zone of the Beaverfoot Formation are completely different from those of the underlying Bighornia-Thaerodonta Zone. Rhexmaphyllum could be Upper Ordovician (Richmondian, Gamachian) to Lower Silurian (Lower Llandovery). Dinophyllum could be Lower to Middle Llandovery. Streptelasma is also present.</ABSTRACT>

29635 <TITLE>Significance of Silurian stromatolite-sphinctozoan reefs.</TITLE>
29636 <SOURCE>Geology 22: 355-358.</SOURCE>
29637 <ABSTRACT>Upper Silurian (Ludlovian) limestones from the Heceta Formation of southeastern Alaska (Alexander terrane) contain skeletal stromatolite reefs and stromatolite mud mounds that were colonized by sphinctozoa sponges. Internal growth cavities, syndimentary marine cements, and stromatolite debris flows in slope deposits indicate that these reefs grew with relief at the seaward margin of the carbonate platform. The biotas under study have evolutionary significance because they contain the earliest widespread reef-building sphinctozoans and represent a previously unrecognized stage in the evolution of Phanerozoic microbial-metazoan (predominantly poriferan) reefs. On the basis of the presence of Silurian stromatolite-sphinctozoan deposits in southeastern Alaska, southwestern and west-central Alaska, and the Urals, this study also establishes a Late Silurian palaeobiogeographic connection between the Alexander terrane, cratonic northwestern North America, and the Uralian region.</ABSTRACT>

- 29648 <TITLE>Paleoecology of sponge-?hydroid associations in Silurian microbial reefs.</TITLE>
- 29649 <SOURCE>Palaios 18, 3: 225-235.</SOURCE>
- 29650 <ABSTRACT>Microbial boundstones from Alaska and Russia yield new insights into the paleoecology of Silurian biotas that inhabited stromatolite reefs. These high-energy reefs were built along the Uralian Seaway in the Late Silurian by a diverse suite of microorganisms in association with accessory metazoans, predominantly sphinctozoan sponges. Within the stromatolite framework, three species of small, solitary, sphinctozoans (aphrosalpingids) encrusted a variety of hard substrates, mostly skeletal remains but also microbial laminae and cavity surfaces. Fossils encrusted by the sponges include the problematic hydroid *Fistulella*, possible stromatoporoids (re-crystallized), crinoids, the possible cyanobacterium *Ludlowia*, corals, and unidentifiable shelly debris. In addition to the ubiquitous microbial laminae, the sponges, *Fistulella*, and ?stromatoporoids were less commonly encrusted by *Ludlowia*, *Renalcis*, or crinoids. Well-developed attachment surfaces, including enlarged holdfasts, allowed the sponges to achieve stability on the seafloor after larvae settled randomly on available hard surfaces. A greater incidence of sponge encrustations on *Fistulella* than on other organisms indicates that some of the sponges may have enjoyed a commensalistic relationship while attached as juveniles to a living substrate. The sponges' orientation on *Fistulella* in the sediment suggests that the relationship between the two taxa may have become parasitic, whereby the weight of the sponges caused *Fistulella* to collapse into the muddy substrate. Recognition of the intimate growth relationships shared by Silurian sphinctozoans, *Fistulella*, and other organisms expands the fossil record of encrusting sponges, identifies a novel sponge-?hydroid association, and reveals organismal responses to competition for space in mid-Paleozoic microbial reefs. - 29676 <ABSTRACT>Lower to Upper Silurian (upper Llandovery-Ludlow) limestones belonging to the Heceta Formation record several episodes of reef growth in the Alexander terrane of southeastern Alaska. As the oldest

carbonates of widespread distribution in the region, the Heceta limestones represent the earliest development of a shallow-marine platform within the Alexander arc and the oldest foundation for reef evolution. The excellent preservation of biostromes, fringing and barrier reefs, and a mud mound in shelf, shelf margin, and slope deposits, respectively, contrasts with the restricted occurrence of many marine sediments that originated within other island arcs. Hence, these deposits provide important insights into the dynamic processes, styles, and bathymetry associated with reef growth in tectonically active oceanic islands. Massive stromatoporoids, corals, and red algae are preserved in fragmental rudstones and represent a fringing reef that formed at the seaward edge of the incipient marine shelf. Accessory constituents in this reef include crinoids and the cyanobacterium *Girvanella*. Small biostromes were constructed by ramose corals and stromatoporoids on oncolitic substrates in backreef or lagoonal environments. These buildups were associated with low-diversity assemblages of brachiopods and with gastropods, amphiporids, calcareous algae and cyanobacteria. Microbial boundstones reflect the widespread encrustation of cyanobacteria and calcified rnicroproblematica on shelly debris as stromatolitic mats that resulted in the development of a stromatactoid-bearing mud mound and a barrier reef complex. Epiphytaceans, other microbes, and aphrosalpingid sponges were the primary framebuilders of the barrier reefs. These buildups attained significant relief at the shelf margin and shed detritus as slumped blocks and debris flows into deep-water sites along the slope. The similarity of these stromatolitic-aphrosalpingid reefs to those from Siluro-Devonian strata of autochthonous southwestern Alaska suggests paleobiogeographic ties of the Alexander terrane to cratonal North America during the Silurian.</ABSTRACT>

29688 <SOURCE>Palaios 15, 4: 273-292.</SOURCE>

29689 <ABSTRACT>In Glacier Bay, Alaska, Silurian limestones record the development and demise of a stromatolite reef complex in the Alexander terrane. These microbial deposits are of regional and paleontological significance because they contain paleogeographically distinctive biotas and yield important insights into Phanerozoic stromatolites that inhabited normal-marine subtidal environments. willoughby limestones exposed on Drake Island reveal that stromatolite growth at the platform margin influenced platform dynamics with the protection of peritidal and lagoonal habitats behind a reef-fringed rim, which experienced early lithification by the precipitation of syndimentary marine cements. 29700 <TITLE>New hexactinellids from the Siluro-Devonian of the Snake Mountains, Elko County, Nevada, and a new locality of Gabelia.</TITLE>
29701 <SOURCE>Journal of Paleontology 65, 5: 709-714.
<http://www.jstor.org/pss/1305800></SOURCE>
29702 <ABSTRACT>New specimens of Gabelia pedunculus Rigby & Murphy 1983, and of the new species Gabelia gigantes and Gabelia fascicula are described from the Siluro-Devonian(?) Roberts Mountains Formation from Loomis Creek Canyon in the Snake Mountains, northeastern Elko County, Nevada. Stalk fragments of G. pedunculus are similar to the holotype from the northern Roberts Mountains, Eureka County, Nevada. Gabelia gigantes n.sp. is a large species with skeletal elements in the stalk twice the size of elements in G. pedunculus. Gabelia fascicula n.sp. is based on thick-walled, cup-like upper parts where gastral layer of coarse, diagonally oriented spicules contrasts to a dermal layer of regular vertical and horizontal bundles of hexactine-based spicules of at least two orders around parietal gaps. The specimens are all part of a probable transported seafloor assemblage.</ABSTRACT>

29713 <TITLE>Hexactinellid Sponges from the Silurian - Devonian Roberts Mountains Formation in Nevada and Hypotheses of Hexactine - Stauractine Origin.</TITLE>
29714 <SOURCE>Brigham Young University, Geology Studies 39: 101-124.</SOURCE>
29715 <ABSTRACT>A moderately diverse fauna of hexactinellid sponges is described from the Devonian(?) upper part of the Silurian - Devonian Roberts Mountain Formation from a locality in Starvation Canyon in the Independence Mountains, Elko County, Nevada. Diagoniella nevadensis Rigby & Stuart 1988, Protospongia conica Rigby & Harris 1979, Protospongia spina n.sp., Protospongia sp. 1, Protospongia sp. 2, and Gabelia pedunculus Rigby & Murphy 1983, are present. These were apparently transported, size sorted, and buried by distal turbidity currents. Many samples have monospecific bedding plane "faunules ", which accumulation [?]. Stratigraphic and phylogenetic systematic evidence for increasing complexity versus simplification for the origin of hexactines and stauractines are summarized and discussed; hexactines as old as stauractines appear to have been the basic early spicule at about the beginning of the Cambrian, although evidence is still equivocal.</ABSTRACT>

29778 <TITLE>Early Devonian conodont-graptolite collation and correlations
with brachiopod and coral zones, Central Nevada.</TITLE>
29779 <SOURCE>American Association of Petroleum Geologists Bulletin 67, 3:
371-379.</SOURCE>
29780 <ABSTRACT>A range chart of some Early Devonian conodont and graptolite
taxa from central Nevada is presented. It is based on the graphic
correlation method of Shaw, and shows correlations with the established
zones for bachiopods and corals as well as conodonts and graptolites.
It indicates that the hesperius through pesavis conodont zones

established for western North America are approximately equivalent to the Lochkovian of the Czechoslovakia sequence, and the Pragian begins approximately with the sulcatus zone. The chart also indicates that the zones based on different groups do not coincide, are of very unequal duration, and that intervals of rapid morphologic change correspond to intervals of higher diversity and greater morphologic variation. Species have significantly different longevities, generally those originating during time of greatest morphologic variation being the shorter lived. The approximate duration of the species studied is 2 to 10 m.y. * Use of the graphic correlation method permits better correlation of shelf and basin faunas and enhances the possibility for constructing accurate shelf margin histories and for correlating provincial shelf faunas with those in other parts of the world.

29804 <TITLE>Devonian corals of late Eifelian age from the Ogilvie Formation of Yukon Territory.</TITLE>

29805 <SOURCE>Canadian Journal of Earth Sciences 17: 594-616.</SOURCE>

29806 <ABSTRACT>Coral faunas from 254.9 - 345.4m above the base of the type section of the Ogilvie Formation on Mount Burgess, and from parts of other Ogilvie sections, are shown to be equivalent to late Eifelian coral faunas of the Hume Formation of western District of Mackenzie, and its correlatives in southwestern District of Mackenzie and northeastern British Columbia. Although older faunas from lower beds and younger faunas from higher beds of the Ogilvie Formation have been described previously, this is the first description of Hume faunas from the formation. * The Redstoneinae, a new subfamily of the Spongophyllidae, is proposed. Two new genera, Tawuphyllum and Gaynaphyllum, and a new species, Radiastrea norrisi, are also established. * Photographic illustrations of interiors of Iteophyllum virgatum Crickmay, Endophyllum barbatum Crickmay, the lectotype of Smithia verrilli Meek, and neotype of Spongophyllum sedgwicki Edwards & Haime are published for the first time. 29819 <ABSTRACT>The mucophyllid genus Stylopleura and the spongophyllid genus Carlinastraea are revised. In western and arctic North America, the temporal ranges of these genera overlap in Lochkovian time. Stylopleura julli and Carlinastraea pygmaea are established as new species. Carlinastraea halysitoides (Etheridge) is revised, and is shown to have had a remarkable geographic range, that, in Lochkovian time, extended from eastern Australia, through China, Mongolia, Asiatic Russia, the Urals, Yukon Territory and British Columbia, to Nevada. An early Pragian coral from Victoria and New South Wales, eastern Australia, is discussed and figured under the name of Carlinastraea sp. cf. C. halysitoides (Etheridge).</ABSTRACT>

29830 <TITLE>Emsian (Lower Devonian) Rugose corals of Nevada: Reservoir of systematics and stratigraphic ranges, and reassessment of faunal provincialism.</TITLE>
29831 <SOURCE>Journal of Paleontology 78, 5: 838-863.</SOURCE>
29832 <ABSTRACT>New collection from measured sections provide much of the material for this study. Holcocystis, Atopocystis, and Stummelasma are erected as new genera. Atopocystis mucronata and Stummelasma sulfurensis are new species; Holcocystis flexa (Stumm), Stummelasma lonense (Stumm), and S. antelopense (Merriam) are new combinations. Revised coral ranges are integrated with the standard Nevada conodont zones and brachiopod-based faunal intervals. A range chart for 33 Rugosa emphasizes their value for correlation in the Icriodus, or brachiopod-poor biofacies of the Great Basin. It also shows that full recovery from the end Lochkovian/early Pragian coral crisis in the region was delayed until the start of the middle Emsian Gronbergi Zone. The recovery was accomplished principally by radiation of the Breviphyllidae and Papilophyllidae, and by immigration of cyathophyllid and other genera. Updated lists of Rugosa genera present in the Great Basin, Mackenzie, and Apophimchi provinces during the Pragian and early Emsian (Kindley-Lenzi zones) and middle to late Emsian (Gronbergi and Iserotinus zones) are given. Qualitative and quantitative data, the latter as Otsuka Coefficients, indicate that the Pragian Great Basin coral faunas can no longer be regarded as part of a temporary westward extension of the Eastern Americas Realm. Nor can they be considered part of the Mackenzie coral province. Genus absence/presence data show that the Great Basin coral province began with a slow recovery of faunas after the late Lochkovian/early Pragian coral crisis, and ended with the arrival of typical Old World Realm families, including the Ptenophyllidae and Stringophyllidae, within the early Eifelian, Costatus Zone. During this time faunas of the Mackenzie coral province were so distinct from those of the exotic Alexander and Farewell terranes of Alaska and British Columbia. The duration of the Devonian Great Basin

- coral province corresponds closely to the duration of a period of depressed seawater temperatures postulated from the distribution of gypsidulid brachiopods. </ABSTRACT>

29882 <TITLE>Rugose corals from the Frasnian (Upper Devonian) Sly Gap and Contadero Formations of the San Andres Mountains, south-central New Mexico.</TITLE>
29883 <SOURCE>Mem. New Mexico Bur. Mines & Miner. Resour. 44: 153-183.</SOURCE>
29884 <ABSTRACT>Devonian strata in the northern San Andres Mountains of southern New Mexico contain abundant faunas of fossil rugose corals in calcareous beds of the Sly Gap and Contadero Formations. The lower and middle Sly Gap Formation contains abundant solitary corals occurring with numerous brachiopods. For the most part, these are Macgeea thomasi, with a few specimens of Tabulophyllum ovinum n.sp. and T.(?) versutum n.sp. Colonial corals, with accompanying solitary forms, are common to abundant in nodular limestones of the uppermost part of the Sly Gap Formation. They are Medusaephyllum woodmani, M. variabile n.sp., lowaphyllum johanni, Hexagonaria capitolium n.sp., and Radiastraea rhodesi n.sp. Tabulophyllum bilaterale n.sp. is the most common solitary form. All rugose corals collected from the Contadero Formation came from limestones forming the uppermost part of the Salinas Peak Member. Almost all individual corals are assigned to Tabulophyllum zonatum n.sp., with a single specimen of Medusaephyllum confluens n.sp. The Sly Gap and Contadero corals comprise typical Frasnian faunal assemblages. The Sly Gap fauna is placed in the Palmatolepis gigas conodont Zone; the Contadero is placed in the overlying lower Palmatolepis triangularis conodont Subzone, thus representing a very late Frasnian fauna.</ABSTRACT>

29895 <TITLE>Late Devonian (Famennian) rugose coral fauna of the Percha Shale of southwestern New Mexico.</TITLE>
29896 <SOURCE>Journal of Paleontology 66, 5: 730-749.</SOURCE>
29897 <ABSTRACT>Solitary rugose corals (Cnidaria, Rugosa) are common to abundant in the calcareous Box Member of the late Famennian Percha Shale (Lower expansa Zone) of southwestern New Mexico; the Box is best developed in the western part of the Percha outcrop belt. The corals include a number of forms characteristic of Strunian faunas throughout the world. Recognized hereby are Gorizdronia sp. cf. G. tenuis Rozkowska, Campophyllum? ursinum n.sp., Caninia cooperi n.sp., Siphonophyllia? folia n.sp., S.? corbicula n.sp., "Bothrophyllum " argenteum n.sp., "B." argenteum argenteum n.subsp., "B." argenteum bilaterale n.subsp., "B." argenteum dibunophylloides n.subsp., Arachnolasmella elytra n.sp., and Cyathoclisia sp. A. This fauna is clearly ancestral to Carboniferous genera and species. Percha species, where represented by large populations, are seen to be remarkably variable, especially in axial structure.</ABSTRACT>

29909 <SOURCE>Boletín de la Real Sociedad Española de Historia Natural, Sección Geológica 92, 1/4: 289-300.</SOURCE>
29910 <ABSTRACT>Rugose corals of mid-late Eifelian age are diverse and relatively abundant in widespread open shelf carbonates of Northeastern British Columbia (lower Keg River and Dunedin formations) and District of Mackenzie (Lonely Bay, Nahanni, Headless and Hume formations). The overlying Givetian carbonate complex of northeastern British Columbia and southern District of Mackenzie (Presqu'île Barrier) has only sparsely developed rugosans, but beds flanking the barrier (upper Dunedin, Pine Point, Sulphur Point formations) locally develop more diverse faunas of early-mid Givetian age. Downslope from the barrier complex, numerous early-mid Givetian pinnacle reefs (upper Keg River, Horn Plateau formations) bear particularly diverse and abundant rugose coral assemblages. In the lower Mackenzie River valley of northern District of Mackenzie a series of reefal complexes of mid-late Givetian age (Ramparts Formation) carries significant rugosan faunas, especially in platform and flanking beds.</ABSTRACT>

29921 <TITLE>Lower-Middle Devonian rugose coral faunas of Nevada: Contribution to an understanding of the "barren" E Zone and Chotec Event in the Great Basin.</TITLE>
29922 <SOURCE>Bulletin of Geosciences 85, 1: 1-26.ISSN 1214-1119</SOURCE>
29923 <ABSTRACT>The "lower Middle Devonian" part of a coral zonation proposed for the region in 1974 comprised in ascending order D2 and D3 subzones and a "barren" E zone. In terms of the conodont zonation currently employed in Nevada, the D2 subzone is Emsian gronbergi and inversus zones. The original stratigraphic definition of the D3 subzone places it in the upper Emsian serotinus Zone on Lone Mountain, whereas the coral index defining the zone has been collected subsequently only from Eifelian upper costatus Zone beds. The original stratigraphic definition of the "barren" E zone places it in a lower part of the costatus Zone, above an inferred depositional break. Thus, as defined on Lone Mountain, the D3 subzone is slightly younger than the E zone. These zones are not barren. Revised taxonomy and age determinations of previously described species, coupled with new data from the southern Sulphur Spring and northern Antelope ranges, have revealed four successive coral assemblages ranging from serotinus to costatus Zone age. Differences between the second and third of these assemblages are particularly significant, and may be considered to represent a local manifestation of the Chotec Event. A detailed review of the genus Synaptophyllum shows it to be an Emsian endemic in the Maghrebo-European Realm, not an early Eifelian endemic in the Eastern Americas Realm. New taxa comprise a family, one genus and two species. Romanophyllum paulyi gen. et sp.nov., which possibly represents one of the last vestiges of the Pragian-Emsian Great Basin coral province, is assigned to the Romanophyllidae fam. n. Xystriphyllum trojani sp.nov. is described as an example of one of earliest ptenophyllid species to return to the Great Basin after the absence of the family from the

- region since late Lochkovian time.</ABSTRACT>

- 29936 <ABSTRACT>Previous Lower to Middle Devonian coral biostratigraphy for Nevada is reviewed. A reassessment of Merriam's 1974 Emsian coral assemblages zones indicates that his D1 Subzone is longer ranging than it was thought to be and his D3 subzone is probably Middle Devonian, costatus zone. Composition of the Breviphyllidae Taylor 1951 is revised to include Breviphyllum Stumm 1949, Breviphrentis Stumm 1949, Nevadophyllum Stumm 1937, Ogilviplasma Pedder 1978, Weyerides gen. nov., Bartineophyllum gen. nov., and possibly Baoshanophyllum Song 1974 and its probable synonym Puanophyllum Wang 1983. Breviphrentis kirki, Nevadophyllum eximium, Weyerides salicensis, W. serus and Bartineophyllum hassli are erected as new species. Ages of all the formally described taxa are calibrated against standard conodont zonations and the Nevada faunal intervals of Johnson (1977).</ABSTRACT>

- 29949 <ABSTRACT>Field work has greatly increased the number of well-dated papiliophyllid corals available from Nevada. The established range of the family is expanded from Pragian and lower Emsian to Pragian and almost the entire Emsian. Ranges of species are calibrated against Johnson faunal intervals and a revised Pragian and lowermost Emsian conodont zonation proposed by Murphy for Nevada. Study of all repositated material has led to some revision of every member of the family, Eurekaophyllum, previously imperfectly known from a single specimen of vague stratigraphic origin, is shown to be a useful upper Emsian index. Nine reported occurrences of the family in Europe and Asia are re-examined and, except for a possible occurrence on Novaya Zemlya, all are rejected. The three named genera of the family are apparently endemic to the southwestern North American craton. Papiliophyllum elegantulum asymmetricum new subspecies, P. murphyi new species and Eurekaophyllum vesicum new species are described by Pedder. [original abstract]</ABSTRACT>

29961 <SOURCE>Acta Scientiarum Universitatis Pekingensis [Pei-ching ta hsueh hsueh pao] 29, 6: 715-728.</SOURCE>
29962 <ABSTRACT>Eleven species (none new) are described from a core of the reef facies of the Evie Lake reef complex. The structures are extensively infiltrated by bitumen that preserves microstructures well. The fauna has Trupetostroma warreni, Stachyodes thomasclarki and S. spongiosa in common with the Swan Hills reefs. It is particularly characterized by the distinctive Actinostroma whiteavesii and Pseudotrupetostroma vitreum. The latter species and Taleastroma logansportense indicate affinity with the Givetian faunas of Poland and the Ohio Valley area.</ABSTRACT>

29987 <SOURCE>Geological Society of America Abstracts with Programs 42, 5: 173.</SOURCE>
29988 <ABSTRACT>The Alamo Impact Breccia is found within the Frasnian-age Guilmette Formation. Chronostratigraphically it occurs with the punctata condont Zone. Stromatoporoids are the main booklist within the Alamo. Six species were found within the Breccia: Hammatostroma albertans, Habrostroma turbinatum, Actinostroma sp., Atelodictyon sp., Hermatoporella sp., and Atopostroma distans. The first five species are considered to be Frasnian and/or Givetian in age; however, Atopostroma distans is Emsian in age. The authors conclude that the bolide that caused the Alamo Breccia excavated as deep as Emsian. As Ordovician conodonts occur in the Alamo as well, the authors further conclude that stromatoporoid-bearing strata older than Emsian do not

occur in southeastern Nevada, and that because the Emsian strata in southeastern Nevada are unfossiliferous dolostones, the specimens of *A. distans* were transported into the area by tsunamis associated with the impact.

30013 <SOURCE>California University, Riverside Campus Museum Contribution 4: 89-98.</SOURCE>
30014 <ABSTRACT>Dolomites at the edge of the shallow Kiddle Devonian shelf in central Nevada contain nests of well preserved brachiopods and tabulate corals in an association of the Rasenriff type. The Nevada occurrence is named the Spinatrypina-Thamnopora Community because of the abundance of those two forms with Cryptatrypa and a few other brachipodes and corals. The Spinatrypina -Thamnopora Community is believed to have inhabited a shallow, quiet water biotope behind the shelf edge. Cryptatrypa paracircula, Spinatrypina asymmetrica, and Syringopora noranna are proposed as new species. [original summary]</ABSTRACT>

30065 <SOURCE>Journal of Sedimentary Research B64: 326-340.</SOURCE>
30066 <ABSTRACT>Parasequence stacking patterns suggest that buildup stratigraphy was controlled by fluctuations in relative sea level. The meter-scale shallowing upward parasequences of the Flume and Cairn formations consist of a basal domal or bulbous Stromatoporoid floatstone / rudstone overlain by a fragmented Amphipora or Thamnopora wackestone / packstone and in turn overlain by either an Amphipora wackestone / packstone or an algal laminite. The domal Stromatoporoid rudstone is interpreted as the deepest of these facies and the laminites as intertidal. The parasequences can be used to correlate sections.</ABSTRACT>

- 30077 <TITLE>Early-Frasnian stratigraphy, Kakwa-Cecilia Lakes, British Columbia, Canada.</TITLE>
- 30078 <SOURCE>Notes et Mémoires 10, Total, C.F.P. Paris, 80 pp.</SOURCE>
- 30079 <ABSTRACT>After 1968 field reconnaissance, a party spent three weeks of summer 1969 in the General Kakwa area (British Columbia). Northward shaling-out of Early Frasnian (Flume carbonates) was detailed both sedimentologically and paleontologically. Field involvement of these techniques secured appropriate faunal sampling which permitted later detailed study of faunal assemblages during winter 1969-1970. Strata herein studied cover this part of the Frasnian outcrop generally known as the Flume member and stratigraphically correlate with the Beaver Hill Lake - waterways subsurface section, and northeastern Alberta exposures. The four studied sections exhibit the shaling-out of Southern carbonates deposited on a shallow open marine shelf. Tentative build-ups were erected at the margins of the shelf amidst biostromal banks. Stromatoporos were the major agents responsible for such reefing. Northerly deepening conditions, or geographical changes in current regimes, hindered both frame builders' life and carbonate deposition, favoring shales accumulation. Marine conditions were almost the same along the horizontal slice of water for bottom dwellers such as Brachiopods. An extremely rich Brachiopod fauna allows very detailed correlations between sections spread over a 15 kilometer strip (coupled with classical coral associations). Part II deals with paleontological breakdown of the Flume section into five main faunal assemblages. The quality of collected material is such that the three medial assemblages are of uppermost value for correlating eastward into the Alberta Plain subcrop, the well-described outcrop of Waterways, and subsurface of Northwest Territories. Corals and Brachiopods correlations are extended to United States. with the help of published Conodont and Cephalopod evidence, relationship with European zones is tentatively established. A reevaluation of the full Frasnian biostratigraphic zonation is proposed in Appendix with emphasis on lower zones, namely DFR2 Ladogioides pax zone, DFR3 Atrypa scutiformis zone (gathering assemblages II and III), and DFR4 Atrypa gregeri zone.</ABSTRACT>

30130 <SOURCE>Journal of Paleontology 58, 1: 185-196.</SOURCE>
30131 <ABSTRACT>Epibionts Tolypamma ? sp. (Protozoa), Eridopora sp. (Bryozoa), Petrocrania sp. (Brachiopoda), Spirorbis ? sp. (Annelida), and Vermiforichnus sp. (Annelida) on the curved conical coralla of Barytichisma sp. (Coelenterata) show a strong preference for the concave side of the corallum and are more abundant on the upper half of the corallum than on the lower half. This distribution helps confirm Bernard's (1904) hypothesis that the corallum assumed a living position lying on its side, after toppling from an early attached upright growth position, and curved upward from the substrate in order to maintain an optimum living position later in life. The distribution also indicates that these epibionts inhabited the host coralla mostly while the polyps were alive. Epibionts Thallophyta (algae or fungi) and Bascomella sp. (Arthropoda) established themselves on the host coralla later than the other epibionts and have a random distribution with respect to the plane of curvature, indicating that these organisms inhabited the hosts mainly after death of the polyps.</ABSTRACT>

30207 <TITLE>Ecological observations on Chaetetes in Southern Nevada.</TITLE>
30208 <SOURCE>Pacific Geology 14: 1-22; Tokyo.</SOURCE>
30209 <ABSTRACT>Occurrences of Chaetetes favosus and Ch. milleporaceus are narrowly restricted, both temporally and lithologically, within the Bird Spring Group in the Arrow Canyon Quadrangle, Clark County Nevada. Ch. favosus is confined to the later Atokan and Ch. milleporaceus to the earliest Desmoinesian in this area, although both taxa enjoy a far greater biozone. Both taxa are restricted further to a few, thin key beds, generally containing many individuals, within their local range. Microfacies and faunal analysis of the Chaetetes biostromes indicate deposition in normal marine waters somewhat below tidal range, at, or just below wave base. Similar rocks and faunal associations, however, occur in the absence of Chaetetes in rocks both below and above the Chaetetes-bearing sequence. Thus the environmental factor restricting Chaetetes distribution remains undetected. * Autoecological study of Chaetetes shows that it required a solid substrate and that it was capable of regeneration after being partially choked by fine -grained sediments. * It is suggested that Ch. favosus and Ch. milleporaceus may be environmentally differentiated forms of the same Mendelian species. 30234 <SOURCE>Journal of Paleontology 59, 4: 979-985.</SOURCE>
30235 <ABSTRACT>Colonial rugose corals are rare and generally poorly diversified in the Upper Pennsylvanian of the western interior region, conterminous USA. Paraheritschioides n.gen., which includes P. grandis

- n.sp. and *P. complexa* n.sp. from the Oquirrh Formation in Idaho, provides a new tool for distinguishing Upper Pennsylvanian rocks in the western interior. The new genus is also represented by *P. stevensi* (Wilson) in the Permian McCloud Limestone of northern California. The new family Heritschioididae is created to include *Paraheritschioides*, *Heritschioides*, *Amandophyllum* and *Heintzella*. </ABSTRACT>

30299 <SOURCE>Palaeoworld 19, 3-4: 401-409.</SOURCE>
30300 <ABSTRACT>Schoenophyllum has been described as a columellate, fasciculate genus in which the corallites bear slender lateral processes regarded as supporting structures or as tubules connecting adjacent corallites. Recent investigation of Serpukhovian specimens from the Etherington Formation and its lateral equivalents in western Canada has shown these lateral processes to be sub-horizontal to moderately elevated tubule-like structures forming the initial stages of new offsets and commonly containing tabulae. They locally reach and may interfere with the walls of neighbouring corallites, but remain structurally distinct from them and do not allow communication between parent and adjacent corallites. The initial, tubule-like stage is followed by a steeply elevated to vertical, sparsely septate stage in which the axial structure is developed as a prolongation of the cardinal septum. The origin and nature of the axial structure suggests assignment of Schoenophyllum to the family Petalaxidae.</ABSTRACT>

30338 <SOURCE>Canadian Journal of Earth Sciences 21, 4: 500-501.</SOURCE>
30339 <ABSTRACT>Microfossils associated with Carboniferous Macgowanella and Sinopora? pascuali allow more precise age determinations than previously determined. Macgowanella, a possible bryozoan holdfast, is represented by two species, M. tenuiradiata (Warren) and M. stellata (Warren), both from the Viséan (Upper Mississippian, Meramecian) Mount Head Formation of the southern Canadian Rocky Mountains. Microfossils indicate a correlation with upper Viséan Zone 14, equivalent to the lower upper Meramecian Marston/lower Opal members of the Mount Head Formation. The syringoporid coral Sinopora? pascuali is from near Kamloops, British Columbia. Microfossils support the Early Pennsylvanian date earlier assigned, correlating it with Zones 20 or 21, Bashkirian = Morrowan to basal Atokan.</ABSTRACT>

- 30376 <TITLE>Exceptional preservation of the sponge *Fissispongia cloaca* from the Pennsylvanian Holder Formation, New Mexico. </TITLE>
- 30377 <SOURCE>Palaios 11: 559-570. <http://www.jstor.org/pss/3515191> </SOURCE>
- 30378 <ABSTRACT>Exceptionally preserved aragonitic demosponge material occurs within the Virgilian Holder Formation, Sacramento Mountains, south-central New Mexico. *Fissispongia tortacloaca* (King) is identified, a species previously known only from completely calcified specimens. Standard optical microscopy and SEM examination of broken surfaces of the *F. tortacloaca* skeleton distinguishes between primary spherulites and a later epitaxial overgrowth. *F. tortacloaca* biomineralization is readily comparable to that of the modern agelasid demosponge *Astrosclera willeyana*, thus confirming the demosponge affinity of this form. Cathodoluminescence microscopy and back scatter SEM examination identifies selective silicification and calcitization of the spherulite centers. These diagenetic minerals affect the initial spherulite biomineralization mimicking the original microstructural fabric. Elemental composition of *F. tortacloaca* (Sr=7600ppm, S=1640ppm and Mg=150ppm) is close to that of modern *A. willeyana* (Sr=10,000ppm, S=1780ppm and Mg=320ppm). Sr concentration in *F. tortacloaca* indicates that late Pennsylvanian seawater had slightly less Sr (7ppm) than modern seawater. S is interpreted as having been incorporated into sponge aragonite as SO₄. The stable isotope composition of *F. tortacloaca* ($\delta^{13}\text{C}=+5.5\%$; $\delta^{18}\text{O}=-2.1\%$) is compatible with other Virgilian skeletal carbonates from the USA, but is about 1% heavier than *A. willeyana* ($\delta^{13}\text{C}=+4.4\%$; $\delta^{18}\text{O}=-0.8\%$). The $\delta^{18}\text{O}$ composition of *F. tortacloaca* indicates tropical to subtropical temperatures between 24-30°C using Grossman and Ku's expression $T^{\circ}\text{C}=20.6-4.34(\delta^{18}\text{O}-\sigma)$: assuming the Pennsylvanian ocean had a $\delta^{18}\text{O}$ composition similar to modern seawater with an 1.2% variation due to glacial ice volume effects. 30402 <TITLE>Oldest and lowest latitudinal occurrence of Paleoaplysina, Middle Pennsylvanian, Ely Limestone, Burbank Hills, Utah.</TITLE>
30403 <SOURCE>Palaios 12, 4: 397-401. <http://www.jstor.org/pss/3515339></SOURCE>
30404 <ABSTRACT>A primitive variety of Palaeoaplysina laminaeformis Krotov is the primary biotic constituent of a two-meter-thick biostrome in the upper Ely Limestone of western Utah. Associated fusulinaceans and stromatoporoids indicate an early Desmoinesian (Middle Pennsylvanian) age, making it the oldest documented occurrence of non-ancestral Palaeoaplysina in the world. Plate-supported packstone with 40-60% interstitial peloidal mud and silt-size fossil debris constitutes the dominant biostrome rock fabric. During the Late Carboniferous, non-ancestral palaeoaplysiniids were restricted to the Ely and Sublett basins of Utah and Idaho, respectively. By Early Permian time, however, they played a significant role in the construction of reefs and biostromes across the entire northern margin of Laurussia.</ABSTRACT>

30416 <SOURCE>Facies 35, 1: 29-58.</SOURCE>
30417 <ABSTRACT>The factors controlling the localization and growth of Lower Mississippian waulsortian mounds have been difficult to establish because of limited exposure of individual mounds and mound-bearing platforms in western Europe, where the Waulsortian facies have been studied most intensively. Mounds on the Lower Mississippian homoclinal ramp of the Lake Valley Formation in the Sacramento Mountains, however, are exposed exceptionally well at platform, outcrop, and mound scales in an area roughly 5 by 20km, and provide the opportunity to better understand these aspects of Waulsortian mounds. n.gen., n.sp., from the lower Horsefeed Formation (Cache Creek Group,
Atlin Terrane), is the first representative of the Tethyan family
Pseudopavonidae described from North America. It is associated with
Siphonodendron sp. and lower Namurian microfossils of mixed North
American and Tethyan affinities. Boreal corals from the lower Asitka
Group (Stikine Assemblage) include Protolonsdaleiastraea? sp., and
Lytvophyllum? sp., which are associated with middle Asselian to lower
Artinskian fusulinaceans and are closely related to Lower Permian
corals from the Ural Mountains, Spitzbergen, and Arctic Canada.

- 30482 <ABSTRACT>The present volume contains descriptions of the major part of
the nondissepimentate taxa of the order Stauriida Verrill 1865 from the
Upper Carboniferous and Lowermost Permian Gaptank Formation and from

Wolfcampian (Lower Permian). The further subdivision of the Stauriida is not certain. From the 4 families distinguished only one is assigned to the suborder Stereolasmatina Hill 1981. The systematic position of the families Lindstroemiidae Pocta 1902, Lophophyllidiidae Moore and Jeffords 1945 and Lophotichiidae Weyer 1972 is uncertain. Thirteen genera of which: Ass mulia and Falsiamplexus are new and 9 subgenera, of which Abeophyllum, Ailigia, Ericina and Vacoa are new, were identified. Among the total number of 61 species described, 33 are new and 10 were left in the open nomenclature. The systematic descriptions were accompanied by introductory considerations on the evolution and paleogeography of the Permian Rugosa. The table of occurrence of all species described, as well as morphologically-comparative tables of more diversified taxa were also included. </ABSTRACT>

30532 <TITLE>Permian corals from the Spring Mountains, Nevada.</TITLE>

30533 <SOURCE>Journal of Paleontology 65, 5: 727-741.</SOURCE>

30534 <ABSTRACT>Rugose and tabulate corals from the Lower Permian (Wolfcampian, Leonardian) Bird Spring Group in the Lee Canyon section of the Spring Mountains, Clark County, Nevada, are referred to eight genera and ten species. New taxa are Fomichevella nevadensis n.sp., F. waltersi n.sp., Mccloudius parvus n.sp., and Paraheritschioides richi n.sp. The fauna is most similar to the shelf fauna in eastern Nevada, but there are significant similarities to corals from the Antler Highland embayments of central Nevada and southern Idaho and to faunas of the same age in northern California and northern British Columbia. The paleogeography is interpreted as shallow water near the east side of the mouth of a south-opening coastal sea, bordered on the east by the continent and on the west by the Antler Highland. Corals migrated south along the western shores of the Antler Highland and mixed with the shelf fauna, perhaps with some corals crossing from Tethys to the coast. The modern eastern Pacific tropical coral faunas, which have several hermatypic coral genera and species derived from the western Pacific in the Pleistocene, may occupy a somewhat similar geography near the mouth of the modern Gulf of California.</ABSTRACT>

30559 <SOURCE>Geology 22: 1095-1098.</SOURCE>

30560 <ABSTRACT>Trend-surface analysis of biogeographic data and probabilistic estimates of diversity and similarity provide a new

approach to understanding the origin of North American suspect terranes. Results from Permian corals indicate that (1) the eastern boundary of the Tethyan coral province was about 2000 km west of the North American craton; (2) Eastern Klamath and Stikinia were close to one another and were up to 6700 km west of North America during the Early Permian; (3) Wrangellia was situated to the southeast of Stikinia, as much as 5000 km west of the craton; (4) the Late Permian location of the Eastern Klamath terrane was 3000-5800 km west of the craton and between 11° and 21° N; and (5) the Eastern Klamath terrane moved westward during the Permian, possibly as a result of back-arc spreading.

30571 <TITLE>Early Permian corals from the Providence Mountains, San Bernardino County, California.</TITLE>
30572 <SOURCE>Journal of Paleontology 68, 5: 938-951.</SOURCE>
30573 <ABSTRACT>Rugose and tabulate corals from the Lower Permian (Wolfcampian) part of the Bird Spring Group in the Providence Mountains, San Bernardino County, southeastern California, comprise eight species in eight genera. *Heritschioides mckassoni* n.sp. is the lowest stratigraphic record for this index genus on the undoubted shelf of western North America. *Paraheritschioides applegatei* n.sp. is the first record for the genus in southern California. *Neomultithecopora providensis* n.sp. is a second species for the genus in the southern Great Basin. The other five species provide close ties to previously described faunas from the Spring Mountains and the Arrow Canyon Range of southwestern and southeastern Nevada. The combined Wolfcampian coral faunas of these three areas are somewhat closer at the genus and species level to the McCloud Limestone Wolfcampian faunas of northern California than to the Wolfcampian shelf faunas in east-central Nevada. Additional species present in the combined faunas are known, originally from the Wolfcampian of central Nevada and Kansas and a genus is not otherwise known south of British Columbia. The faunas suggest a sub-province of the Durhaminid Coral Province for the southern California and southern Nevada area and perhaps imply partial isolation from the more northerly parts of the province by land barriers such as the Antler Highlands.</ABSTRACT>

30611 <SOURCE>Univ. of Illinois, Dept Geology: vi + 105 pp., 5 figs, 11 tables, 6 pls; unpublished MSc Thesis</SOURCE>
30612 <ABSTRACT>Late Wolfcampian corals in the Las Vegas and Arrow Canyon Ranges include *Lithostrotion dilitata* Easton, L. cf. *L. dilitata* Easton, *Diphyphyllum connorsensis* Easton, *Heterocaninia* sp., *Pseudozaphrentoides* n.sp., *Roemeripora* n.sp., and *Syringopora multattenuata* McChesney. *Roemeripora wimani* Heritsch, *Syringopora multattenuata* McChesney and *Multithecopora hypatia* Wilson occur in the Virgilian. The rugose corals and *Roemeripora* spp. primarily occur in rocks of Nowak and Carrozi's (1973) microfacies 7, which indicates a lagoonal environment. *Syringopora* also occur in the lagoonal environment, but are more abundant in microfacies 2 and 3, which represent the seaward face and crest of the bar confining the lagoon. * The following fusulinids provide biostratigraphic control of the coral occurrences: * Wolfcampian - *Triticites creekensis* Thompson and *Schwagerina* (?) *multispira* Thompson and Hazzard; * Virgilian - *Pseudofusulinella utahensis* Thompson and Bissell, *Oketaella* n.sp., *Triticites birdspringensis* Cassity and Langenheim. The more fusiform *P. utahensis* and *Triticites* spp. characterize the seaward slope and crest of the bar in contrast to the more globose *O.* n.sp. and *S.* (?) *multispira* in the lagoon.</ABSTRACT>

30624 <SOURCE>Journal of Paleontology 81, 6: 1241-1256.</SOURCE>
30625 <ABSTRACT>A small faunule of silicified hexactinellid sponges and root tufts has been recovered from the upper Guadalupian Reef Trail Member of the Bell Canyon Formation, from the Patterson Hills, in the southwestern part of the Guadalupe Mountains National Park in western Texas. Some demosponges from the type section of the Reef Trail Member,

near the mouth of Mckittrick Canyon on the front of the Guadalupe Mountains in the park, have also been documented. Included in the faunule from the Patterson Hills localities are the new amphidiscosid hexactinellid pelicasponge *Trailospongia reischii* n.gen. and sp., the questionable pelicaspongiid *Hexirregularia nana* n.gen. and sp., and the dictyospongiid hexactinellids *Microstaura doliolum* Finks, 1960, and *Microstaurella minima* n.gen. and sp., and *Microstaurella parva* n.gen. and sp. They are associated with specimens of the lyssacinosid brachiosponges *Toomeyospongiella gigantia* Rigby and Bell, 2005, *Toomeyospongia modica* n.sp., and *Toomeyospongia* [sic! should be *Toomeyospongiella*] *minuta* n.gen. and sp., and fragments of three different types of root tufts, termed Tufts 1, 3, and 4. Two specimens of the new cylindrical demosponge *Mckittrickella pratti* n.gen. and sp. are associated with Tuft 2 in the collection from the type section of the Reef Trail Member, and a third specimen was collected from the member in the Patterson Hills. These sponges from Localities 1-7 are the youngest Permian sponges known from the region, and possibly from North America.

30636 <TITLE>A new occurrence of the [hydrozoan](#); *Radiotrabeculopora reticulata* Fan, Rigby and Zhang, 1991, in the Permian of California.</TITLE>

30637 <SOURCE>Journal of Paleontology 78, 2: 410-413.</SOURCE>

30638 <ABSTRACT>Examples of the [hydrozoan](#); *Radiotrabeculopora reticulata* Fan, Rigby, and Zhang, 1991 have been recently recovered from Lower Permian rocks in the Inyo Mountains, Owens Valley area, of east-central California by G. Linder and C. Stevens. That genus and species were originally described from the Middle Permian (Leonardian-Lower Guadalupian) Maokou Formation from western Hubei, China, by Fan et al. (1991). This is the first report of the genus and species from North America. * The fossils were collected from Unit 7 of the Owens Valley Group, US Geological Survey Map I-1932 (Stone et al., 1989). This unit represents a carbonate buildup composed of wackestones, packstones, and grainstones that formed on an uplift composed of an Upper Carboniferous-lowermost Permian deepwater limestone sequence. Basinward, this unit lenses into rocks that accumulated in deeper water. Fossils from Unit 7, in order of abundance, include pelmatozoan parts, epimastoporid and phylloid algae, and fusulinids. Tubiphytes Maslov, 1956, bryozoans, and the [hydrozoans](#); are much less common, and brachiopods and corals are rare. Algae are abundant throughout the section, becoming dominant in the upper part, where they are associated with the [hydrozoans](#); . [initial part of a short note]</ABSTRACT>

- 30664 <ABSTRACT>A rugose coral faunule consisting of one solitary and three massive species occurs in an Upper Wolfcampian Series stratum of the McCloud Limestone at Tombstone Mountain, Shasta County, California. It is the youngest coral fauna in the formation and has species in common with the older parts of the formation and with Lower Permian formations of Oregon and Spitsbergen. *Wexolina tombstonensis* n.gen., n.sp. is a very large solitary coral. *Kleopatrina* (K.) *svalbardense* Fedorowski was described from the Lower Permian (Sakmarian) Treskelodden Formation of Spitsbergen. *Langenheimia klamathensis* Wilson ranges lower in the formation elsewhere. *Petalaxis occidentalis* (Merriam) was described from the Lower Permian Coyote Butte Formation of Oregon. Coarsely clastic sediments, algae, and corals indicate a high-energy, shallow-water, warm, marine paleoenvironment. (Original summary)

- 30677 <ABSTRACT>Twenty-two species of Early Permian colonial rugose corals belonging to 12 genera, and 10 locations in the Stikine River area in northwestern British Columbia, Canada, are described. These include three new species of *Fomichevella* (*F. magna*, *F. southeri*, *F. bamberi*), two species of *Heintzella*; five species of *Heritschioides*, of which three are new (*H. bagleyae*, *H. garvinae*, *H. hoganae*), two new species of *Petalaxis* (*P. guaspariniaae*, *P. neriae*), and two new species of *Lytvophyllum* (*L.? mongeri*, *L. wersoni*). In addition, five new species assigned to five new genera are here named: *Eastonastraea complexa*, *Federowskiella simplex*, *Pararachnastraea lewisi*; *Stikineastraea thomasi*, and *wilsonastraea rigbyi*. * These corals occur in rocks forming part of the Stikine terrane, the largest tectonostratigraphic unit in western Canada. This coral fauna shows a very close affinity with that of the Lower Permian McCloud Limestone of eastern Klamath Mountains of northern California, and there is some similarity to the Coyote Butte fauna of Oregon. Several species compare most closely with species from Spitsbergen, but there are few similarities with any

- 30678 cratonal North American faunas and none with Tethyan faunas. </ABSTRACT>

30703 <ABSTRACT>Two species, belonging to different genera, but collected from the same two localities USNM 740D and 725F in the Guadalupian Bell Canyon Formation of SW Texas, USA, exhibit a striking similarity, almost identity in their measurements and in some morphological features. Also, intermediate generic morphological characteristics have been recognized in some coralla. In addition, there is a group of specimens that achieved their new generic character (the columella) not by inheriting it from the earlier columellate species, but by some morphological changes in the half-aulate species, co-existing with the columellate species. Such a derivation indicates that the columella is only analogous, not homologous, in both descendent groups of specimens. The data presented emphasize the need for careful taxonomical studies.</ABSTRACT>

30714 <TITLE>Diffingiina, a new suborder of the rugose corals from SW Texas.</TITLE>
30715 <SOURCE>Acta Palaeontologica Polonica 30, 3-4: 209-240. [imprint 1985]</SOURCE>
30716 <ABSTRACT>Diffingiina subordo n., tentatively included in Stauriida Verril, 1865, is characterized by the adaxial split of the inner end of at least one (the cardinal) septum; the development of the basal plate

and the vertical position of the young corallite at the beginning of its growth; the absence of the septal furrows; the shortening of the counter septum at least during some part of the neanic growth; the trabecular microstructure of septa; and the biform tabularium. The attachment scars have once been illustrated for the Rugosa, but they were recognized only in this paper. All taxa included in the suborder are new, because their basic characteristics have not been reported so far as present in the Rugosa. Two new families have been established: the monotypic family Plerodiffiidae fam. n., containing only a single species *Plerodiffia eaglebuttensis* sp. n., and the family Diffingiidae fam. n. subdivided into two subfamilies. In the monotypic subfamily Diffingiinae subfam. n. seven new species have been recognized. The presence of two opposite trends in the morphological development suggests the possibility of further increase in the number of genera within the subfamily. The subfamily Turgidiffiinae subfam. n. contains two genera: *Turgidiffia* gen. n. with three new species and the new genus and species left in the open nomenclature. </ABSTRACT>

30728 <SOURCE>Journal of Paleontology 83, 6: 946-953.</SOURCE>
30729 <ABSTRACT>Permian colonial corals from Artinskian to Kungurian strata in the Conglomerate Mesa area, Inyo Mountains, east-central California, include five new species, one of which is assigned to a new genus. The new taxa are: *Malpaisia maceyi* n.gen. and n.sp., *Pararachnastraea bellula* n.sp., *P. delicata* n.sp., *P. owensensis* n.sp., and *Cordillerastraea inyoensis* n.sp. These species, several of which compare most closely with other Artinskian and Kungurian species from eastern Nevada and northern Mexico, represent three distinct stocks that differentiated on an isolated submarine uplift offshore from the main part of the Cordilleran carbonate shelf. 30740 <TITLE>A new Permian waagenophyllid coral from the Klamath Mountains, California.</TITLE>
30741 <SOURCE>Journal of Paleontology 61, 4: 690-699.</SOURCE>
30742 <ABSTRACT>Specimens of a new species of the Permian waagenophyllid coral genus *waagenophyllum*, w. *klamathensis*, have been recovered from limestone lenses near the top of the Upper Permian Dekkas Formation in the eastern Klamath Mountains, and similar specimens have been collected from an isolated limestone mass in the eastern Hayfork terrane of the southwestern Klamath Mountains, northern California. Another specimen of *waagenophyllum*, which may represent another species, has been recovered from another limestone mass in the Hayfork terrane. These specimens of *waagenophyllum*, a genus which otherwise is

restricted to the Tethyan Province, provide the only tie between the Permian limestone masses of the eastern Hayfork terrane, which also contain typical Tethyan foraminifers, and the eastern Klamath Mountains terrane (McCloud belt), which contains many fossils with non-Tethyan affinities.</ABSTRACT>

30753 <TITLE>Wolfcampian Rugose and Tabulate corals (Coelenterata: Anthozoa) from the Lower Permian McCloud Limestone of Northern California.</TITLE>

30754 <SOURCE>Contrib. Sci. 337: 1-90 (Los Angeles)</SOURCE>

30755 <ABSTRACT>Six sections measured across the McCloud Limestone, Shasta County, northern California, are Lower Permian (Wolfcampian Series), represent a composite thickness of at least 5.500 feet (about 1.700 m), and contain rich invertebrate faunas including at least 49 species of rugose and tabulate corals. 42 species in 17 genera of rugose corals are described, including four new species. The general generic composition is characteristic of the Durhamid Coral Province known from rocks in the Ural Mountains, Novaya Zemlya, Spitzbergen, Arctic North America, and western North America as far south as southern California. Some genera appear to be endemic to western North America. The corals did not form reefs but were randomly spaced on calcareous bioclastic substrates in shallow waters of the Cordilleran eugeosyncline near the Permian paleoequator in an area temporarily lacking much volcanic sedimentation. [original summary] The tabulate corals described here are: Bayhaium merriamorum, B. virginiae n.sp., Enigmalites roberti n.sp., Michelinia nelsoni n.sp., Neomultithecopora sandoi n.sp., Syringopora mcutcheonae, S. multattenuata. Among the Rugosa mostly new species are described; solitary corals (Aulophyllum, Clisiophyllum, Gshelia, Heterocaninia); fasciculate corals (Durhamina, Heritschioides, Mccloudius n.gen., Siphonodendron, Yatsengia); cerioid corals (Bassius n.gen., Dillerium n.gen., Kleopatrina, Kl. (Porfiriella), Langenheimia n.gen., Petalaxis, Traskina n.gen.); cerioid-astreoid corals (Arachnastraea).</ABSTRACT>

30766 <TITLE>Gigantospongia, new genus, the largest known Permian sponge, Capitan Limestone, Guadalupe Mountains, New Mexico.</TITLE>

30767 <SOURCE>Journal of Paleontology 70, 3: 347-355.www.jstor.org/pss/1306431</SOURCE>

30768 <ABSTRACT>Several specimens of the large, discoidal, new inozoid genus and species, Gigantospongia discoforma, have been discovered in the Upper Permian, Upper Capitan Limestone in the northern Guadalupe Mountains of New Mexico, near Carlsbad Caverns. The holotype is nearly 2.5m across, as exposed, and ranges from 8-20mm thick, with numerous canals transverse and parallel to the principal plane. These canals are approximately 1mm in diameter and separated by tracts 1-2mm thick. Thickened dermal and gastral layers, each approximately 1mm thick,

occur at tops and bases of both the holotype and associated paratypes in the **"**Sponge window**"**; exposures of Bat Cave Draw, and in specimens from Chinaberry and Hackberry Draws. Inverted *Lemonea conica* Senowbari-Daryan, 1990, is apparently attached to the base, and appears to have grown inverted in a void formed or capped by the tabular inozoid. Well-preserved specimens of *Amblysiphonella* also appear inverted, as do examples of *Lemonea cylindrica* (Girty, 1908), a new species of *Lemonea*, and *Guadalupia explanata* (King, 1943), which occur between the holotype and an underlying paratype. All appear coated with *Archaeolithoporella* crusts. Microstructure of the inozoan skeleton is obscured by diagenesis. [original abstract] </ABSTRACT>

- 30806 <SOURCE>Palaeontology 39, 3: 733-762.</SOURCE>
- 30807 <ABSTRACT>The Permian Capitan reef was a predominantly heterotrophic ecosystem strongly differentiated into open surface and cryptic communities. Unlike modern phototrophic corallgal reefs, most of the preservable epibenthos was housed within the cryptos and zonation developed only in the shallow parts of the reef. Contrary to established opinion, most sphinctozoan sponges did not grow upright to form a baffling framework but rather were pendent cryptobionts, as were nodular bryozoans and rare solitary rugose corals and crinoids. Indeed, many members of the cryptos were obligate cryptobionts. Much of the Middle Capitan reef framework was constructed by a scaffolding of large frondose bryozoans, with the subsidiary platy sphinctozoan *Guadalupea zitteliana*. Bathymetrically shallow areas of both the Middle and Upper Capitan reef, however, were characterized by platy sponges. In parts of the Upper Capitan, some platy sponges (*Gigantospongia discoforma*) reached up to 2 m in diameter and formed the ceilings of huge cavities which supported an extensive cryptos. In the absence of destructive forces (both biotic and physical) prevalent on modern reefs, the relatively fragile Capitan reef remained intact after the death of the constructing organisms. Rigidity was imparted to this community by a postmortem encrustation of *Tubiphytes* and *Archaeolithoporella*, together with microbial micrite. The resultant cavernous framework was partially infilled with sediment and preserved by symsedimentary intergrowth of aragonitic botryoids and *Archaeolithoporella*. Extensive cement precipitation was favoured by a number of factors including deep anoxia, which generated upwelling waters with elevated alkalinity. Although the accumulation rate of the Capitan may have been comparable to that of modern corallgal reefs, both the trophic structure and relative contributions of inorganic and organic carbonate were profoundly different.</ABSTRACT>

- 30820 <ABSTRACT>The outer-shelf of the Tansill Formation (Late Guadalupian; Kazanian) in the northern Guadalupe Mountains (Permian Reef Complex, New Mexico, USA), located between the peritidal pisolitic shelf crest and the submerged shelf margin, is characterized by a patch reef facies in the seaward part and a peritidal island facies in its landward part. These isolated buildups represent the youngest Permian bioconstructions of SW-North America which formed before the onset of the salinity crisis in the Delaware Basin during latest Permian (Ochoan evaporites). Three types of patch reefs were observed: 1) wave resistant calcisponge / algal / cement reefs of a modified Capitan reef facies located next to the shelf margin, 2) partially wave resistant reef mounds scattered across the seaward part of the outer-shelf, and 3) non-wave resistant skeletal mounds restricted to the landward part of the outer-shelf. After the demise of the underlying shelf margin reef rim ("Capitan Reef") which was caused by a regional relative sealevel drop, increasing salinity in the adjacent Delaware Basin prevented a new

formation of a continuous reef rim. Instead, the site of reef building shifted landward onto the shallow outer-shelf, where on-shelf currents and aperiodic precipitation were responsible for effective mixing of water masses and lowering of hyper salinity. Distribution of those patch reefs in space and time documents a progradational pattern reflecting the general shallowing-upward trend and continuous salinity increase during latest Guadalupian.</ABSTRACT>

30831 <TITLE>Comparative Analysis of Late Permian Reefal Limestones From the Capitan Reef (New Mexico, USA) and the Oman Mountains.</TITLE>

30832 <SOURCE>Goettinger Arbeiten zur Geologie und Palaeontologie, Special Volume 2 [Reitner J., Neuwiller F. & Gunkel F. (eds): Global and Regional Controls on Biogenic Sedimentation I. Reef Evolution]: pp ???</SOURCE>

30833 <ABSTRACT>Late Permian reefal limestones from the Capitan Reef (New Mexico, USA) and the Oman Mountains were investigated with respect to microfacies and quantitative composition. The communities correspond to sponge reefs, algal cement reefs, phylloid algal reefs, and probably rugose coral reefs. The carbonate budget (the percentage of macro-reefbuilders, micro-framework, internal sediment, and marine-phreatic cements on the base of field-derived acetate sheets) is characteristic for the different case studies. The quantitative data from the Capitan reef point to dominance of low-growing organisms and marine phreatic cements. The communities from the Oman Mountains are rich in sediment. Taphonomic processes including breakdown of reefbuilders by waves or bioerosion were less important than constructional processes.</ABSTRACT>

30844 <TITLE>Evolution of the Upper Capitan-Massive (Permian), Guadalupe Mountains, New Mexico.</TITLE>

30845 <SOURCE>Brigham Young University, Geology Studies 43: 167-187.</SOURCE>

30846 <ABSTRACT>A photo-transect of the seaward reef tract and six subvertically arranged reef maps covering about 13 m² of outcrop surface provide digitized images and quantitative data for the interpretation of the evolution of the upper Capitan-massive near Whites City, New Mexico. The seaward reef front consists of a sequence from a phylloid algal sub-community to varied sponge-algal/cement reef sub-communities to a Tubiphytes-dominated reef. Progradational geometries suggested by seaward-shifting of facies boundaries are especially apparent in the Gigantospongia zone due to basinward extension of sheet-like inozoans sheltering elongate cavities. The unit above is characterized by a gradual disintegration of the framework as evidenced by an increase in platform sediment and decrease in framework. In the youngest Tubiphytes-dominated reef stage, only small incrusting reefbuilders constructed the framework, while

macro-reefbuilders decreased significantly. Sponge-algal/cement reef sub-communities are the dominant element of the reef front. A quantitative analysis of digitized maps from this sub-community indicates that macro-reefbuilders, chiefly calcareous sponges (1-7%) and phylloid algae (0-3%) formed only a minor part of the framework. Post-mortem biostratonomic processes caused local skeletal breakage and fragment alignment. The most important reef element with an areal cover of 57-96% is the micro-framework, a consortium of low-growing organisms (e.g., Tubiphytes or Archaeolithoporella) and syndimentary, marine-phreatic cements. Open reef cavities were either filled with early diagenetic cements (0-22%) or internal sediment (0-38%) of different origins including reef-derived wacke/packstones, platform-derived grainstones, and/or brownish quartz-rich sediments. The grainstones locally yield the fusulinid *Codonofusiella paradoxa* indicative of an Upper Yates or Lower Tansill age. </ABSTRACT>

30857 <TITLE>Strengths and Weaknesses of the Reef Guild Concept and Quantitative Data: Application to the Upper Capitan-Massive Community (Permian), Guadalupe Mountains, New Mexico-Texas.</TITLE>

30858 <SOURCE>Facies 40, 1: 131-156.</SOURCE>

30859 <ABSTRACT>Analyses of large acetate sheet tracings, close-up photos and 105 sub-horizontal quadrat surfaces at four localities near the base of the Guadalupe Mountains Escarpment indicate that the biotic framework of the upper Capitan reef was built by about 35 species: one codiacean (*Eugonophyllum* sp.), 17 calcisponges, 9 bryozoans, one richthofenid brachiopod, some crinoids (known only from columns), 4 Problematica and microbes. This widespread fossil community included members of the Constructor, Baffler and Binder Guilds. A re-evaluation of the Guild Concept (Fagerstrom 1987, 1991) highlights the validity of the functional roles of the Constructor and Binder Guilds for reef construction. Members of the Baffler Guild, however, need to be revised and an interpretation of microbial micrite and cryptic biota remains controversial. Open surface phylloid algal and cryptic sponge-bryozoan dominated sub-communities were of only local importance. The upper Capitan-massive differs from its Permian counterparts in the low diversity and areal cover of the frame-building biota, low micrite content and abundant micro-frameworks, i.e. intergrown small sponges, Problematica and syndepositional cements (botryoidal and isopachous, fibrous calcite). 30870 <TITLE>Syndepositional deformation of the Permian Capitan reef carbonate platform, Guadalupe Mountains, New Mexico, USA.</TITLE>

30871 <SOURCE>Sedimentary Geology 154, 3-4: 89-126.</SOURCE>

30872 <ABSTRACT>The average rate of fault displacement (0.021 m/ka) and the maximum rates of fault propagation (0.088-0.123 m/ka) were normally

less than the platform accumulation rates (0.053–0.336 m/ka). Thus, the faults were normally blind and rarely broke the platform top so that slumps and fault-scarp degradation breccias are rare. The fault zones were substantially modified by diagenesis during platform development. They are up to 9m wide, taper both up and downward, have irregular margins and complex fills mainly of sedimentary origin. Their margins and fill were subject to extensive modification by karstic(?) / mixing zone dissolution, gravitational collapse and dolomitising fluids. Consequently, tectonic fabrics and kinematic indicators are rare. Preserved tectonic fabrics consistently indicate a normal and reverse dip-slip sense of movement. Previously, these faults were mistaken for neptunian dykes and fissures, so that the Seven Rivers and Yates 1-2 HFS shelf stratigraphy has been miscorrelated across them. It is apparent that the stratal relationships exposed in the Guadalupe Mountains do not simply preserve the original depositional morphology of the Capitan-equivalent shelf. The subsidence history, stratigraphy and development of the platform succession is more complex than previously thought. The study has important implications for many aspects of the Capitan system, including: (i) shelf-reef correlations, (ii) the controls on platform architecture and development, (iii) Capitan reef palaeobathymetry, (iv) diagenesis, and (v) the amplitude of sea-level changes affecting the platforms stratigraphic development.  30898 <ABSTRACT>Bioclastic accumulations composed of crinoids, brachiopods, molluscs, spongiomorphs and scleractinian corals occur within Upper Triassic strata of the lower Baldonne Formation at Pardonnet Hill in northeastern British Columbia, Canada. These small buildups (~100 to 500 m³) have planar bases and broadly convex tops. These mounds are interpreted as small patch reefs composed of packstone, bioclastic floatstone / rudstone and carbonate breccia intercalated with mixed siliciclastic carbonate sediments deposited in a shallow subtidal setting (i.e. above fairweather wave base). Amalgamated hummocky cross-stratified to current ripple-laminated, quartz-dominated sandstone beds and numerous sharp-based, normally graded bioclastic

(commonly encrinitic) packstone / grainstone-quartz-sandstone couplets characterize inter-reef lithologies. Conodont biostratigraphy indicates that the Pardonet Hill patch reefs occur within strata dated as earliest Upper Carnian (lower nodosus zone). The Pardonet Hill patch reefs originated and developed during an interval of regional sea level lowstand. Strata within which these patch reefs occur represent the westernmost migration of the Triassic shoreline in western Canada. Disappearance of coral reefs in the study area may have been affected by rapid marine transgression and failure of reef faunas to recolonize the new shore zone further to the east. The Pardonet Hill locality occurred on the western margin of the North American craton during the Triassic. Prior to their discovery reef-like structures dominated by corals in the western Panthalassa were limited to allochthonous terranes (now part of the Cordillera). The Pardonet Hill patch reefs occur at approximately 30° Triassic paleolatitude. In modern settings, this is at the extreme latitudinal margin of subtropical zooxanthellate reef development. The presence of benthic faunas characteristic of low-paleolatitude settings on the northwestern coast of Pangea has significant implications in paleotectonic and paleoenvironmental reconstructions.</ABSTRACT>

30922 <TITLE>Triassic corals and spongiomorphs from Hells Canyon, Wallowa Terrane, Oregon.</TITLE>

30923 <SOURCE>Journal of Paleontology 63, 6: 800-819.</SOURCE>

30924 <ABSTRACT>Twenty-one species of corals and three species of spongiomorphs occur in a series of richly fossiliferous, molluscan-dominated beds with silicified bioclasts in the Upper Triassic Martin Bridge Limestone of Hells Canyon, Oregon. Two of these, Maeandrostylis grandiseptus and Recticostastraea wallowaensis are new species. Recticostastraea is designated as a new genus. The Fauna is early Norian and occurs in the island arc wallowa terrane, one of many tectonostratigraphic terranes in western North America. Like other examples, it appears to have developed independently of the North American craton and to have links with Wrangellia. The fossil corals and spongiomorphs are para-autochthonous, occurring in a series of tempestite beds. They are interpreted to have inhabited a shallow-water carbonate platform that developed around a tropical island arc following cessation of volcanic activity. The corals and spongiomorphs are associated with abundant gastropods and a diverse epifaunal

suspension-feeding bivalve fauna. Relative to the corals, branching spongiomorphs, *Spongiomorpha ramosa*, are more abundant and occur with relatively common branching, sheet to plate-like, colonial corals. Solitary corals are relatively rare. The associated bedded limestone includes a variety of shallow-water microfacies but throughout the Hells Canyon sequence, reef structure is absent. Together, the 24 coral and spongiomorph taxa show mixed paleogeographic affinities with Upper Triassic faunas known only from alpine regions of the western Tethys (five species), the Pamir Mountains, USSR (two species), and the island of Timor (one species). Five additional species are pan-Thethyan and exceptionally cosmopolitan, but 11 species (45,8 %) occur only in displaced terranes. Of these, a significant component (six species) is endemic to the wallowa terrane. At least four Hells Canyon taxa, previously thought endemic to North American terranes, have recently been reported from the high-latitude Koryak terrane of northeastern USSR, a displaced tropical volcanic terrane of the northwestern Pacific. For Triassic corals, this is the first example of a clear link between western Pacific and eastern Pacific terranes. Less similarity exists with the Wrangell Mountains, Alaska, where identical age lower Norian silicified corals and spongiomorphs are known. </ABSTRACT>

 30949 <SOURCE>Journal of Paleontology 83, 3: 470-491.</SOURCE>
 30950 <ABSTRACT>Acid processing allowed systematic identification of 458 Upper Triassic silicified scleractinian corals (20 genera, 47 species) from the Alexander terrane (southeast Alaska) and Wrangellia (Wrangell Mountains, southern Alaska and Vancouver Island, Canada). Coral faunas, here presented, show taxonomic affinity with coeval collections from other Cordilleran terranes, specifically the Wallowa terrane (northeastern Oregon and Idaho) and Peru (South America) as well as the distant Tethys region. Genera from the Alexander terrane include: *Kompsasteria Roniewicz*, *Gablonzeria Cuif*, *Cuifia Melnikova*, *Paracuifia Melnikova*, *Distichophyllia Cuif*, *Retiophyllia Cuif*, *Kuhnastraea Cuif*, *Margarosmia Volz*, *Distichomeandra Cuif*, *Astraeomorpha Reuss*, *Pamiroseris Melnikova*, *Crassistella Roniewicz*, *Stylophyllum Frech*, and *Meandrostylis Frech*. Genera from Wrangellia include: *Gablonzeria Cuif*,

30961 <TITLE>Triassic sponges (Sphinctozoa) from Hells Canyon, Oregon.</TITLE>
30962 <SOURCE>Journal of Paleontology 62, 3: 419-423.</SOURCE>
30963 <ABSTRACT>Two Upper Triassic sphinctozoan sponges of the family Sebergasiidae were recovered from silicified residues collected in Hells Canyon, Oregon. These sponges are Amblysiphonella cf A. steinmanni (Haas), known from the Tethys region and Colospongia whaleni n.sp., an endemic species. The latter sponge was placed in the superfamily Porata by Seilacher (1962). The presence of well-preserved cribrate plates in this sponge, in addition to pores of the chamber walls, is a unique condition never before reported in any porate sphinctozoans. Aporate counterparts known primarily from the Triassic Alps have similar cribrate plates but lack the pores in the chamber walls. The sponges from Hells Canyon are associated with abundant bivalves and corals of marked Tethyan affinities and come from a displaced terrane known as the Wallowa Terrane. It was a tropical island arc suspected to have paleogeographic relationships with Wrangellia, however these sponges have not yet been found in any other Cordilleran terrane.</ABSTRACT>

30987 <TITLE>Middle Triassic Cnidarians from the New Pass Range, Central

- Nevada.</TITLE>
30988 <SOURCE>Journal of Paleontology 72, 2: 246-256.</SOURCE>
30989 <ABSTRACT>We described three scleractinian corals and one species of hydrozoan from the New Pass Range, central Nevada, which together constitute the oldest Triassic cnidarian assemblage from North America. They occur in carbonate rocks tentatively correlated with the Augusta Mountain Formation, Star Peak Group. At generic and higher levels, these cnidarians seem representative of early Mesozoic Tethyan faunas and carbonate lithofacies, but they indicate some endemism. Although the original aragonitic skeletons and microstructure are destroyed by recrystallisation, the corals still yield important details allowing their correct taxonomic assignment. They contain the minitrabecular cerioid coral, *Cerienstella variabilis* new genus and species, the thick-trabecular, thamnasteroid coral *Mesomorpha newpassensis* new species, and an undeterminable cuifastroid coral tentatively assigned to *Cuifastraea*. The discovery of *Mesomorpha* marks the first occurrence of this genus outside the Jurassic and Cretaceous seas. Also discovered is a remarkably coral-like hydrozoan, *Cassianastraea reussi* (Laube), already known from the Carnian stage of the western Tethys. This is the first occurrence of this species outside the western Tethys.</ABSTRACT>

31000 <TITLE>The first Upper Triassic silicified hypercalcified sponges from the Alexander Terrane, Gravina Island and Keku Strait, southeast Alaska.</TITLE>
31001 <SOURCE>Journal of Paleontology 82, 2: 344-350.</SOURCE>
31002 <ABSTRACT>This paper describes the first silicified Upper Triassic (Early Norian) hypercalcified sponges known from the Alexander terrane, southeast Alaska. Sponges consist of five taxa from the Cornwallis Limestone of Keku Strait, southeast Alaska: *Amblysiphonella* Steinmann, *Parauvanella* Senowbari-Daryan and *Di Stefano*, *Nevadathalamia cylindrica* (Seilacher), *N. minima* n.sp., and *Stellispongia* (S. cf. *subsphaerica* Dieci, Antonacci, and Zardini). The hypercalcified sponges of the Alexander terrane as described in this paper provide paleogeographic linkage with other far-flung terranes of western North America, namely the western Great Basin of Nevada, *Stikinia* of the Yukon, as well as the Antimonio terrane of northwestern Mexico. In addition, *Parauvanella* cf. *ferdowensis* is known from the Upper Triassic Nayband Formation, Iran. Finally *Stellispongia* cf. *subsphaerica* is known from the Upper Carnian Cassian Formation of the Dolomite Alps. Sponges (particularly hypercalcified inozoans, sphinctozoans, chaetetids, and sponge-like organisms) are known worldwide from many Upper Triassic reef and nonreef sites. Although Upper Triassic deposits within the Cordilleran terranes and cratonal North America do not typically contain reeflike buildups, hypercalcifying sponge-like organisms were noted as occurring as part of the intricate paleoecological structure within a biostrome along the western shoreline of Gravina Island, southeast Alaska (southern Alexander terrane). This is in contrast to Keku Strait, southeast Alaska (central Alexander terrane), where hypercalcified sponges were identified from limestone beds within nonreef deposits.</ABSTRACT>

Mountains, Oregon: first reported occurrence in the United States.
</TITLE>
31027 <SOURCE>Palaios 01: 172-177.</SOURCE>
31028 <ABSTRACT>The first known occurrence in the United States of a
Dachstein-type reef sequence is here reported from the wallowa
Mountains of northeastern Oregon. It is a massive reef limestone
overlain by a bedded, bioclastic unit. The debris-producing organisms,
framework-building corals and sponges, as well as the associated
sedimentary features and microfacies, show striking similarities to the
Late Triassic Dachstein Reef Limestone of central Europe. The only
other reef sequence with which they compare is in the Yukon of Canada.

- 31067 <ABSTRACT>Upper Triassic patch reefs in the southern Yukon include tabular reefs, about 30m thick, and semicircular and elongate reefs, over 100m thick. The tabular reefs consist predominantly of framework built by small calcareous sponges, spongiomorphs, and corals; they are designated as framework buildups, analogous, in a genetic sense, to modern coral reefs. On the other hand, framework is a minor component of the semicircular and elongate reefs, which consist predominantly of skeletal sediment. The skeletal sediment of these reefs is interpreted as a local accumulation of small and disarticulated organisms produced independently of reef framework. Consequently, sediment producers, rather than framebuilding fossils, are inferred to have been the primary builders of these structures, designated as sediment buildups genetically analogous to modern algal bioherms. The sediment buildups in the Yukon are similar to upper Rhaetian patch reefs in Austria. However, the origin of the Austrian reefs has been attributed to framebuilding fossils and sediment producers have not been identified as important reef builders.</ABSTRACT>

31093 <ABSTRACT>Massive Upper Triassic (Norian) reef limestone at Eaglenest Mountain, Takla Group, British Columbia, contains a wide variety of shallow-water fossils in two different carbonate units. A sponge-coral facies contains the sponges *Fanthalamia astoma* (Seilacher, 1962), *Fanthalamia multicanalis* new species, *Cinnabaria expansa* (Seilacher, 1962), and *Cinnabaria?* sp. *Cinnabaria expansa* is a widely distributed North American terrane species which, along with *F. astoma*, was previously known from the Luning Formation of Nevada. Also included is the "disjectoporoid"; *Pamiropora sonorensis* Stanley, 1994, and a massive spongiomorph, *Spongiomorpha tenuis* Smith, 1927, previously endemic to the Eastern Klamath terrane of California. Colonial corals include: *Retiophyllia quesneliana* new species, *Chondrocoenia waltheri* (Frech, 1890), *Crassistella* cf. *juvavica* (Frech, 1890), *Distichomeandra* cf. *austriaca* (Frech, 1890), and *Alpinophyllia flexuosa* Roniewicz, 1989. A limestone conglomerate overlying these beds is dominated almost exclusively by the planktonic hydrozoan, *Heterastridium conglobatum* Reuss, 1865. A problematic taxon *Lovcenipora* cf. *chaetetiformis* Vinassa de Regny, 1915, is reported for the first time outside Timor and the Tethys. The faunas provide a first glimpse into the reef biota of the Quesnel terrane. They contain taxa previously known from the distant Tethys but also include endemics from other inboard terranes. 31117 <TITLE>Middle Jurassic Corals from the wallowa Terrane, West-Central Idaho.</TITLE>
31118 <SOURCE>Journal of Paleontology 64, 3: 352-362.</SOURCE>
31119 <ABSTRACT>New colonial corals from near Pittsburg Landing, Idaho, are clearly dated as Middle Jurassic (Bajocian) in age. They consist of *Coenastrea hyatti* (wells) and *Thecomeandra vallieri* n.sp., and occur abundantly with molluscan fossils in thin, biostromal limestone beds in the Coon Hollow Formation. These fossils are the youngest shelly faunas yet known from the wallowa terrane. The similarity of the coral and bivalve fauna to endemic faunas of the Western Interior suggests that during Middle Jurassic time, the wallowa terrane was close enough to the North American craton for faunal exchange with the western Interior Embayment. The Pittsburg Landing corals appear dissimilar from Middle Jurassic corals known from other terranes of the western Cordillera.

31130 <TITLE>A coral reef in the Telkwa range, British Columbia: the earliest Jurassic example.</TITLE>
31131 <SOURCE>Canadian Journal of Earth Sciences 30: 819-831.</SOURCE>
31132 <ABSTRACT>A very early Jurassic (Sinemurian) coral reef is described from Telkwa Range (British Columbia, Canada). The 48 m thick bioherm is dominated by large dendroid/phaceloid corals, mainly Phacelostylophyllum rugosum, also known from the Upper Triassic of Italy. The reef seems to be the first Jurassic reef after the end-Triassic mass extinction which profoundly affected reef ecosystems.</ABSTRACT>

31143 <TITLE>Corals from an Early Jurassic coral reef in British Columbia: refuge on an oceanic island reef.</TITLE>
31144 <SOURCE>Lethaia 27: 35-47.</SOURCE>
31145 <ABSTRACT>An Early Jurassic (Sinemurian) reef in the Telkwa Range, British Columbia, Canada, yields coral species previously known from Morocco, Great Britain, Italy, Peru, and Chile. The principal constructional coral, Phacelostylophyllum rugosum (Laube), known from the Upper Triassic Dolomite Alps in northern Italy, is a holdover species. This coral survived the mass extinctions of the end-Triassic without leaving any other Jurassic records outside Canada. Other corals from the Telkwa reef include Stylophyllopsis victoriae (Duncan) and Actinastraea minima Beauvais known from Jurassic rocks of the Tethys. Closely related corals, Phacelostylophyllum chocolatensis (Wells) and Actinastraea plana (Duncan), are from southern Peru. The paleogeographic occurrence of the Canadian reef in the volcanic terrane of Stikinia supports the contention that volcanic islands in distant outposts of the ancient Pacific served as refugia. In the aftermath of the end-Triassic reef decimation affecting the Tethys, corals and reef building activities continued on ancient islands of the ancestral Pacific. The Hispanic Corridor, connecting the western Tethys with the western Pacific, may have played an important role during Sinemurian time.</ABSTRACT>

- 31156 <TITLE>Lower Albian Sequence Stratigraphy and Coral Buildups: Glen Rose Formation, Texas.</TITLE>
- 31157 <SOURCE>SEPM Special Publications 87 [R.W. Scott (ed.): Cretaceous rudists and carbonate platforms: environmental feedback]: 181-191. ISBN 9781565761278</SOURCE>
- 31158 <ABSTRACT>The Glen Rose Formation of the Comanchean Series represents the second circum-Gulf carbonate shelf that extended from Florida to Mexico. The Glen Rose comprises limestone, dolomite, and thin interbeds of marl and calcareous shale that overlie the Hensel sandstone and underlie the Fredericksburg Group in Texas. The Glen Rose is here formally divided into Lower and Upper, mappable members separated at the top of the regionally persistent Corbula Marker, and a boundary stratotype section is designated. The age of the Glen Rose Formation ranges from latest Aptian to near the end of the Early Albian, from approximately 113.3 Ma to 108.0 Ma, and encompasses four ammonite zones. Three local assemblage zones facilitate correlation of Glen Rose outcrops in Texas. The Salenia texana Credner Assemblage Zone spans a marl, 3 to 4 m thick, with a diverse shelf biota in the upper part of the Lower Member. The Corbula Range Zone is at the top of the Lower Member. The Loriola rosana Cooke Assemblage Zone is in the middle part of the Upper Member. The Glen Rose together with the underlying Hensel Sandstone comprise at least five medium-scale depositional cycles separated by transgressive unconformities. Two types of biotic accumulations are well developed in the Lower Glen Rose Member, coral-rudist assemblages and caprinid-dominated assemblages. Coral-rudist biostromes crop out at the Narrows of the Blanco River and had no bathymetric relief and do not qualify as reefs. Colonial corals are common and are part of a Tethyan fauna; toudasiids and other mollusks comprise a diverse assemblage. Coral diversity is underestimated because of incomplete preservation and sampling. These biostromes are overlain by grainstone capped by a subaerial contact that serves as a sequence boundary between cycles one and two. The younger caprinid bioherms at Pipe Creek have up to 10 m of depositional relief. The bioherm facies grade landward into shoreface grainstone and seaward into shelf wackestone. The caprinid species, Coalcomana ramosa, dominates this low-diversity assemblage and is endemic to the Caribbean Province. The bioherm facies are overlain by dolomitic, stromatolitic facies with dinosaur tracks. The contact with the overlying Salenia Zone is a sequence boundary between cycles two and three. Two more long-term cycles may be identified in the Upper Glen Rose Member. The coral-rudist biostromes and the caprinid bioherms formed paleocommunities on the landward ramp of the interior marine shelf. The coral-rudist biostromes developed below normal wave base but above storm wave base and shoaled above wave base and were subaerially exposed. The caprinid bioherms formed on a ramp and grew into the zone of normal wave action in mainly normal marine salinities.</ABSTRACT>

31182 <TITLE>An unusual upper Cretaceous (Santonian) hexactinellid sponge from the Great Valley sequence, western Sacramento valley, northern California.</TITLE>
31183 <SOURCE>Journal of Paleontology 70, 5: 713-717.
<http://www.jstor.org/pss/1306475></SOURCE>
31184 <ABSTRACT>The new farreid hexactinellid sponge Hormathospongia dictyota new genus and new species, is described from the upper Santonian Dobbins Shale Member of the Forbes Formation of the Upper Cretaceous Great Valley Sequence from the west side of the Sacramento Valley, northwest of Sacramento. The relatively simple skeleton is composed of quadrangularly arranged hexactines with overlapping rays, an arrangement strikingly similar to the skeletal structure of early Paleozoic reticulosid hexactinellid. However, the California Cretaceous sponges clearly show those spicules embedded in siliceous beams that are united to form a solid dictyonal skeletal framework of only a single layer of regular mesh. Such an occurrence and stratigraphic relationships suggests that the dictyonine sponges had their origin from the simply spiculed reticulosid hexactinellids rather than from the more complex dictyosponges.</ABSTRACT>

31222 <SOURCE>Transactions of Gulf Coast Association of Geological Societies 53: 490 -503.</SOURCE>
31223 <ABSTRACT>Biohermal buildups, or "patch reefs", have become an important play type in Maverick County in southwest Texas. Their primary method of discovery is by 3-D seismic analysis. The bioherms produce mainly gas and condensate. The porous biohermal section and associated facies are >70 feet thick and consist from the base upward of (1) burrowed, mud-dominated lime packstone that increases in grain content upward and includes fragmented and whole requienid rudists, (2) mud-rich lime packstone containing abundant whole requienids, stromatoporoids, corals, and a few caprinid rudists, (3) lime boundstone (bafflestone and bindstone) consisting of requienids, stromatoporoids, corals, Chondrodonta, rare caprinids, echinoid and mollusk fragments, and binding stromatoporoids and Lithocodium, and (4) coarse-grained lime grainstone (rudstone) that has the same components as the boundstone. The biohermal section has an average porosity of 9.2% and an average permeability of 2.9md. The bioherms are found in the highstand systems tract of the lower Glen Rose high-frequency sequence (third-order-sequence 7 of Kerans and Loucks, 2003) within the longer term Glen Rose composite highstand sequence. It is anticipated that in this setting, strings of subparallel isolated buildups will be encountered rather than a continuous barrier that would be associated with a late highstand prograding system at the shelf margin. 31247 <TITLE>Octocorals from the Eocene Stone City Formation, Texas.</TITLE>
31248 <SOURCE>FC&P 06, 1: 17.</SOURCE>
31249 <ABSTRACT>The geologic history of the Octocorallia is poorly known. A fossil record extends back to the Cretaceous, and doubtful or problematic octocoral-like fossils have been reported as far back as the Pre-Cambrian. * However, the record is sparse because the organisms are largely of soft tissue which is not preserved, because the spicules

or stem fragments of calcite are easily overlooked unless they are being particularly sought, and because the full range of taxa within the subclass can not be recognized on the basis of the limited material that can be found as fossils. * The octocoral collection from the Stone City Formation, consisting of 35 stem fragments and holdfasts, belong to the order Gorgonacea. They represent the fifth reported occurrence of octocorals in the Tertiary strata of the Gulf Coast, the second reported occurrence in the Texas Tertiary, and the first certain reported fossil occurrence of the family Gorgoniidae. * In addition to studying the octocoral fossils along the Gulf Coast, a stratigraphic distribution chart is being prepared for the octocorals on a global basis. If any Newsletter readers have found octocoral fragments in their collections of other fossil materials, I would be happy to try and provide them with a taxonomic identification in exchange for locality and stratigraphic information. I would also appreciate any information on published or unpublished literature concerning this topic - especially as octocorals may be mentioned as ancillary remarks in a paper with a different major subject. 31260 <TITLE>Paleoecology of a Pliocene coral thicket from North Carolina: an example of temporal change in community structure and function.</TITLE>

31261 <SOURCE>Journal of Paleontology 60, 6: 1159-1176.</SOURCE>

31262 <ABSTRACT>A two meter stratigraphic interval within the Chowan River Formation of North Carolina contains a thicket of branching coral, *Septastrea crassa* (Holmes), associated with a diverse macrofaunal assemblage. The thicket modified a local shelf habitat by providing protection and feeding opportunities for certain vagrant epifaunal species. Faunal adjustments wrought by the thicket and thicket growth represent autogenic succession. Coral growth rates and preservation suggest a time span of about 100-300 years for thicket development. Bottom shoaling, associated with a eustatic regression, caused movement of a depth controlled environmental gradient during thicket growth. As the habitat changed, a plane bottom macrofaunal assemblage replaced the thicket assemblage by reordering abundances of intergradational species and introducing a few new species. Faunal density, diversity, trophic structure and modes of life of component species were altered during replacement. Observed temporal community changes are best explained as gradual faunal adjustments along a shelf stress gradient. Short term allogenic or autogenic events may temporarily perturb gradual changes. Changes associated with the thicket development are interpreted as a brief autogenic perturbation of long term community replacement.

- Antipatharia) from the southern California Bight. </TITLE>
31274 <SOURCE>Zootaxa 852: 1-10.</SOURCE>
31275 <ABSTRACT>A new species of antipatharian coral (Anthozoa: Antipatharia) is described from the southern California Bight. The species, Antipathes dendrochristos new species, forms large, multi-branched, bushy colonies that can reach a height of 2 m or more. The species is characterized by having small branchlets arranged primarily bilaterally and alternately, but in varying degrees of regularity; by small conical spines less than 0.1 mm tall, and by small polyps usually less than 1.4 mm in transverse diameter. The species occurs in colors of white, orange/gold, pinkish-orange, pink, red, and red-brown.</ABSTRACT>

31287 <SOURCE>Pacific Science 54, 1: 10-14.</SOURCE>
31288 <ABSTRACT>A new species, Sycon escanabensis Duplessis & Reiswig, is described from material retrieved by submersible from 3500m depth in the Escanaba Trough, central Gorda Ridge, off northern California. The species differs from all other members of the genus by the combination of conspicuous tripartite body organization and slender, lancet-head diactins that ornament the external surface and the oscular margin. This is the first deep-water (> 1000m) calcareous sponge described from the North Pacific Basin. [original abstract]</ABSTRACT>

31325 <TITLE>Age of the hexactinellid beds of the Roberts Mountains Formation, Snake Mountains, Elko County, Nevada and additions to the sponge fauna.</TITLE>
31326 <SOURCE>Journal of Paleontology 69, 6: 1020-1029. <http://www.jstor.org/pss/1306407></SOURCE>
31327 <ABSTRACT>The graptolite, Bohemograptus bohemicus tenuis (Boucek, 1936), was collected with additional hexactinellid sponges from the Roberts Mountains Formation in the Snake Mountains of Elko County, Nevada, and dates the sponge beds as Ludlovian. To the modest fauna of hexactinellid sponges described by Rigby et al. (1991), can be added the new sponge genera and species Divaricospongia dilata and Fistellaspongia inclinata. The new species, Gabelia intermedia, is intermediate in size between the moderately fine-textured Gabelia pedunculus Rigby and Murphy, 1983, and the large Gabelia giganta Rigby et al. 1991. Additional specimens of Gabelia pedunculus were collected in association with well-preserved specimens of Gabelia fasciculata Rigby et al. 1991, which show additional skeletal and canal details. Associated coarse root tufts and patches of protosponge skeletal mesh were also discovered as part of the new collections and are described here, although not generically nor specifically identifiable. 31351 <TITLE>Biostratigraphic and biogeographic constraints on the Carboniferous to Jurassic Cache Creek Terrane in central British Columbia.</TITLE>
31352 <SOURCE>Canadian Journal of Earth Sciences 38, 4: 551-578.</SOURCE>
31353 <ABSTRACT>Conodonts, radiolarians, foraminiferids, and corals provide constraints on the geology and tectonics of the Nechako region. They also support the notion that the Cache Creek Terrane is allochthonous with respect to the North American craton. The 117 conodont collections, assigned to 20 faunas, range in age from Bashkirian (Late Carboniferous) to Norian (Late Triassic); 70 radiolarian collections

representing 12 zones range from Gzhelian (Late Carboniferous) to Toarcian (Early Jurassic); 335 collections assigned to 11 fusulinacean assemblages (with associated foram-algal associations) range from Bashkirian to Wordian (Middle Permian); and two coral faunas are of Bashkirian and Wordian age. The fossils document a long but sporadic history of sedimentary events within the Cache Creek Complex that included two major carbonate buildups in the Late Carboniferous (Pope limestone) and Middle Permian (Copley limestone), punctuated by intervening Early Permian deepening; basaltic eruptions during the mid Carboniferous and mid Permian; the onset of oceanic chert sedimentation close to the Carboniferous-Permian boundary and its persistence through the Late Triassic (Sowchea succession); latest Permian and Early Triassic mixed clastics and volcanics (Kloch Lake succession); Middle and Late Triassic reworking of carbonates (Whitefish limestone), including cavity fill in older limestones (Necoslie breccia), and fine-grained clastic sedimentation extending into the Early Jurassic (Tezzeron succession). Tethyan, eastern Pacific, and (or) low-latitude biogeographic attributes of the faunas are noted in the Gzhelian (fusulines); Artinskian (conodonts, fusulines), Wordian (fusulines, corals, conodonts), and Ladinian (conodonts, radiolarians). The Cache Creek Terrane lay far to the west of the North American continent during these times. [original abstract] </ABSTRACT>

31455 <TITLE>Upper Triassic invertebrates from the Antimonio Formation, Sonora, Mexico.</TITLE>
31456 <SOURCE>Paleont. Soc. Mem. 36 (Journal of Paleontology 68, 4, supplement): 33 pp.</SOURCE>
31457 <ABSTRACT>A diverse Upper Triassic tropical marine fauna from northwestern Sonora, Mexico, includes 31 taxa of tropical invertebrates including scleractinian corals, spongiomorphs, disjectoporoids, " hydrozoans", thalamid and nonthalamid sponges, spiriferid and terebratulid brachiopods, gastropods, bivalves, coleoids, and anomuran microcoprolites. They occur within the late Karnian to Norian part of the Antimonio Formation (Antimonio terrane), which is juxtaposed against a fragmented portion of the North American craton. Most of the fauna is also known from the Tethys region. Sixteen Sonoran taxa co-occur in the western Tethys and five have never been known outside this region. Four additional taxa (one identified only at genus level) are geographically widespread. Some taxa occur in displaced terranes of North America, especially in west-central Nevada (Luning Formation). A weak link exists with the California Eastern Klamath terrane but stronger ties exist with Peru. Among Sonoran sponges, Nevadathalamia polystoma was previously recognized only from the Luning Formation, western Nevada. Sponges Cinnabaria expansa, Nevadathalamia cylindrica, and a coral, Astraeomorpha sonorensis n.sp., are also known from Nevada. The corals Distichomeandra austriaca, Chondrocoenia waltheri, Pamiroseris rectilamellosa, and Alpinophyllia flexuosa co-occur in central Europe. Two new taxa, a spongiomorph hydrozoan, Stromatoporiidium lamellatum n.sp., and a disjectoporoid, Pamiropora sonorensis n.sp., have distinct affinities with the Tethys. The geographically widespread North American brachiopod, Spondylospira lewesensis, and Pseudorhaetina antimoniensis n.gen. and sp. are among the Sonoran fauna. The Sonoran coleoid (aulacocerid) Dictyoconites (Dictyoconites) cf. D. reticulation occurs in the Tethys realm and Calliconites cf. C drakei is comparable with a species from the Eastern Klamath terrane. Calliconites milleri n.sp. is the first occurrence of the genus outside Sicily. The bivalves Myophorigonia jaworskii, M. salasi, and Palaeocardita peruviana are known from Sonora and Peru. Eight gastropod taxa include Guidonia cf. G. intermedia and G. cf. G. parvula, both previously known from Peru, and Eucycloscala subbisertus from the western Tethys. The gastropods are unlike those already known from other North American terranes.</ABSTRACT>

31468 <TITLE>Norian sponge and coral biostromes in the Antimonio formation, Northwestern Sonora, Mexico.</TITLE>
31469 <SOURCE>Revista mexicana de Ciencias Geologicas 14, 2: 160-166.</SOURCE>
31470 <ABSTRACT>A diverse marine invertebrate fauna has previously been documented from the Norian carbonate interval of the Antimonio terrane. However, little research has been aimed at understanding its paleoecology fine scale stratigraphy, and depositional environments. Preliminary field work by the authors represents the first attempt of the present paper have documented four sedimentary rock types: (1) argillites and mudstones, (2) lime-cemented sandstones, (3) sandy limestones, and (4) massive limestone. Each of these lithofacies contains distinct associated biofacies. The coincidence of lithofacies and biofacies indicates that these biostromes were dominated by physical processes which, to a large extent, controlled their biological development. In addition to the similarity of faunal components of these biostromes of Sonora with the Luning Formation in west-central Nevada, the paleoecological patterns and biotic structure are also remarkable coincident. This observation suggests that the relationship of the Antimonio Formation to units farther north in the United States requires more investigation.</ABSTRACT>

31482 <SOURCE>Revista mexicana de Ciencias Geologicas 14, 2: 202-207.</SOURCE>
31483 <ABSTRACT>New Late Triassic corals have been recovered from sponge, coral, and mollusk biostromes in the middle part of the Antimonio Formation, Sierra del Alamo, northwestern Sonora. Together with taxa already described from that formation, these corals contribute to our knowledge of Late Triassic faunas. Three stylophyllid corals are described: Anthostylis acanthophora (Frech), Anthostylis sp., and Meandrostylis antimoniensis new species and a cuifastraeid, Cuifastraea granulata Melnikova. These corals range from the Norian to Rhaetian stages. One species is endemic and others are known from the Pamir Mountains, Russia, and the Alps of Austria. Cuifastraea granulata is already known from the wallowa terrane of Oregon.</ABSTRACT>

- 31509 <ABSTRACT>The majority of the Mesozoic scleractinian corals reported from Mexico, 117 species or about 80 percent, are from Cretaceous strata. Comparatively little is known of the earlier Mesozoic corals. The Jurassic corals, a total of 17 species, have been described from five localities in Mexico, all in Upper Jurassic rocks. The 10 Triassic coral species described from Mexico are from the Upper Triassic Antimonio Formation of northwestern Sonora. The majority of the Jurassic and Triassic coral species reported from Mexico have been described previously from occurrences in Europe.</ABSTRACT>

31546 <TITLE>Depositional Environment of Coral-Rudist Associations in the Upper Cretaceous Cardenas Formation (Central Mexico).</TITLE>
31547 <SOURCE>Geologica Croatica 56, 2: 187-198.</SOURCE>
31548 <ABSTRACT>In the Cardenas Formation (central Mexico), a 175 m thick sedimentary sequence of Maastrichtian age was analyzed with respect to its palaeontology and sedimentology. A wide variety of lithological and palaeontological features characterize this sequence comprising unfossiliferous and fossil-bearing sand-and siltstones, and diverse rudist and coral -rudist associations in carbonate or mixed carbonate/clastic lithologies. A total of 24 rudist and coral-rudist associations are exposed in the investigated section, which are grouped into 5 limestone units. Radiolitid assemblages, coral -rudist reefs, coral-dominated reefs, and hippuritid-dominated reefs are present. The stacking pattern of these reef intervals indicates a general transgressive trend through the entire section. Smaller-scale facies trends could be distinguished within each limestone unit, comprising deepening-upward sequences, defined by a shoreface -calcareous algae -radiolitid-marl facies transition, and shallowing-upward sequences defined by a hippuritid -actaeonellid -coral/rudist facies transition. This cyclic sedimentation pattern is obscured by an episodic input of clastic sediments derived from the uplifting Sierra Madre Oriental, which in turn triggered either the development or decline of reefs.</ABSTRACT>

31585 <TITLE>Palaeoecology of corals and rudists in mixed volcanoclastic-carbonate small-scale rhythms (Upper Cretaceous, Jamaica).</TITLE>
31586 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 186, 3-4: 237-259.</SOURCE>
31587 <ABSTRACT>The Guinea Corn Formation (central Jamaica, west Indies) is represented by alternating platform carbonates and volcanoclastic sandstones and siltstones and represents the most landward shift of facies in an Upper Campanian ? to Maastrichtian transgressive-regressive cycle. The succession consists of 2-30-m-thick rhythms comprising a lower volcanoclastic siltstone/sandstone division; a middle volcanoclastic siltstone/limestone with abundant corals or the rudist *Antillocaprina trellata*; and an upper division of rudist rudstones and floatstones. The lower division consists of either bioturbated sandy siltstones with lignite and abundant gastropods and infaunal bivalves (lower rhythms in the Guinea Corn Formation), or interbedded volcanoclastic siltstones and normally graded sandstones. The rudist limestones are parallel-bedded and consist of high abundance mono- to paucispecific assemblages. The boundary between the middle and upper parts of rhythms contains a concentration of oncoids with coral nuclei and a mantle of microbial laminates, red algae and serpulids. Four coral assemblages are recognised based on diversity and coral morphology. The *Paracycloseris*-*Dasmosmia* assemblage occurs in the lower division of the rhythms and is interpreted as a soft-substrate assemblage that was adapted to elevated nutrient levels. The *Ovalastrea*-*Actinacis*, *Actinacis*-*Multicolumnastrea* and *Actinacis*-*Calamophyllia*-*Gyrodendron* assemblages occur in the middle parts of the rhythms and consist of bedded rudstones, rudstone mounds and rarer platestones, pillarstones and mixstones. *Polyparia* arrangements, colony morphology and low diversity suggest the *Ovalastrea*-*Actinacis* and *Actinacis*-*Multicolumnastrea* assemblages were adapted to high sedimentation rates. The more diverse *Actinacis*-*Calamophyllia*-*Gyrodendron* assemblage is interpreted to have grown under more optimum conditions (low sedimentation rates and high light intensities). Rudists are classified on their growth orientation (elevator, clinger, recumbent) and on their communal relationships (isolated or clustered). The cluster elevator *Biradiolites mooretownensis* occurs in the lower division of rhythms and the recumbent *A. stellata* occurs in the middle part of rhythms. The upper part of rhythms contains abundant rudists including isolated elevators (*Antillocaprina occidentalis*), cluster elevators (*Bournonia* sp.,

- Biradiolites jamaicensis, Thyrastylon spp. And Chiapasella radiolitiformis) and clingers (Plagioptychus spp.), with the topmost part contains large recumbent Titanosarcolithes.</ABSTRACT>

- 31600 <ABSTRACT>The coral species from the Upper Cretaceous (Maastrichtian) strata of the Ocozocoautla Formation in Chiapas, Mexico, are identified, described and illustrated for the first time. This coral fauna is composed of 12 species, nine of which are colonial, presumably zooxanthellate, reef-building forms. This is the first time that six of these species have been reported from Mexico. The majority (11) of these species are endemic to the Caribbean region and known only from the Late Cretaceous.</ABSTRACT>

- 31613 <ABSTRACT> In the Cerro de Oro and Tuape areas in northwestern Mexico the Mural Limestone of the Bisbee Group is characterized by carbonate/clastic shallow water sequences with interbedded biohermal intervals. Scleractinian corals are reported from two limestone intervals in the Tuape area (Late Aptian-Early Albian) and a succession of massive biohermal limestones in the Cerro de Oro area (Late Aptian). They comprise 32 taxa belonging to six suborders. Two new species are described: Dermosmilia tuapensis n.sp. and Pleurophyllia microsa n.sp.</ABSTRACT>

- 31625 <SOURCE>Journal of Paleontology 80, 6: 1033-1046.</SOURCE>
- 31626 <ABSTRACT>A detailed taxonomical description of scleractinian corals

from the Maastrichtian of Mexico (Cardenas Formation) is given for the first time. The coral association comprises 16 taxa which belong to 9 families: Dictyophyllia conferticostata (Vaughan), Cladocora jamaicensis Vaughan, Cladocora gracilis (d'Orbigny), Antiguastrea cellulosa Duncan), Multicolumnastraea cyathiformis (Duncan), Placocoenia major Felix, Siderastrea vancouverensis Vaughan, Siderastrea adkinsi (Wells), Goniopora sp., Actinacis haueri Reuss, Actinacis parvistella Oppenheim, Actinohelia elegans (Goldfuss), Meandrophyllia oceani (de Fromentel), Dermosmiliopsis orbignyi Alloiteau, Trochoseris aperta Duncan, and Cyathoseris formosa d'Achiardi. The corals described herein were collected from mixed coral-rudist and coral-dominated assemblages in the Arroyo de la Atarjea, and one unnamed riverbed which lithologically correspond to the Arroyo de la Atarjea section, both of which belong to the upper member of the Cardenas Formation. On the genus level, 94% of the Mexican fauna corresponds to the Maastrichtian coral assemblages of Jamaica. Moreover, the Cardenas fauna shows close affinities to both Upper Cretaceous coral associations of central Europe and the Caribbean, as well as to Lower Tertiary faunas of Central America and the Caribbean. On the species level, 68.8% of the Cardenas corals are known from Lower Tertiary strata of Central America, the Caribbean, South America, Asia, European / Mediterranean region, and/or southeastern parts of the USA. </ABSTRACT>

31637 <TITLE>Taxonomy, stratigraphic distribution and palaeobiogeography of the Early Cretaceous coral genus Holocystis.</TITLE>

31638 <SOURCE>Revista Mexicana de ciencias geológicas 23, 3: 288-301.</SOURCE>

31639 <ABSTRACT>The Early Cretaceous Scleractinian coral genus Holocystis Lonsdale, 1849 - first reported for southern England and for a long time believed to be restricted to this region - is easy to recognise but it is also rare. Abundant material from the Late Barremian to Early Albian found in Sonora (Mexico) as well as the available type material and additional material from Europe and East Africa allowed a systematic revision. Five species are distinguished. One of them - Holocystis nomikosi - is described as a new species. Three species previously described for other genera were assigned to the genus Holocystis and two species formerly assigned to Holocystis were found to belong to other genera. Two genera (Tetracoenia and Nowakocoenia) are considered junior synonyms of Holocystis. The stratigraphic extent of the genus was limited to the range from the Barremian to the Early Albian. Holocystis is not a common coral genus but occurred in a large geographic area comprising the central Tethys, the Caribbean, and even the eastern to south-eastern Tethys. It is restricted to sediments with a certain terrigenous input.</ABSTRACT>

- 31650 <TITLE>Barremian corals from San Antonio Texcala, Puebla, Mexico - a review of the type material of Felix 1891.</TITLE>
- 31651 <SOURCE>Boletin del Instituto Geologico de Mexico 114: 1-68 (CD-ROM).</SOURCE>
- 31652 <ABSTRACT>The Barremian coral fauna from San Antonio Texcala described by the German palaeontologist Johannes Felix is revised. The material is completely recrystallized; therefore, it was not possible to study the internal structures. Studies were exclusively confined to the coral surface. The original type locality of the material was not located in the field. Corals found in the outcrops at the presumed type locality area differ in their preservation and taxonomic composition. The nearby localities of the San Juan Raya Formation yielded corals different from those of San Antonio Texcala. The only material available for a revision is therefore the collection material at the Leipzig University (Germany). Forty-two species are assigned to 26 genera, six species more than described by Felix. Most species belong to the suborders Stylinina, Faviina, and Microsolenina, the most common genera are Cryptocoenia and Polyphylloseris. The suborders Archeocaeniina, Amphistraeina, and Rhipidogyrina, which are usually common in the Early Cretaceous, are conspicuous by their complete absence from the fauna of San Antonio Texcala. Stratigraphically, the fauna shows affinities with faunas between the very Late Jurassic and the Campanian, though the closest correlation is with early Aptian associations. Palaeobiogeographic relationships are slight and exist mainly with Barremian-Aptian faunas of the central Tethys, the Caribbean, and even Asian and Boreal provinces.</ABSTRACT>

- 31677 <SOURCE>Journal of Paleontology 83, 3: 333-349.</SOURCE>
- 31678 <ABSTRACT>From the oldest Cretaceous marine sediments of Jamaica, the Copper Limestone within the Devils Racecourse Formation (Benbow Inlier, Clarendon Block), the oldest known coral fauna of the Caribbean is described. The small but diverse fauna encompasses 18 species in 17 genera of the suborders Amphistraeina, Archeocaeniina, Heterocoeniina, Faviina, Fungiina, Microsolenina, and Stylinina. The fauna contains the first representatives of the suborder Amphistraeina in the Caribbean and the Americas. One genus of the family Amphistreaeidae, Monoaulastrea, and three species - Monoaulastrea rawi, Latusastrea rubrolineata, Camptodocis corralesi - are described as new. The

- preoccupied coral genus *Floria* is replaced by the new name *Floriastrea*. The new fauna shows relationships to faunas from the late Berriasian to late Albian. Most species are shared with the Hauterivian faunas from Georgia in the central Tethys and the Paris Basin in the Boreal, but also with younger faunas such as the Barremian of Central Mexico, the early Aptian of Greece and the early Albian of the Bisbee Basin (Northern Mexico). 31689 <TITLE>Lower Cretaceous corals and stratigraphy of the Bisbee Group (Cerro de Oro and Lampazos areas), Sonora, Mexico.</TITLE>
31690 <SOURCE>Cretaceous Research 20, 4: 465-497.</SOURCE>
31691 <ABSTRACT>Stratigraphic sections of the Bisbee Group in northwestern Mexico have been studied. Several lithostratigraphic units from the Cerro de Oro and Lampazos areas, characterized by mainly carbonate / clastic shallow water sequences, are discussed in this paper. In the Lampazos area these sediments are grouped into the Agua Salada, Lampazos, Espinazo del Diablo, and Nogal Formations. In the Lower Cretaceous sections of the Cerro de Oro area, the Cerro de Oro, Morita, and Cintura Formations, as well as the Mural Limestone are distinguished. Scleractinian corals are reported from Upper Barremian to Middle Albian reefal limestone intervals within the Cerro de Oro, Espinazo del Diablo and Nogal Formations, and within sequences of the Mural Limestone. They comprise 32 genera belonging to seven suborders. Six new species are described: *Columastrea paucipaliformis* n.sp., *Columnocoenia minima* n.sp., *Keriophyllia roniewiczzae* n.sp., *Cladophyllia mexicana* n.sp., *Pleurostylina major* n.sp., and *Stiboriopsis sonoraensis* n.sp. 31702 <TITLE>The Cretaceous corals of Mexico: occurrences and history of research.</TITLE>
31703 <SOURCE>Revista Mexicana de Ciencias Geologicas 20, 1: 52-78.</SOURCE>
31704 <ABSTRACT>An extensive, detailed compilation of known occurrences and described species of Cretaceous scleractinian corals in the country of Mexico, based on published scientific literature, is presented for the first time. Cretaceous corals have been reported from more than 170 localities in more than 200 published studies dating from at least as early as 1839. Unfortunately, relatively few of these 200 publications actually described coral species; the entire research history on Mexican Cretaceous coral systematic paleontology is contained in only 16 studies. A total of 116 coral species have been described from these occurrences, inclusive of unnamed coral species and with previously suggested synonymies taken into consideration. Overall the coral occurrences span nearly the entire Cretaceous Period, from the Berriasian through the Maastrichtian, but at least 60 percent of them are from the Early Cretaceous. Furthermore, the vast majority (about 90

percent) of the total number of Mexican Cretaceous coral species are known from the Early Cretaceous. Based on these data, it seems likely that many of the Cretaceous corals of Mexico are still unknown. The detailed review of the literature on Mexican Cretaceous corals [is] presented in this study establishing a modern foundation for future investigations of the paleobiography and systematic paleontology of the members of this significant group of reef-building organisms. 31717 <ABSTRACT>The lithological succession of the Guinea Corn Formation in
the Slippery Rock River, central Jamaica, comprises 91 m of limestones
and subsidiary mudstones. The biostratigraphic distribution of
rudist bivalves and corals demonstrates that the succession of
biostratigraphic markers is consistent with the previously documented
standard Guinea Corn Formation succession in the Rio Minho between
Grantham and Guinea Corn, central Jamaica. Additionally, the Slippery
Rock River succession shows the boundary between the Chiapasella
radiolitiformis and C. trechmanni zones that has not previously been
documented. The marker horizons are also consistent with major facies
changes within both sections, demonstrating that both lithological
changes and biostratigraphic markers are synchronous within the
limestone successions of central Jamaica. This may prove to be a
valuable tool for stratigraphic correlation elsewhere in Jamaica and
within the Antillean region.</ABSTRACT>

Mexico.</TITLE>
31729 <SOURCE>American Association of Petroleum Geologists Bulletin 58, 5:
800-809.</SOURCE>
31730 <ABSTRACT>The late Mesozoic depositional cycle in eastern Mexico began
with red bed deposition in the Jurassic, included deep - and shallow
water marine carbonates (Late Jurassic to Late Cretaceous) - and
concluded with terrigenous detritus from the deformation of the Sierra
Madre Oriental (Eocene). Rudist fringed shallow water carbonate
platforms attained their maximum areal extent and facies contrast with
the surrounding carbonate basins in the Albian-Cenomanian. The
resultant lithofacies are: (1) a suite of platform carbonates; (2)
dark, cherty, pelagic, basinal limestones; (3) basin-margin carbonates

consisting of platform-derived breccias and bioclastic rocks interlayered with pelagic limestones. Scale and relief of the Mexican platforms compare with those of the Capitan reef and the Bahama Banks. Steep-sided, high-relief platforms provide optimum conditions for basin-margin debris accumulations, but the necessary and sufficient combination of conditions for debris accumulation and for platform development is unsolved.</ABSTRACT>

31741 <TITLE>Paleontology of the Eocene Bateque Formation, Baja California Sur, Mexico.</TITLE>

31742 <SOURCE>Contrib. Sci. 434: 1-55.</SOURCE>

31743 <ABSTRACT>This study is the first detailed account of marine Eocene macrosized invertebrate fossils from Baja California Sur, Mexico. The fossils, which are locally richly abundant, are from exposures of the middle lower Eocene ("Capay Stage") to upper middle Eocene ("Tejon Stage") Bateque Formation along the Pacific coast from the eastern Laguna San Ignacio area to the San Juanico area about 105km to the south. Ninety-nine species were found and are one red alga, one green? alga, five large benthic foraminifers, traces of one demosponge?, one calcareous sponge, one spongiomorph? organism, one helioporid octocoral, one gorgonian, eight colonial corals, four solitary corals, two bryozoans, one polychaete worm, one scaphopod, 37 gastropods, 23 bivalves, two nautiloids, two crabs, and three types of cidaroid echinoids (based on spines), as well as two cassiduloid? and two spatangoid echinoids. 31768 <SOURCE>Rev. Biol. Trop. 49, suppl. 2: 195-201.</SOURCE>

31769 <ABSTRACT>A new species of scleractinian coral is described: Euphyllia

donatoi. This is the first report of this genus from Central America. The outcrop is located on the north-west of Costa Rica. It consists of large colonies (1.2 m high by 0.5 m in diameter), from a patch reef which had a dendroid habit. They are part of a very distinctive facies in a micritic limestones of the Barra Honda Formation (Paleogene). The finding is important because these are the only macrofossils found in Barra Honda Formation. The growth took place under unstable ecological conditions resulting in a low diversity autochthonous community. It probably developed in very shallow water with a high sedimentation rate.

31781 <SOURCE>Geobios 22, 5: 761-775.</SOURCE>

31782 <ABSTRACT>worm reeflets described here are composed of parallel and straight, curved, or bifurcated tubes, which are up to 10 cm long and have an average diameter of 1.4 mm. Their walls are composed of microgranular calcite and are multilamellar. The reef-builders settled on soft bottoms within the tidal or uppermost zone. They tolerated high water turbulence and a certain rate of sedimentation. Dead parts of the reef were recolonized by a new population. The reefs stabilized the sediment, produced biogenic debris, and offered new ecological niches for endo- and epilithic organisms. They mark a regional ecological event at the Oligocene / Miocene boundary. *Diplochaetetes mexicanus* as well *D. longitubus* demonstrate close relationships to a modern skeletal-forming polychaete worm, *Dodecaria*. *Diplochaetetes* is definitely not a sclerosponge and demonstrates a convergence with the chaetetid basal skeletons of sponges and favositid corals.</ABSTRACT>

31820 <SOURCE>Cainozoic Research 3 (1-2): 83-107.</SOURCE>
31821 <ABSTRACT>Sedimentary rocks of the White Limestone Group of Jamaica were deposited in the range of shallow to deep-water marine settings from the Middle Eocene to Middle Miocene. Horizons rich in scleractinian corals occur throughout this lithologic unit. The present study, using large, new collections (>2.000 specimens) and museum specimens, recognises 98 scleractinian species in 42 genera in the White Limestone Group. Thirty-six of these species have not been previously described in the literature. From the Middle to Upper Eocene, eleven species are reported from the Troy Formation, twelve from the upper Middle Eocene Swanswick Formation and eleven species from the Late Eocene Somersset Formation. In the Moneague Formation, fifty-two species are recorded from the lower part of the Upper Oligocene succession in units formerly mapped as the Browns Town Formation. Also, in the uppermost Oligocene of the Moneague Formation, sixty-four coral species are reported from rocks formerly mapped as the Newport Formation. An additional fifteen species are reported from the Early Miocene portions of the Montpelier Formation. In addition to scleractinian corals, a stony octocoral species (Parapolytremacis sp.) is found in the Upper Oligocene of the Moneague Formation, and at least two species of Millepora (class Hydrozoa) are recorded from the Eocene and Oligocene portions of the White Limestone Group. Coral assemblages from the Eocene of the white Limestone group are largely dominated by scattered, thinly branched and free-living corals, while Late Oligocene assemblages contain a diverse group of large massive, plate-shaped and branched corals in a system of patch reefs and coral carpets. The Early Miocene assemblages represent a possible deeper fore-reef community transported into deep water sediments in a olistostromic block. The total number of species found exceeds that known from any other single region or lithologic unit in the Caribbean Eocene through Miocene.</ABSTRACT>

- 31859 <SOURCE>Bulletins of American Paleontology 93, 328: 05-22.</SOURCE>
- 31860 <ABSTRACT>Multivariate statistical procedures are used to distinguish species in the reef-coral genus Stephanocoenia through a continuous Neogene sequence (five-million year time interval) in the Cibao Valley of the Northern Dominican Republic. This genus is the only member of the family Astrocoeniidae that occurs in the sequence. The material consists of 56 colonies (17 of which are measured) from 24 localities in four river sections, the most important being Rio Gurabo and Rio Cana. Ten characters are measured on each of 10 corallites per colony. The data are analyzed using cluster and canonical discriminant analysis to group colonies into clusters representing species. Identical measurements on modern colonies collected near Discovery Bay, Jamaica are included for comparison. Two fossil species are defined in the analysis, one of which is new (*Stephanocoenia duncani*, n.sp.). Both species are significantly distinct from the single modern species (*S. intersepta*) that is the sole living representative of the genus. Study of collections from other reef localities shows that both fossil species occur only during Neogene time and only at a limited number of localities. Patterns within each species are traced up a composite stratigraphic section using nonparametric statistical analyses. One of the two fossil species (*S. spongiformis*) is found to remain stable through time, whereas the other (*S. duncani*) changes its morphology in a direction approaching the cluster for the modern species. Further study of patterns of variation within the one modern and two fossil clusters shows that intraspecific variation is unusually complicated in this genus. The clusters overlap, and colonies within each cluster differ widely. Variation between populations within the modern species occurs in the same characters as those which distinguish the modern species from the fossil species converging with it (*S. duncani*).

However, these two species form a morphologic continuum that cannot be explained by environment alone. Therefore, they may represent two gradually intergrading chronospecies within one lineage. [part of extensive summary]

31871 <TITLE>The Emperador limestone rediscovered: Early Miocene corals from the Culebra Formation, Panama.</TITLE>
31872 <SOURCE>Journal of Paleontology 80, 2: 283-293.</SOURCE>
31873 <ABSTRACT>Caribbean reefs underwent significant biotic change during the Late Oligocene and Early Miocene. This was a critical time in the evolution of the modern Caribbean fauna characterized by increasing endemism resulting from regional extinction of lineages that survive in the modern Indo-Pacific. An understanding of the dynamics and potential causes of the Oligocene/Miocene transition, however, is hampered by the relative lack of well-preserved Oligocene to early Miocene coral faunas in the Caribbean. Here we examine new exposures in the Culebra Formation of Panama that contain a well-preserved coral fauna of Early Miocene age. Taxonomic, stratigraphic, and paleoecologic study of the Culebra Formation exposed along the Gaillard Cut of the Panama Canal allows us to infer the paleoenvironments and reef coral communities from the Panama Canal Basin during this critical interval. The Culebra Formation consists of a deepening upward sequence with shallow-lagoon sediments at the base, overlain by fringing reef facies in the middle of the section, and open-shelf to bathyal facies at the top of the section. We recovered 31 species of reef corals from a combination of new and old collections. Comparison of our collections with other Late Oligocene to Middle Miocene reef coral assemblages confirms that there was a major faunal turnover after deposition of the Upper Oligocene Antigua Formation. This turnover consisted of a large number of extinctions followed by an increased rate of first occurrences so that regional diversity did not change appreciably. Improved stratigraphic resolution at this and other Caribbean localities is required to understand fully the dynamics of change during the Oligocene/Miocene transition.</ABSTRACT>

31884 <TITLE>Neogene Paleontology in the Northern Dominican Republic. 3. The Family Poritidae (Anthozoa: Scleractinia).</TITLE>
31885 <SOURCE>Bulletins of American Paleontology 90, 325: 1-123.</SOURCE>
31886 <ABSTRACT>Various multivariate statistical procedures are used to distinguish species in the reef-coral family Poritidae through a continuous Neogene sequence (5myr time interval) in the Cibao Valley of the Northern Dominican Republic. Some older (by approximately 10 myr) material from the same region is also included in the analyses. The material consists of approximately 450 colonies (120 of which are measured) from 92 localities in four river sections. The colonies are

first sorted into three genera, and approximately 30 characters measured on five calices per colony. The data are analyzed using cluster and canonical discriminant analyses to group the colonies into clusters representing species. Five species are so defined in *Porites* and three in *Goniopora*. These groupings are then used statistically to reclassify type specimens for 22 of the 25 described species of Neogene Caribbean poritids. Eight described species are thereby synonymized with four previously-described species in *Porites* and one new species of *Porites*, *Porites convivatoris* n.sp., is discovered. Five described species are synonymized with two previously-described species in *Goniopora*. The stratigraphic range of three species of *Porites* and three species of *Goniopora* is also shown to extend back to the late Oligocene, thereby diminishing the significance of any presumed early Miocene adaptive radiation. Only one species was found to be endemic to the Dominican Republic and only one confined to the northern Caribbean. The rest are widely distributed throughout the Caribbean. Thus, the endemism previously believed common during the Neogene is shown to be far less extensive. Evolutionary trends within each species are preliminarily analyzed for various characters using nonparametric statistical procedures. In general, the results show that seven species experienced little or no evolutionary change (= stasis) through the sequence. Slight increases in corallite size are detected in two species, an increase in colony height in one species, and a more rounded colony shape in one species. These trends may be related to the general deepening of the environment; however, little correlation is found between lithology and morphology within species. Preliminary analyses of the relationship between intraspecific variation and poritid abundance and diversity yield significant results, suggesting that intraspecific trends may be environmental and that future study of coral species associations may offer insight into paleoenvironmental interpretations. * Statistical comparisons with the Miocene Mediterranean show that no species co-occur in the two provinces during the Neogene. Similarly, none of the studied Neogene species of *Porites* resemble modern Caribbean species of *Porites*, signifying that all nine poritid species studied must have become extinct and that the modern Caribbean species of *Porites* radiated during the late Pliocene or early Pleistocene. 31899 <ABSTRACT>Seventeen species and seven genera of the family Faviidae that bud intramurally are described in collection from the Neogene sequence in the Cibao Valley of the northern Dominican Republic. The material consists of 220 colonies from 85 localities along five river sections that range in age from Late Oligocene to Early Pliocene. Most of the specimens were collected along two river sections (39 localities in Rio Gurabo, 37 localities in Rio Cana) that expose an exceptionally continuous sequence extending from Late Miocene to Early Pliocene time. 31924 <SOURCE>Sedimentary Geology 144, 3-4: 291-306.</SOURCE>
31925 <ABSTRACT>The Port Morant Formation consists of a mixed clastic-carbonate sedimentary sequence that was deposited as a lagoon fill during the Sangamonian interglacial. Ten sedimentary facies are recognized and sequence stratigraphic analysis indicates the presence of transgressive and highstand systems tracts. The transgressive systems tract consists of a basal transgressive conglomerate (facies I), crustose coralline algal bindstones-boundstones (II) and 2 m high Solenastrea coral heads (III). The highstand systems tract is represented by sediments of a braided delta/fan-delta prograding into the lagoon (IV and V), marine pebbly sandstones deposited adjacent to mangrove swamps (VII), more distal algal mudstones (VIII), and sheet-like (VI) and channelized (IX) conglomerates filling delta-top distributary channels. A barrier and/or fringing reef is present (X), but its relationship with the lagoon-fill sediments is obscure due to poor exposure. Carbonates are restricted to the transgressive systems tract and the barrier/fringing reef (transgressive and/or highstand systems tract). Two transgressive events are recognized, the transgressive systems tract (facies I to III) and facies VII, the latter either a second sea-level rise or due to delta abandonment. A single coral date from facies VII gave an age of 132 ± 7 kyr. This indicates that the upper transgressive event (facies VII) belongs to the early highstand that has been recognized in isotope substage 5e. The lower transgressive event (facies I to III) in the Fort Morant Formation is therefore either also of this age, or older.</ABSTRACT>

31937 <SOURCE>Geology Today 14, 1: 26-30.</SOURCE>

- 31938 <ABSTRACT>Exhumed early Pleistocene reefs along the eastern coast of Jamaica expose deep-water environments downslope from the more familiar, shallow-water reef frameworks. Such environments have quite different faunas from the shallow parts of the reefs, including common 'Palaeozoic-type' biotas like the brachiopods and crinoids. These animals are found in deeper-water settings around the Caribbean today; however, these biotas are not readily, available nor easily studied. The slightly older Pleistocene faunas are much more accessible and informative. Here the past may be the key to the present.</ABSTRACT>

- 31951 <ABSTRACT>The 125,000 y.b.p. (Sangamon) Falmouth Formation is an emergent fringing-reef complex exposed along the north coast of Jamaica. Q-mode cluster analysis using constituent composition of Falmouth Formation rocks collected near Discovery Bay was employed to differentiate two distinctive facies. These are a dense, well-lithified skeletal packstone containing abundant calcareous algae (Halimeda and coralline algae) and molluscs, and a poorly lithified skeletal grainstone composed primarily of sand-sized coral fragments and coralline algae with only minor amounts of Halimeda. The composition of sediments within these facies is comparable to the composition of back-reef and shallow (5-8m deep) fore-reef sediments of the Holocene Jamaican fringing-reef system. These results contradict the pervasive idea that sand-sized, reef-derived sediments are ineffective as environmental indicators owing to post-depositional transport away from the reef system. Petrographic and X-ray analyses of the mineralogy of Falmouth Formation limestones reveal that back-reef packstones retain much of their original aragonite and high-Mg calcite. In fore-reef grainstones, however, better soiling (increased permeability) results in dissolution and leaching of these metastable phases and reprecipitation of low-Mg calcite. Thus, variability in original sediment texture may create a preservational bias in the fossil record against the more permeable fore-reef deposits.</ABSTRACT>

- 31964 <ABSTRACT>An extremely well-preserved Holocene fringing coral reef occurs at an average elevation of 5 m below sea level around the margins of the central Enriquillo Valley, Dominican Republic. The reef records the latest marine incursion from the east into an 85-km-long, 12-km-wide tectonic depression and appears to represent a unique

preservation. Excellent cross sections of the reef exposed in erosional gullies reveal the composition and zonation typical of modern Caribbean reefs that are found in offshore low-energy environments. Radiocarbon age determinations (2) indicate that reef growth coincided with sea-level rise following the last ice age (5,930 + 100 to 4,760 ± 90 yr B.P.). Deltaic deposition and possible vertical movements on active fault scarps dammed the eastern mouth of the valley and created Lago Enriquillo, the level of which was then rapidly lowered by evaporation in an arid climate to produce a saline lake ca. 40m below sea level. Stratigraphic studies of rocks along the valley edge and data from drill holes in the basin center indicate that there were earlier post-Miocene marine incursions similar to that described here. </ABSTRACT>

31975 <TITLE>Distribution and Bathymetric Zonation of Shell-boring Endoliths in Recent Reef and Shelf Environments: Cozumel, Yucatan (Mexico).</TITLE>

31976 <SOURCE>Facies 22: 233-262.</SOURCE>

31977 <ABSTRACT>Pelecypod shells from bottom sediments of the shelf and upper slope off Cozumel (Mexico), at depths ranging from 1 to 47m, were studied with regard to the taxonomy, frequency and distribution of microboring produced by endolithic organisms. Scanning electron microscopy of plastic casts of the borings reveals the existence of 29 microboring types, distinguished on the base of shape, size, mode of branching, overall boring pattern and sporangia. The endoliths include cyanobacteria, chlorophycean algae, rhodophycean algae, fungi, sponges and several microborers of uncertain taxonomic affinities. Although most of the borings exhibit a wide bathymetrical range, a subdivision of the photic zone is indicated by the abundance and vertical distribution of some species. The upper part of the photic zone (1-30m) is characterized by higher species diversity, by the green algae *Phaeophila engleri* and *Entocladia testarum*, and by the abundance of the cyanobacteria *Hyella gigas*. Fungi occur at all depths but are more common in the lower photic zone (30-47m). The bathymetrical position of the boundary might be influenced by the vertical sampling distance. Generally, there is a good agreement with other bathymetrical patterns of recent endoliths, especially with those from the Puerto Rican carbonate shelf. There is no distinct difference in the frequency or taxonomic composition of shell-boring endoliths from reefs and interreef areas (platforms covered by bioclastic sands). Boring intensity, measured by point-counting of SEM photographs, is generally high; in 58% of the samples 60 to 99% of the outer shell surface is bored, predominantly by fungi and by the green alga *Phaeophila engleri*. Mean boring intensities show no relationship with water depths.

31988 <TITLE>The Shelf of Cozumel, Mexico: Topography and Organisms.</TITLE>

- 31989 <SOURCE>Facies 23: 185-240.</SOURCE>
- 31990 <ABSTRACT>The Caribbean Island of Cozumel lies 18 km off the north-eastern coast of the Mexican Peninsula of Yucatan. A relatively narrow shelf is developed on both sides of the roughly NS striking island, whereby terraces and marked steps are evident. On the western shelf 3 terraces can be found at 5m, 10m and 20m below sea level. The shelf edge lies at approximately 20m. On the eastern side 5 distinct terraces are developed (3m, 10m, 20m, 30m and 50m) and the shelf edge lies about 50m deep. These terraces are interpreted as abrasion platforms of the rising sea level in the Holocene. In the W the insular slope drops almost vertically to a depth of about 400m. In the E it drops even further, with interruptions to over 1000m. The northern shelf area remains flat (20-30m) and ends at the Banco Arrowsmith, about 50km NNE of Cozumel. - 32016 <ABSTRACT>The distribution of Holocene sediment types on the British Honduras shelf is correlated broadly with bathymetry as a result of the modifications in water circulation and turbulence imposed by bathymetric relief. Subsurface information demonstrates that this relief has been inherited in large part from an underlying, pre-Holocene limestone erosion surface. * On the northern shelf the relatively subdued pre-Holocene relief is symptomatic of temperate or doline karst; on the southern shelf the considerable relief on the same surface is suggestive of tropical or conical karst. This difference in offshore-relief expression is consistent with parallel changes in the mainland limestone topography and with differences in the presumably causal factor of rainfall distribution. In both karst regimes, however, solution morphology has been directed in its expression by underlying structure. * Significantly, Holocene carbonate sedimentation has accentuated the drowned topographic relief through an accelerated rate of carbonate deposition on the highs. Thus the climatically and structurally determined variations in karst topography not only control the distribution of Holocene sediments but also their three-dimensional geometry. The same relation should apply to the geologic record.

32068 <ABSTRACT>The taxonomy of Early Cretaceous shallow marine coral faunas

- from the Bisbee Basin (northwestern Mexico and Arizona, southwestern USA) and the Comanche Platform (Texas, USA) are compared to each other and to coral associations of the same age around the world. The analysis here employs a large, comprehensive computer database on Mesozoic corals. The database is used to develop a uniform palaeogeographic framework for the comparisons (300 palaeo-provinces are distinguished worldwide for the Cretaceous), and a distance matrix cluster analysis of shared presence is performed on the data to correlate coral faunas both within and outside of the study area. The study is based entirely on coral material recently collected in the field and studied in museum collections. Of the 754 coral samples examined, a total of 160 species is identified from 54 sample locations. This large total number is in contrast to the low to moderate number of species found in each locality, with a maximum number of 28 species from one locality in northwestern Mexico. This demonstrates that coral distribution was controlled by regional (even local) factors. Outside of the sample area, the coral faunas show a strong correlation to central Tethyan faunas, with strongest affinities to that of the Iberian Peninsula, and also to eastern Tethys and western Pacific faunas. This argues against the commonly held concept of a distinct New World coral faunal realm, and is explained by a west-to-east orientation of warm oceanic connections and the close proximity of the land masses during the Early Cretaceous. </ABSTRACT>

32081 <ABSTRACT>From the Young-Precambrian (Vendian) Corumba-Group of Mate Grosso, Brazil, Corumbella wernerii n.gen. n.sp. is described, preserved by the chitinous periderm of several specimens. The body consists of a basal "stalk" with 4 sclero-septa and a branched upper part containing many small tubes, arranged biserially. With this, Corumbella superficially resembles the Charniidae and the Pennatularia, but both these groups have no chitinous periderm. A new subclass of Scyphozoa, Corumbellata, is erected for Corumbella.</ABSTRACT>

32092 <TITLE>Sponges and chancellorids from the Cambrian of Argentina.</TITLE>
32093 <SOURCE>Journal of Paleontology 68, 2: 208-217.
<http://www.jstor.org/pss/1306062></SOURCE>
32094 <ABSTRACT>Anthaspidellid sponges are reported from the La Laja Formation in the Chica de Zonda Range in the Precordillera Oriental, Argentina. These are generically unidentifiable fragments of trabs and more or less well-defined dendroclone spicules. They occur as skeletal elements in small transported fragments and are the only Cambrian

occurrence of anthaspidellids known thus far from South America. Walcott (1920) proposed to include an array of dissociated spicules, including triradiate prodiaenes, hexactines, and probable monactine spicules, in the genus *Kiwetinokia*. Assemblages tentatively identified as *Kiwetinokia utahensis*? Walcott, 1920, are reported from the Estancia San Martin Formation, of latest Early Cambrian and early Middle Cambrian age from San Isidro Gulch near Mendoza. Similar spicule assemblages occur in the La Laja Formation from the Chica de Zonda Range, in the Precordillera Oriental near San Juan, and in the Los Sombreros Formation in the Tontal Range of the Precordillera Occidental. Sclerites of the sponge-like *Chancelloria eros* Walcott, 1920, are described from the upper Lower to lower Middle Cambrian La Laja Formation. *Chancelloria* sclerites are also reported here from rocks of the Middle Cambrian *Glossopleura* Zone in the San Isidro Formation in Empozada Gulch in the San Isidro area of the Precordillera Austral, west of Mendoza, in Mendoza Province. Sponges and chancelloriids from the Cambrian of Argentina are known basically from dissociated skeletal elements. [original abstract] </ABSTRACT>

32105 <TITLE>Cambro-Ordovician sponge spicule assemblages in the Ordovician of the Argentine Precordillera and paleoenvironmental ties.</TITLE>

32106 <SOURCE>N. Jb. Geol. Palaont. Abh. 204, 2: 221-246.</SOURCE>

32107 <ABSTRACT>well preserved silicified sponge spicule assemblages are described from residues of conodont samples from Ordovician strata in the Precordillera of western Argentina. The material has been recovered from Cambrian olistoliths in the Los Sombreros Formation (Llanvirn-Caradoc) and from autochthonous limestones of the San Juan, Gualcamayo and Las Aguaditas formations. The poriferan taxa include Polyactinellidae and Heteractinellidae (Calcarea) as well as hexactinellid and demospongian spicules. Associations of exclusively hexactine spicules are restricted to outer platform and slope deposits, whereas on the shallow platform a relatively high diversity of different types of polyactinellid and heteractinellid spicules may be observed in the upper part the San Juan Formation. There, these assemblages are related to reef-mound horizons and biostromes with sponges, stromatoporoids, receptaculitids and some autotrophic organisms. The restriction of spicule associations to distinct environments is discussed with respect to previous studies treating the distribution of Early Paleozoic sponge faunas in different facies, and 3 different sponge biofacies zones for the Cambro-Ordovician platform and slope settings in the Precordillera are described.</ABSTRACT>

32119 <SOURCE>Facies 34, 1: 177-192.</SOURCE>

- 32120 <ABSTRACT>Late Arenigian biohermal reef mounds and biostromes within the shallow-marine platform facies of the upper San Juan Formation of the Precordillera (western Argentina) represent a new Early Ordovician reef type. The meter-sized reefs are dominated by Zondarella communis n.g. n.sp. The new taxon is characterized by domical, bulbous and laminar morphotypes exhibiting growth layers and thin horizontal and vertical as well as intermingled skeletal elements included within different sets. The fossil may be compared with stromatolites and stromatoporoids but an interpretation as primitive stromatoporoids is favored.</ABSTRACT>

32183 <TITLE>First Silurian conulariids from Paraguay.</TITLE>
32184 <SOURCE>Journal of Paleontology 64, 6: 897-902.</SOURCE>
32185 <ABSTRACT>Two new conulariid species, *Conularia clarkei* Babcock and *C. paraguayensis* Babcock from the Vargas Pena Shale, are the first Silurian conulariids to be described from Paraguay. They increase to three the number of Silurian species to be described from South America. The concept of *Conularia* Miller in Sowerby 1820, is emended. It includes as junior synonyms *Conularia* (*Plectoconularia*) Boucek 1919, *Diconularia* Sinclair 1952, and *Yangoconularia* Xu and Li 1985. The age of the Vargas Pena Shale has long been disputed, but conclusions based on organic-walled microfossils indicate an Early Silurian (Llandoveryan) age for the unit.</ABSTRACT>

32197 <SOURCE>Ameghiniana 39, 4: 479-490.</SOURCE>
32198 <ABSTRACT>Very few coral species have been described to date from the Silurian and Devonian rocks of Argentina. An important association of rugose and tabulate corals was collected from the Silurian and Devonian siliciclastic rocks in western Argentina. The coral assemblage was recovered from the Pridolian and Lockovian transition in the Cerro del Fuerte and Talacasto sections in the Argentine Precordillera. The tabulate *Argentinella argentina* (Thomas) is described and figured, building thick accumulations of gregarious colonies in a shallow, near shore environment associated with a sea level fall in the base of the Lochkovian. From the same levels an indeterminate favositid is also described. In the subjacent Pridolian rocks the solitary rugose *Enterolasma* sp. and a tabulate, pleurodictyform indet. were recovered from fossil-rich beds associated with tempestites. This is the first record of the genus *Enterolasma* and the Family *Pleurodictidae* in South America. [original abstract]</ABSTRACT>

32211 <ABSTRACT>The type material of Favosites argentinus Thomas, 1905, from the Lochkovian of Cerro del Fuerte (Argentine Precordillera), along with various topotypical material belonging to the same collection, is described and figured. The study of this material serves as a basis for establishing the new genus Argentinella. This genus is characterized by branching colonies, with a marked development of the septal elements, especially pronounced in the calices which present 12 spiny septa ridges, peripheral thickening of the walls and tabulae, and a wall microstructure where microlamellae prevail but coexist with lamellae.</ABSTRACT>

32224 <ABSTRACT>A new species of Tabulate coral, Parastriatopora sanjuanina, coming from two localities sited in the southern part of the Argentinian Precordillera is described. The studied material was collected in some calcareous levels near the base of the Talacasto Fm., lower Lochkovian in age. This species is assigned to the genus Parastriatopora and is characterized by a small axial zone made up of some few corallites and by the main development of a compact peripheral rim in the mature branches. The outer surface of these branches shows the calices bearing between eight and twelve ridges separated by eight rounded hollows.</ABSTRACT>

32236 <SOURCE>Geobios 28, 2: 175-183.</SOURCE>
32237 <ABSTRACT>Some specimens of tabulate corals from Lower Devonian of the Precordillera Central in San Juan province (Argentina) are described. These branches are assigned to the genus Parastriatopora Sokolov 1949 and they are found close to Parastriatopora gigantea Knod 1908. Other material, probably conspecific with this, has been reported in the bibliography such as Favosites argentinus Thomas 1905. The age of this finding is discussed and some palaeobiogeographic considerations on their occurrence in South America are proposed.</ABSTRACT>

32263 <ABSTRACT>A paleoecological study was done based on the Middle Carboniferous coral fauna cited for the Amazon Basin in an attempt to characterize a relationship among those individuals and the environment during that time. Coral species used in this work are those present in the Itaituba Formation (Morrowan-Atokan) in the State of Para, northern Brazil. *Amplexizaphrentis petrii* Pinto, *Dibunophylloides duncanae* Pinto, *D. geiseli* Pinto, *Lophamplexus* sp., *Stereostylus leinzi* Pinto and *S. mendesi* Pinto represent the Rugosa; being *Multithecopora milani* Pinto the only one Tabulata coral species noticed for the region. Those individuals are characteristic of a coral fauna related to inner seas, being accustomed with shallow waters of high turbidity. The absence of organic reefs in the region can be related with a low capability of individuals to settle down in a poorly consolidated shelf.</ABSTRACT>

32302 <ABSTRACT>A vicariant model is proposed to evaluate the distribution pattern of thirty-nine Bashkirian rugose coral genera cited for both the Amazon basin and selected Western Laurasian regions. Laurasian regions embrace the western Interior, Eastern Interior and Midcontinent region in the USA, part of the Mediterranean Province (Northern Spain) and Donets basin in Europe; Amazon basin is included in the western Gondwana. The selected rugose coral genera were grouped into seven suborders and a phylogenetic study was carried out in an attempt to produce area cladograms. A reduced area cladogram was produced using BPA (sensu Wiley 1988), which shows area relationships and ancestor-groups distribution. The results attest to a close relationship of the Amazon basin to the Midcontinent region. A possible sea-way linking Western Laurasian regions during Early Bashkirian is also suggested via the Canadian Arctic Archipelago. Previous suggestions about a sea connection running from North Africa to the Amazon basin is rejected. The biogeographic model proposed is in agreement with that of Rodriguez et al. (1996) for the Bashkirian interval.</ABSTRACT>

32391 <TITLE>Les Scleractiniaires jurassiques (Bajocien) d'Argentine (Bassin de Neuquen). Systematique.</TITLE>
32392 <SOURCE>Geobios 29, 6: 671-706.</SOURCE>
32393 <ABSTRACT>In this paper the scleractinian corals from Lajas Formation outcrops (Lower Bajocian) - Neuquen Basin, western central Argentina - are described. The Lajas Formation is mainly constituted by shore-face arenaceous sediments, and not one of the studied outcrops presents a reef facies. At the moment, this kind of facies is unknown in the Argentinean Middle Jurassic. The coral fauna is comprised of 15 species among which 6 are new ones. They are distributed in 11 genera, three of which are new. The new taxa described are Araucanastrea mimiscula nov. gen. nov. sp., Araucanastrea majuscula nov. gen. nov. sp., Garateastrea bardanegrensis nov. gen. nov. sp., Kobyastrea louisae nov. sp., Neuquinosmia gerthi nov. sp. and Mapucheastrea andina nov. gen. nov. sp. The specimens possess a similar morphology to those having the same age and belonging to the rich Tethys coral fauna, but the microstructure observed in some species appears to be closer to that of more ancient forms. However the exactness of the identification is

somehow limited by the parallelisms existing in scleractinian systematics. This parallelism is originated by the determinations of scleractinians founded only on well preserved microstructures, but which are not observable in all specimens. It can too induce inaccuracy in the paleobiogeographical reconstruction and in the phylogenetic interpretations.</ABSTRACT>

32405 <SOURCE>Bulletin of the Tohoku University Museum 1 [Proceedings of the 8th International Symposium on Fossil Cnidaria and Porifera]: 320-332.</SOURCE>

32406 <ABSTRACT>Lower Jurassic scleractinians from the Neuquen Basin (Argentina) are newly described. Inferred paleoenvironmental conditions are based on coral life positions and sedimentology for corals of the Puesto Araya and Piedra Pintada Formations. Coral bearing levels are placed in a precise chronostratigraphic sequence according to ammonoid faunas, which indicate a Pliensbachian age. These units belong to the transgressive phase of a depositional sequence. In one outcrop, coral bearing levels are classed as autobiostromes. In the other outcrops, the corals do not form any biologically constructed structures. Taxa are regarded as eight species, among which six are noted for the first time in Argentina. Species are as follows: Stylophyllopsis? sp. cf. S. victoriae, Phacelostylophyllum sp. cf. P. peruvianum, Meandrostylis? jaworskii, Distichomeandra sp. cf. D. austriaca, Retiophyllia? sp., Microphyllia sp. cf. M. flemingi, Myriophyllum sp. and Goldfussastraea? toarciensis. Some specimens are similar morphologically to those of the rich coral faunas of Tethys of the same age, but others appear to be closer to older forms. However, the exactness of identifications is limited by the state of preservation of specimens, and somewhat, by differing diagnostic criteria (microstructure vs macrostructure) used in the systematic classification of Scleractinia. 32417 <TITLE>First shallow water scleractinian coral reef from the Danian, northern Patagonia, Argentina.</TITLE>

32418 <SOURCE>Ameghiniana, Suplemento 40, 4: 79R.</SOURCE>

32419 <ABSTRACT>Hermatypic coral reefs have not been reported from the earliest Paleocene with a few exceptions of the unverified records (e.g. Paris Basin). On the other hand azooxanthellate coral reefs from the early Paleocene of Greenland and Faxe, Denmark are well-documented. We describe the first Danian hermatypic coral reef from the Roca Formation at Lomita Baya, La Pampa, Argentina. The coral reef is primarily formed by the colonial taxa Siderastrea adkinsi (Wells, 1934) and Haimesastraea conferta Vaughan, 1900, and is distinctly dominated

by *S. adkinsi* (62%-88% in shallowest parts of the reef, 82%-100% in adjacent areas). In the shallowest parts of the reef colonies of *S. adkinsi* are massive-folious or encrusting, ranging between a few centimeters to over 1m in diameter. Specimens of *H. conferta* are distinctly smaller, generally knobby, and range between a few millimeters and 15cm in diameter. Frequently, corals of the rolling stone type occur which, in addition to the presence of folious-encrusting morphotypes and the microfacies images, indicate that the reef developed in a highly wave-agitated environment of 0-10m depth. Sponges and coralline algae played an important role in the reef frame. Other members of the coral reef community are the branching coral *Cladocora* cf. *C. gracilis* (Orbigny, 1850), the solitary coral *Sideroseris durhami* Wells, 1945, the echinoid *Micropsis desori* (Cotteau, 1856), which is an inhabitant of hard substrates, the bivalves *Acesta* cf. *A. latens* (Feruglio, 1935), and *Venericardia iheringi* (Böhm, 1903), as well as several species of warm water gastropods.  32443 <TITLE>Massive corals in Paleocene siliciclastic sediments of Chubut (Argentina).</TITLE>
 32444 <SOURCE>Facies 51, 1-4: 233-241.</SOURCE>
 32445 <ABSTRACT>A horizon with large, massive corals in growth position was discovered in the Paleocene, probably upper Danian, part of the Maastrichtian-Paleocene Lefipán Formation of Chubut (Patagonia, Argentina). All corals belong to one species, the cosmopolitan *Haimesiastrea conferta* Vaughan, which survived the end-Cretaceous mass extinction. The occurrence of massive corals at this site is exceptional both because of the siliciclastic depositional regime and because of the high palaeolatitude setting. An unusual autecology of this coral and strongly reduced sedimentation rates, were probably the prerequisites for coral growth, but a link to palaeoclimate is less likely.</ABSTRACT>

32456 <TITLE>Una nueva especie de coral solitario (Scleractinia, Turbinoliidae) de la Formación San Julián (Oligoceno superior; Santa Cruz) en su contexto estratigráfico y paleoambiental.</TITLE>
32457 <SOURCE>Revista del Museu Argentino de Ciencias Naturales n.s. 10, 2: 255-262.</SOURCE>
32458 <ABSTRACT>Small scleractinian corals (Family Turbinoliidae) were collected from the Late Oligocene San Julian Formation, in Santa Cruz province (southern Patagonia, Argentina). The specimens were assigned to Sphenotrochus aff. gardineri and to Bothrophoria compressa n.sp., the second record of the genus. According to the lithofacies association and the remaining fossil invertebrates, these free-living and ahermatypic turbinoliids would have lived in temperate to warm waters (Juliense sea) and in sandy substrates of the inner shelf-upper shoreface. 32497 <ABSTRACT>Sponge morphology adapts itself to marine conditions. Due to their changeableness, sponges have been selected as paleoenvironmental indicators of the San Juan formation. Two morphotypes are : 1) Column and glass shaped and 2) Rounded and plate shaped. The first one reveals an open subtidal environment, showing no waves or currents, whereas the second one indicates a more shallow environment, showing greater energy and dominant currents. There are also sponges in vital position, interstratified with micritic layers in the platform external edge (buildup).</ABSTRACT>

32522 <SOURCE>Geobios 33, 6: 709-724.</SOURCE>
32523 <ABSTRACT>The revision and detailed description of the original material and several topotypic specimens of Parastriatopora gigantea (KNOD, 1908) from the Lower Devonian of Yaco (Bolivia) allow the selection of a lectotype and its diagnosis. A more precise geographic and stratigraphic location of the type locality is provided, together with a reassessment of its most probable age (Pragian-Emsian). Present knowledge of South American Devonian tabulate corals has important implications on their paleobiogeography. Data from Bolivia and Argentina suggest an earlier age for the extinction of Malvinokaffric

- taxa and reveal a greater abundance and specific diversity.</ABSTRACT>

- 32549 <ABSTRACT>Rugose and tabulate corals of Middle Devonian, and Lower Pennsylvanian age are described from localities in the northern part of the Sierra de Perija, western Venezuela. The Palaeozoic stratigraphy of the area is briefly reviewed and the ages and relationships of the coral faunas are discussed. The new taxa *Bowenelasma typa* gen. & sp.nov., *B. brevisseptata* sp.nov., *Amplexizaphrentis sutherlandi* sp.nov., *Briantelasma oliveri* sp.nov. and *Heliophyllum wellsii* sp.nov., as well as species of *Stereolasma*, ?*Stewartophyllum*, *Syringaxon*, *Heterophrentis* (H.), *Cylindrophyllum*, *Durhamina*, *Plasmophyllum* and *Favosites* are described.</ABSTRACT>

32600 <SOURCE>Journal of Paleontology 64, 1: 60-78.</SOURCE>
32601 <ABSTRACT>Permian corals of Bolivia are confined to the Lower Permian (Wolfcampian, Leonardian) Co-pacabana Limestone. The coral fauna of the formation in the Lake Titicaca to the central altiplano areas of the Department of La Paz consists of two solitary rugose coral species, two colonial rugose coral species (one each of fasciculate and cerioid), and two tabulate coral species. New taxa are Stylastraea branisai n.sp., Durhamina pandolfi n.sp., Michelinia escobari n.sp., and Cladochonus carrascoi n.sp. Lophophyllidium striatum (d'Orbigny 1839), based on Bolivian specimens, is redescribed, a lectotype designated, and the range extended to North America. Although the fauna is small, its taxonomic composition shows clear affinity with faunas of similar age northward through South and Central America to Mexico and the USA Texas-Oklahoma-Midcontinent region. The Bolivian fauna thus is confirmed as belonging to the Cyathaxonid Coral Province, which is restricted to the above areas. A species of Durhamina previously erected for Guatemalan specimens occurs in the Copacabana Limestone of Peru strengthens the province assignment of the formation.</ABSTRACT>

32638 <TITLE>Upper Triassic corals from Peru.</TITLE>
32639 <SOURCE>Palaeontographica A233, 1-6: 75-98.</SOURCE>
32640 <ABSTRACT>Seventeen coral and one spongiomorph taxa are described from the Upper Triassic silicified specimens of the Pucara Group in central Peru. Among these, three new species are distinguished: Stylophyllopsis gracilis n.sp., Pinacophyllum peruvianum n.sp., and Retiophyllia pascoensis n.sp. In situ paleoecological associations of biostromes 1-10m thick occurring within bedded carbonate rocks of the Chambara Formation, reveal no evidence of reef development. The growth types of the corals and the fine-grained lithofacies of the enclosing rock types suggest shallow-water, low-energy settings on an extensive carbonate ramp. The composition of the fauna reveals some links to Cordilleran terranes of North America. Similarities exist with northeastern Oregon and western Idaho, Nevada, and northern California. Despite a degree of endemism, Tethyan relationships are indicated for 11 of the taxa. Of these, six coral species are restricted to the western Tethys. It is the first occurrence of the Alpine corals, Margarosmia charlyana (Frech) and Retiophyllia frechi (Roniewicz) in the Americas.</ABSTRACT>

32664 <TITLE>Mesozoic sponges of the Pucara group, Peru.</TITLE>
32665 <SOURCE>Palaeontographica A233, 1-6: 57-74.</SOURCE>
32666 <ABSTRACT>The Pucara Group of central Peru represents nearly 3,000 m of shallow-water carbonate deposition spanning from the Late Triassic to Middle Jurassic in time. The Upper Triassic carbonate rocks, the Chambara Formation, and the Jurassic units, the Aramachay and Condorsinga Formations, exhibit distinctive associations of sponges, which are described in this paper. From the Triassic succession of Huanincocha near the Lake Junin in central Peru three genera of inozoan sponges, including Eusiphonella, Corynella and Peronidella and two genera of sphinctozoan sponges, Amblysiphonella and Colospongia have been found. Amblysiphonella tubifera is described as a new species. A specimen of Colospongia was observed in the field but not collected. Jurassic sponges were collected from several localities southeast of the town of Cerro de Pasco in central Peru. The Carhuazcocha locality south of the town of Junin contains the most diverse sponge fauna including the following described taxa: Stellispongiella ? juninensis n.sp. Stellispongiella ? ramosa n.sp. Stellispongiella ? minor n.sp. Trammeria dendroidea n.gen., n.sp. Cornuaspongia longidepressa n.gen., n.sp. Cornuaspongia reticulata n.gen., n.sp. Neither the Triassic nor the Jurassic sponge associations of Peru, are known from other Triassic or Jurassic localities of the world.</ABSTRACT>

32677 <TITLE>Early Mesozoic carbonate rocks of the Pucara group in northern and central Peru.</TITLE>
32678 <SOURCE>Palaeontographica A233, 1-6: 1-32.</SOURCE>
32679 <ABSTRACT>From northern and central Peru 19 Triassic and Jurassic localities were investigated. Measured sections and collection sites yielded abundant and diverse groups of silicified fossils and carbonate microfacies from the Pucara Group, a carbonate rock unit exceeding 2,000 m in thickness which is well-exposed in the Peruvian Andes. Over eighty years of geologic investigation on the stratigraphy, ore deposits, and paleontology of the Pucara have resulted in biostratigraphic classifications, recognition of depositional

environments, correlations, age and stratigraphic framework, but study of many fossil groups has tagged behind. Fossils from previous investigations have not been precisely located and age-diagnostic fossils are usually scarce in the carbonate rock sequence of the Pucara. New fossils described from the 19 localities have helped in refining dating and correlations. The thick Pucara succession in Peru is important because relative to many other regions of the world, it records a fairly complete history of late Triassic to Early Jurassic rocks and fossils, including the Triassic-Jurassic systematic boundary. It also includes an extensive record of marine sedimentation along the Pacific Cordillera of South America. Abundant and diverse marine fossils of the Pucara Group include Upper Triassic (Norian) and Lower Jurassic (Hettangian - Sinemurian) tropical, shallow-water sponges, corals, spongiomorphs, calcareous sponges, gastropods, bivalves, ammonites, crinoids and echinoderms. Conodonts also occur in the Late Triassic portion of the sequence. Abundant shallow-water depositional environments, including small-scale coral, sponge and oyster biostromes characterize the sequence. The 19 localities and the measured sections described in this paper are utilized by most authors in this volume [to] designate their fossil material. </ABSTRACT>

32704 <SOURCE>N. Jb. Palaeont. Mh. 1986, 12: 736-750.</SOURCE>

32705 <ABSTRACT>Five hermatypic coral genera from the north Chilean Pre-Cordillera are presented; one of the species is probably new. The coral limestones mark the beginning of a transgression in the Bajocian. Except in boreal regions, the occurrence of hermatypic corals is world-wide in this period and indicates a warm and balanced climate. An unusual biogeographic phenomenon is the abundance of meandroid forms in N-Chile. The following genera and species are described: *Actinastrea* cf. *ramulifera*, *A. pentagonalis*, *A. ssp.*, *Dendrastrea langrunensis*, *Isastrea richardsoni*, *Microphyllia* cf. *pulchella*, *M. sp.*, *Latomeandra sp.*</ABSTRACT>

32716 <TITLE>Lower Jurassic marine carbonate deposits in Central Peru: Stratigraphy and paleontology.</TITLE>
32717 <SOURCE>Palaeontographica A233, 1-6: 43-56.</SOURCE>
32718 <ABSTRACT>Field investigation of Lower Jurassic rocks of central Peru belonging to the Condorsinga Formation near Manzanares, yielded a rich variety of carbonate microfacies with diverse invertebrate fossils including sponges, corals, brachiopods, echinoderms, molluscs, foraminifers, serpulid tubes, microcoprolites of crustaceans, and the probable crustacean trace fossils of Thalassinoides. Organic constructional microfacies were lacking and coarse to fine-grained, bedded carbonate rocks predominate. Locally five biofacies were delineated: 1) coral wackestone with solitary and colonial corals Stylophylloopsis, cf. S. victoriae, Stylophylloopsis sp. and Hispaniastraea ramosa, 2) thalamid sponge pelleted wackestone, characterized by large in situ *Stylothalamia*; 3) serpulid wackestone with in situ clusters of tubes, 4) bioturbated bioclastic pellet packstone, and 5) brachiopod packstone coquina. The microfacies types, fauna and flora indicate the presence of a broad carbonate platform (ramp) with much of the carbonate sediment deposited on the outer slope. Based on the Manzanares section, this platform was differentiated into subenvironments of low-energy, deeper water protected and more open, fairly agitated environments. Reef structures are absent. The invertebrate fauna bear similarities with taxa known from both the western Tethys and North America.</ABSTRACT>

32743 <SOURCE>Journal of Paleontology 58, 4: 1136-1142.</SOURCE>
32744 <ABSTRACT>During the Hauterivian-Barremian local coral biostromes, possibly patch reefs, developed within shallow marine lagoons fringing

Early Cretaceous volcanoes in Peru. The dominant coral is *Stylina columbaris* n.sp., which is similar to European stylinid species of Late Jurassic and Early Cretaceous age having sixfold septal plans. The biostrome is part of the Atocongo Formation, Lima Group, exposed at Perico Hill (Cerros Perico) about 95 km south of Lima. Only two other Lower Cretaceous stylinid corals have been described from South America.

32794 <TITLE>Prototethys: Fact or phantom? Palaeobiogeography in relation to the crustal mosaic for the Asia-Australia hemisphere in Devonian-Early Carboniferous times.</TITLE>
32795 <SOURCE>International Symposium Shallow Tethys 2: 87-111.</SOURCE>
32796 <ABSTRACT>More than 40 discrete crustal blocks (micro/mini continents, minor "suspect terranes"; excepted) delineated by ophiolite belts, major geosutures, flysch wedges and radiolarites can be identified in the Asia-Australia region. For the Palaeozoic, analysis has suffered from inadequacy of longitudinal constraints; this has led to important differences in models previously proposed for the dispositions and motions of island arcs and continental fragments, especially for pre-Permian reconstructions - the era of "Prototethys "; or the "Prehercynian Ocean";. The age of suturing of successive blocks can be shown to decrease in a general way from the Siberian Block towards the east, southeast and south. Prototethys (and its successor, Tethys) and the northern margin of East Gondwana changed markedly in configuration through Palaeozoic and early Mesozoic times as block after block moved northwards and then sutured with the enlarging Asian Block (Eurasian Block from Bashkirian times onwards). It is against this background that preliminary results for the biogeography of Devonian and Lower Carboniferous brachiopod faunas are presented. Not all blocks have adequate faunas for useful analysis. Those which do, show a greater level of provincialism, consistent with greater dispersion of blocks relative to one another, than might have been anticipated, especially if they are construed as having formed part of a single land-mass with open seaways which should have facilitated ease of interplay between shallow marine faunas.</ABSTRACT>

32807 <TITLE>Biostratigrafiya i Paleontologiya nizhnego Kembriya Sibiri. [Biostratigraphy and Paleontology of the Lower Cambrian of Siberia; in Russian]</TITLE>
32808 <SOURCE>Biostratigrafiya i paleontologiya nizhnego Kembriya Sibiri. Izdatiel'stvo Nauka, Sibirskoye Otdeleniye, Novosibirsk, volume 406.</SOURCE>
32809 <ABSTRACT>Volume with articles on : - morphology and systematic of the Erbcocyathacea (L.N. Kashina); - pathological reactions of Archeocyathan skeleton (A.Yu. Rozanov, R.A. Gangloff); - detailed subdivisions of some homological ranks in systematics of Archeocyatha (I.T. Zhuravleva). [unfortunately, these last two important works are inadequately revised, the number of misprints makes the translation particularly difficult; besides, too many inconsistencies can be pointed out (edelsteini listed as Alexandricyathus or Flexandricyathus within the same table (9 - Altai Sayan), turgidus as Porocyathellus or Kijacyathella pl. IX, 11 - pl. X, fig. 1-2; preoccupied names for genus: Porocyathellus and many variations on specific names within the diagnosis itself infinitus or infirmus etc.); definitions of most of the new genera is based on slight variations of porosity characters; this method seems dangerous to the reviewer and will soon lead the group to an useless inflation of taxa - as reviewed by F. Debrenne (?)]

- 32873 <SOURCE>Geology 23, 7: 649-652.</SOURCE>
- 32874 <ABSTRACT>The oldest sponge reef is a small Early Cambrian bioherm at the base of the Tomotian Stage (~535-540 Ma) in southeast Siberia. The mainly archaeocyath construction may be a response to turbid conditions. Cambrocyathellus bowls fused to create a rigid cavernous frame colonized by cryptic Archaeolynthus and calcified microbes (Renalcis). In addition to these constructors and binders, other reef guilds are present: bafflers (other archaeocyaths, spiculate sponges, and hyoliths) and dwellers (hyoliths, mollusks, and many others). This is the oldest known reef possessing an open skeletal frame structure built by animals and a mixed animal-autotroph composition. It provides a blueprint for younger Phanerozoic reefs.</ABSTRACT>

- 32885 <TITLE>Facial assemblages of Archeocyathids of the Lower Cambrian (middle course of Lena River).</TITLE>
- 32886 <SOURCE>In Problemy Biostratigrafii i Paleontologii nizhnego Kembriya Sibiri: 31-109; Izdat. Nauka, Moskva.</SOURCE>
- 32887 <ABSTRACT>The author studies the relationships between environmental facies and archeocyathids assemblages during the development of the basin of Lena River. She distinguishes the following facial types: (1) bioherms: a) isolated bioherms; b) massive bioherms; (2) biostromes; (3) taphostromes; (4) interbioherms: a) near the bioherms; b) far from the bioherms. * Steps are recognized for the evolution of the Basin - 4 main conclusions: - one cannot speak of the diminution of the thickness of the rocks at the East and an augmentation at the west, but only of local variations; - migrations of the assemblages are observed towards the East; - 3 main types of organic building are recognized (bioherms, biostromes, taphostromes); - the differences of complexity of the bioherms are not only due to their size or their duration but also to the environmental conditions. * This article is the first important attempt to point out the links between the different species of Archeocyathids, and the types of the rocks including them. The unsurpassed experience of the author concerning the phylum Archaeocyatha as well as the stratigraphy of Siberian platform make this article a precious guide for further studies in other regions. It shows clearly that Archaeocyathids are not only good biostratigraphical markers, but could be used for ecology and biogeography.</ABSTRACT>

32950 <TITLE>Cnidarian-like embryos associated with the first shelly fossils in Siberia.</TITLE>
32951 <SOURCE>Geolgy 27, 7: 609-612.</SOURCE>
32952 <ABSTRACT>Phosphatized spheroids 0.5mm in diameter in the Lower Cambrian Manykay Formation at the Bolshaya Kuonamka River in northern Sakha (Yakutia) are interpreted as cnidarian embryos of late developmental stages. One of the poles has a double cross-like structure, consisting of two sets of four bands each. The bands of the upper set radiate at 90° from each other; those of the lower set also radiate at about right angles from each other, but the set is rotated 45° in respect to the upper set. Although there is a resemblance to the cross-like arrangements of cells in pregastrulation spiralian eggs, in particular those of annelids, the combined evidence favors an interpretation of the bands as incipient tentacles of a cnidarian actinula larva. The embryos occur with one of the first assemblages of shelly fossils in northern Siberia, that of the Angustiochrea lata zone. The co-occurring shelly fossils, anabaritids, probably also represent the phylum Cnidaria, but because their tubes have a consistent triradial symmetry, the connection with the tetradially symmetrical embryos is problematic. The size of the embryos suggests that they are nonplanktrophic, and the presence of actinula-like features suggests the lack of a free planula stage.</ABSTRACT>

33068 <SOURCE>Paleontologicheskii Zhurnal 2001, 4: 11-15.</SOURCE>
33069 <ABSTRACT>For the first time, a large variety of Stromatoporoidea is recorded from the Ordovician of the southern facies zone of the Taimyr Peninsula. Seven new species and two new genera are described. The majority of Ordovician Stromatoporoidea have secondary tissue surrounding the vertical skeletal elements.</ABSTRACT>
33070 <FCnP>31-1, p. 72, ID=1653</FCnP>

following genera: (*) Tabulata - Nyctopora, Eocatenipora, Catenipora, Halysites, Cystihalysites, Agetolites, Paleofavosites, Priscosolenia, Multisolenia, Mesosolenia, Mesofavosites, Favosites (Favosites), F.(Sapporipora), Gephuropora, Parastriatopora, Syringopora, Fletcheriella, Cyrtophyllum, Sibiriolites; (*) Rugosa - Streptelasma, Crassilasma, Dinophyllum, Tungussophyllum, Holophragma, Miculiella, Ptychophyllum, Cyathactis, Neocystiphyllum, Palaeophyllum, Entelophyllum, Strombodes, Tryplasma, Ketophyllum, Dentilasma, Diplochone, Cyatiphyllum, Kymocystis, Holmophyllum, Nipponophyllum, Yassia.</ABSTRACT>

33119 <TITLE>Evolution of Stromatoporoidea in the Ordovician-Silurian epicontinental basin of the Siberian Platform and Taimyr.</TITLE>

33120 <SOURCE>Russian Geology and Geophysics 51: 684-693.</SOURCE>

33121 <ABSTRACT>Stromatoporoids were collected from 29 measured sections from along the Khakoma, Moiero, Moilerokan, Bugarikata, Yukkali, Bolshaya, and Parmaya Rivers. This paper does not include descriptions of the stromatoporoids, but rather notes the stratigraphic occurrence and evolutionary relationships of the genera present. The author notes that correlation of strata at the Siberian localities with the new Ordovician stages is fairly tentative; (p. 687). The emergence of new genera is noted by stage: * Darriwilian: Priscastroma, Cystostroma; * Sandbian: Stromatocerium, Rosenella, Lophiostroma, Pachystylostroma, Labechia; * Katian: Aulacera, Nestoridictyon, Stratodictyon, Stelodictyon, Ecclimadictyon, Dermatostroma, Taymyrostroma; * Hirnantian: Clathrodiction; * Aeronian: Clavidictyon, Plectostroma, Mamellolabechia; * Telychian: Stromatopora, Vikingia, Parallelopora, Neobeatricea, Yabeodictyon, Yavorskiina; * Sheinwoodian: Plexodictyon, Parallelostroma; * Gorstian: Hermatostromella. The author concludes that Ordovician stromatoporoid genera emerging in this basin indicate that the basin was one of the global centers of stromatoporoid origination.</ABSTRACT>

33134 <ABSTRACT>The author describes the successive change of life forms in the coral communities of palaeozoic seas, from Ordovician till Permian, based mainly on tabulate corals. Reef-type ecosystems are shown to possess all possible sets of life forms. Large cerioid coral colonies appear only in reef biocenoses. Silting leads to predominant

- distribution of ramose and phaceloid colonies that form settlements of the coral *meadow*; type.

33198 <SOURCE>Paleontologicheskij Zhurnal 1988, 2: 109-110.</SOURCE>
33199 <ABSTRACT>Some of the rugose corals from the Siberian Platform, investigated between 1950-1960, were clearly different from all rugosa known before, but material was too insufficient to establish new taxa. During the following years additional material could be collected which now gave new insights concerning the skeletal structure. Diagnoses of the new taxa are given. Tetrafossularia Ivanovskij gen. nov. (Densiphyllidae), type species Triplophyllum tetrafossulum Ivanovskij 1962; diagnosis: solitary corals with distinct fossulae between each of the protosepta; distribution: lower - middle Llandoveryan (Siberian Platform); Cereoelasma Ivanovskij gen. nov. (Cyathophylloidea), type species Cereoelasma sibirica sp.nov.; diagnosis: corallum cerioid, septa short, tabulae complete and incomplete, dissepiments sporadical or forming a narrow dissepimentarium, sometimes lonsdaleoid dissepiments may be developed; distribution wenlockian (Gotland, Podolia, Siberian Platform); Aphroelasma Ivanovskij gen. nov. (Phillipsastreidae), type species Frechastraea russakovi Spasskiy et Kravtsov 1975; diagnosis: aphroid Phillipsastreidae with short ripidacanth septa, small globose tabulae, one row of horseshoe-dissepiments is developed; distribution: Devonian, Emsian (Yakutia and Canada).</ABSTRACT>

33211 <SOURCE>Trudy Instituta Geologii i Geofiziki AN SSSR 353: 1-80.</SOURCE>
33212 <ABSTRACT>The work summarizes all known data of the Cystiphora Rugosae from North-East of USSR and of the Siberian platform. Terminology and Morphology, as much as evolution of Cystiphyllidae, during the whole of the paleontological history are considered. The common system for the Silurian and Devonian cystiphora is firstly given on the base of analysis of the morphofunctional patterns. The analysis of the stratigraphical and geographical spreading of these Rugosae and also of their monographical description is carried out. [described are representatives of the genera: Dentilasma Ivanovskij 1962 (D.

- honorabilis oris n.sp.); Diplochone Frech 1886; Cystilasma Zaprudskaya & Ivanovskiy 1962; Cystiphyllum Lonsdale 1839; Kymocystis Strelnikov 1968; Hedstroemophyllum Wedekind 1927; Holmophyllum Wedekind …]

- 33238 <ABSTRACT>Abundant and significant complex of favositids (23 species) and rugose corals (26 species) from the Lower Devonian of Yakutia is firstly described. The authors offer a new [insight] in detailed stratigraphic scale of these deposits. * Emsian - Krivorutchevskaya Formation: Subcladopora elegans, Caliapora parva; * Pragian - Nelitcheskaya Formation: Alveolitella crassicaulis, Subcladopora abnormis; * Pragian - Sagirskaya Formation: Yacutiopora fallacies, Y. irinae; * Lochkovian - Nelyuklinskaya Formation: Favosites socialis, F. admirabilis. The genus Victorilites elegans (Dubatolov) is established. Described are species of the genera: Tabulata: Favosites, Striatoporella, Victorilites, Squameofavosites, Pachypora, Striatopora, Subcladopora, Alveolitella, Scoliopora, Fainella, Coenites, Egosiella; Rugosa: Briantelasma, Breviphyllum, Pseudamplexus, Papiliophyllum, Thoulelasma, Acanthophyllum, Taimyrophyllum, Embolophyllum, Astrictophyllum, Spongonaria, Zelolasma, Bensonastrea, Aphroelasma, Exilifrons, Paradisphyllum, Aristophyllum, Hemiaulacophyllum, Zonophyllum, Cystiphyllodes, Microplasma, Stereophyllum, Digonophyllum.</ABSTRACT>

- 33342 <ABSTRACT>The dispersal of Tabulate corals in the Devonian seas of Siberia and contiguous realms was conditioned by paleo-geographical environment. In the Early Devonian between the seas of Altai-Sayan, Indigiro-Kolymian and Mongolo-Okhotsk provinces there were large geographical barriers, that made difficult the exchange of Tabulate species of adjacent seas. These conditioned sharp geographical differentiation of fauna. In the Middle Devonian the boundaries of the provinces became obliterate. It resulted in the fact that constant content of fauna in different basins was more uniform. Faunal integration continued up to the end of the Frasnian.</ABSTRACT>

- 33381 <ABSTRACT>Als Ergebnis der Untersuchung der Tabulata aus dem forlaufenden Profil am Taree-Fluss (Zentral Taimyr) lassen sich biostratigraphische Zonen und drei Etappen der Entwicklung der Tabulata, vor allem der Favositida, erkennen. Sie sind am zahlreichsten vertreten und unabhängig von wechselnden Sedimentationsbedingungen. Die Vertreter des Genus Parastriatopora sind an eine Küstenfazies angepasst. Aufgezeigt wird die charakteristische Zusammensetzung der Tabulata und die Morphologie der Favositida jeder Etappe. * Die Frage einer Revision der Grenze zwischen Unter- und Mittel-devon des Taimyr wird auf der Basis der Faunenevolution diskutiert. Die natürliche Grenze findet sich nicht im Hangenden der Taribichaiskiye Schichten, sondern vielmehr an deren Basis. An dieser Grenze erscheinen die Tabulata in weiter Verbreitung in benachbarten Becken. Dazu trug offensichtlich auch ein Wechsel paläoökologischer Bedingungen bei, wie die D.K. Patrynov feststellte.</ABSTRACT>

- 33472 <ABSTRACT>As a complement to the concise description of the sedimentology, paleoecology, biostratigraphy and paleomagnetism of Late Famennian and Tournaisian strata of the Omolon region (NE-USSR) which had been published in these Annales in 1983 by K.V. Simakov et al., a sedimentological and paleontological atlas of the same strata is presented here. The data published in these two papers serve as a basis for more detailed studies on the deposits of the Omolon area, which will be carried out in the forthcoming years. At the same time, these represent the preliminary results of the joint investigations carried out by a team of geologists from the USSR, Belgium and the Netherlands during the period between 1981 and 1984.</ABSTRACT>

- 33524 <ABSTRACT>A new genus Yakutophyllum (Rugosa) from limestones of Sette-Daban Range (Yakutia) is being described. This new genus contains four new species: Y. settedabanense, Y. grande, Y. pumilum, Y. elegans. It can conditionally be classed with the family Uraliniidae Dobrolyubova 1962 since this new genus shows great morphological similarities to some representatives of Yakutophyllum. The main differences to typical Uraliniidae can be seen in the continuation of a long major septa and the missing or a drastic reduction of the width of the dissepimentarium in the grown-up (ephebeical) stage of the coral development. 33574 <TITLE>Spicules analysis - the possible perspectives of its use for studies of bottom sediments in Lake Baikal.</TITLE>
33575 <SOURCE>Vth International Sponge Symposium, Brisbane [1998?]; poster. </SOURCE>
33576 <ABSTRACT>Sponges are beside diatoms, because of their wide spatial distribution in geological time, the only endemic species for paleostratigraphy in Lake Baikal. This poster presents first attempts in this field. * For a sure identification of species of baikalian sponges it is necessary to know the architectonics of their skeletons and the form of their spicules The difficulty: in Lake Baikal bottom sediments is that we have only isolated skeleton spicules. Therefore to identify the spicules in the sediments we compared photos of skeleton architectonics in recent sponges, their spicules and spicules of the sediments. It has been found that some species of baikalian sponges can be easily identified by their typical morphological and morphometric peculiarities of their spicules (B. robusta, B. recta, Rezinkovia sp., Swartschewskia sp.). The spicules of such species as B. intermedia, B. bacilifera, B. tenera, gen. Lubomirskia, are more variable, therefore the identification of these species by spicules is done with less trustworthiness degree. The use of this method has given a possibility to identify species composition of spongiofauna of Holocene-Pleistocene deposits of underwater Akademicheskii Ridge in Lake Baikal.</ABSTRACT>

33589 <ABSTRACT>This monograph deals with all the known data of solitary, monozonate corals from the Northeastern USSR, the Southern Verkhoyansk region and the Siberian Platform. Questions are discussed concerning the terminology, morphology and problems of the systematics of Streptelasmata, the history of investigations of this group, and the discussion of the taxonomic characteristics. A description of the fauna is given as well as a taxonomic scheme. Described are the following taxa: Kenophyllum subcylindricum Dybowski, Dalmanophyllum dalmani (Milne-Edwards et Haime), Densigrewingkia, Grewingkia contexta Neumann, Helicelasma whittardi Smith, Streptelasma corniculum Hall, S. cyrtum Neumann, S. obesa (Lindstroem), S. sibiricum (Nikolaeva), S. concavifundatum (Ivanovskiy), Crassilasma completum (Nikolaeva), C. simplex Ivanovskiy, C. crassiseptatum (Smith), Dinophyllum involutum (Lindstroem), D. apertum (Soshkina), D. brevisseptatum Ivanovskiy, D. bilateralicum n.sp., D. ambiguum n.sp., D. solidovolutus n.sp., Pseudophaulactis lycophylloides Zaprudskaya et Ivanovskiy, Povifirievella stokesi (Milne-Edwards et Haime), P. fossulatum (Ivanovskiy).</ABSTRACT>

33613 <TITLE>Dynamics of biodiversity of tabulatomorph corals of Siberia.</TITLE>
33614 <SOURCE>Russian Geology and Geophysics 39, 10: 1329-1365.</SOURCE>
33615 <ABSTRACT>Biodiversity of Devonian tabulatomorph corals of the Salair, West-Siberian, Taimyr, and Central-Siberian seas has been investigated for years. The data obtained demonstrate its significant variability. We have tentatively recognized periods of great and small biodiversity as well as borderlines at which the taxonomic diversity of tabulatomorphs either increased or decreased drastically. It is shown that in the Salair sea, tabulatomorphs were the most diverse during the Lochkovian, Emsian, and Givetian. The same stages are observed in the Altai sea, although the dynamics of tabulatomorph biodiversity was not so well-pronounced in the Lochkovian or Givetian. Biodiversity was little variable in the West-Siberian, Taimyr, and Central Siberian seas. In all Siberian seas, it reached its minimum in the Famennian. This was related to a change in the composition of predominant corals, when Thamnoporina and Alveolitina became extinct and gave way to Syringoporidae and Auloporidae. Of favositids, Micheliniidae and Cleistoporidae were of the greatest abundance.</ABSTRACT>

33678 <TITLE>Ediacarian sponge spicule clusters from southwestern Mongolia and the origins of the Cambrian fauna.</TITLE>
33679 <SOURCE>Geology 25, 4: 303-306.</SOURCE>
33680 <ABSTRACT>Carbon and strontium isotopic data are used to show that the earliest sponge spicule clusters and associated phosphatic sediments (with Anabarites) from southwestern Mongolia are of Ediacarian age. Spicule morphologies include bundles of oxeas arranged in three-dimensional quadrules, linked together at junctions by tetracts, pentacts, hexacts, or polyactines. All are referred to the phylum Porifera, Class Hexactinellida. These sponge spicules provide the oldest remains that can be assigned without question to an extant phylum, and also the first firm evidence for filter feeding and metazoan silica biomineralization in the fossil record. It is suggested that siliceous and phosphatic members of the [Cambrian fauna](#); may have had their origins in eutrophic and outer shelf facies of the Late Proterozoic.</ABSTRACT>

33692 <SOURCE>Nauka, Moskva</SOURCE>
33693 <ABSTRACT>Collective book comprising a paleontological description of fauna and flora present in beds of Upper Proterozoic and Lower Paleozoic. Archaeocyatha are present in Atdabanian and Botomian parts of the sections. 30 genera and 70 species are described. Some of them are new: 3 genera (Fonin 2, A. Zhuravlev 1) and 32 species (4 described by Voronin, 7 by A. Zhuravlev, 21 by Fonin). These studies give a base for biostratigraphic and paleogeographic reconstruction of the area, and propose distant correlation with other Cambrian regions, particularly Soviet Union and China.</ABSTRACT>

33731 <SOURCE>Trudy Paleont. Inst. AN SSSR 209; Nauka, Moskva; 144 pp.</SOURCE>
33732 <ABSTRACT>Monography in which 52 genera of taenialian Archaeocyatha are described, among them 28 new. Detailed analysis of each taxon is made in the point of view of its morphological characteristics, systematic position, ontogenetic evolution and stratigraphic position. The idea of the author concerning the splitting into two main groups of the Irregulares (Dictyonalia with rods and Taenialia with plates or pseudosepta) is here applied to Irregular Archaeocyatha with twisted plates. Revision of Soviet type-species has been carefully made, leading to a coming back of the genus Retecyathus versus Archaeocyathus on the base of its simple inner wall. Unfortunately the author has ignored the recent revisions of the western authors, and used wrong names (such as Flindersicyathus j. syn. of Pycnoidocyathus instead of Graphoscyphia) errors that will be unfortunately perpetuated in Russian literature. Nevertheless, it is a very valuable book, the first attempt to carefully investigate the generally neglected Irregulares.</ABSTRACT>

- 33797 <ABSTRACT>This second volume includes a revised comparative chart of zonal subdivisions; it is devoted to the biostratigraphy of the Kiya River Basin (Kuznetsk Alatau, Siberia) based on sponges with calcified skeleton such as archaeocyaths, and isolated spicules of siliceous sponges. Archaeocyaths described by the present authors belong to 4 orders, 50 families, 116 genera among them 11 new, and 280 species with 40 new. Isolated spicules are related to heteractinellid sponges and demosponges. [abstract of first part] * This paper follows two previous articles devoted to calcibionts, acritarchs, mollusks, SSF (Pospelov et al. 1995) and to a part of the archaeocyathan fauna (Zhuravleva et al. 1997). It includes a comparative chart of zonal subdivisions; based on sponges with calcified skeleton and spicular sponges and a biostratigraphic column, connecting this work to the global studies of the faunal assemblages of the Lower Cambrian Kiya River Section. 33860 <TITLE>Early Cambrian bioconstructions from the Zavkhan Basin, western Mongolia.</TITLE>
33861 <SOURCE>Geological Magazine 133: 429-444.</SOURCE>
33862 <ABSTRACT>The Neoproterozoic-Cambrian succession in the Zavkhan Basin of western Mongolia preserves Early Cambrian bioconstructions of Nemakit-Daldynian to Botomian age. As elsewhere (Siberia, Morocco), the older bioconstructions (upper Tsagan-Oloom to lower Bayan-Gol Formations = Namakyt-Daldynian) were purely calcimicrobial; in the upper Bayan-Gol Formation (?Tommotian), spectacular calcimicrobial reefs are present. In contrast, the Salaany-Gol Formation bioherms (late Atdabanian-early Botomian) are varied and well developed and included archaeocyaths and other metazoans as bioconstructors together with calcimicrobes. Three types of bioconstructions are recognized : 1) Gordonophyton-Razumovskia crusts supporting a cryptic community of corallomorphs, cribricyaths and archaeocyaths; 2) radiocyathan - archaeocyath bioherms; the abundant and diverse archaeocyath fauna served a binding function, while calcimicrobes were relatively minor; 3) calcimicrobial bioherms including layered fabric of intergrown erect bushes and rafts of calcimicrobes with associated oligotypic archaeocyaths and bioclastic debris. Comparisons with coeval bioconstructions of the Gondwana margins are made; among them, the Zavkhan Basin archaeocyathan - radiocyathan bioherms represent the moderate to high-energy spectrum with archaeocyaths, mud and cement dominant.</ABSTRACT>

33914 <ABSTRACT>The preface contains a brief stratigraphical introduction. The paleontological part describes new representatives of the family Proheliolitidae Kiaer 1899: Mongoliolites paradoxides n.gen. et n.sp., and of the family Billingsariidae Okulitch 1956: Transitolites hongorensis n.gen. et n.sp. The age of the new taxa is determined as Lower Ashgillian.</ABSTRACT>

33927 <ABSTRACT>From a section of Cangan-den the fauna of heliolitoid corals is described and data are given concerning the stratigraphical range of the forms. Variability and morphogenesis of the new genus Khangailites (subfamily Proheliolitinae) are discussed. The new genus Khangailites with the type-species K. heteromorphosus n.sp. as well as the species K. sinkiangensis (Yu) are described.</ABSTRACT>

- 34005 <ABSTRACT>Presented are descriptions of all taxa from genus to order levels of stromatoporoids, tabulates, heliolitids and rugosans from Ordovician, Silurian & Devonian deposits of Mongolia. Described are 23 orders, 82 families and 179 fossil genera. All major groups are supplied by short note of systematical position, morphology, ecology, biogeography and stratigraphic distribution. Each genus is with one illustrated species, and with a list of its other species recorded from Mongolia. The book contains also an index of latin names of taxa.</ABSTRACT>

34018 <ABSTRACT>This monograph includes an introductory section by several authors on the stratigraphy of the area. The general material on stromatoporoids by Bolshakova includes sections on Morphology, Methods of Study, Systematic Position, Paleogeology, Stratigraphic Occurrence, and Paleobiogeography. In the Systematic Section there are descriptions of 25 genera, and the plates illustrate 24 species of stromatoporoids. [comments by C.W. Stearn]</ABSTRACT>

34174 <ABSTRACT>The following new species are described from upper Wenlockian and Pridolian strata in the Abartkan Preserve: Ecclimadictyon abartkanica, E. irinae, Desmostroma fasciatum. In addition the new genus Faciledictyon (type species - Simplexodictyon torosum Lessovaya 1972) is established and two new species of the genus described F. olgae, F. nuratinia. The new genus is characterized by single laminae and separate pillars confined between two laminae, numerous astrorhizae of fistular type arranged in vertical systems with a common vertical canal, and compact microstructure. The genus ranges from Wenlockian to Lower Devonian. The genus includes F. simpex (Nestor) the type species of Petridiostroma Stearn.</ABSTRACT>

34252 <ABSTRACT>Stratigraphy and the Tabulata (62 species and subspecies, 13 of which are described for the first time) from the Silurian, the Lower Devonian and the Middle Devonian of Mongolia are presented. A new interpretation of classification and correlation of Silurian, Lower and Middle Devonian deposits of Mongolia, the Gobi Altai and the eastern part of the Gobi are discussed. By means of the Tabulata, local zonal differentiations can be undertaken which are compared with each other.</ABSTRACT>

34395 <ABSTRACT>In this monograph, a review of the Devonian stratigraphy of the Near-Balkhash and Djungarian Alatau is followed by a description of Tabulates and Tetracorals of that period. The analysis of corals rendered possible the division of the Djungaro-Balkhash Province into two paleobiogeographical regions, each having characteristic and correspondent complexes of genera and species. On the basis of the study of corals, the Early and Middle Devonian are subdivided each into three parts. The relationship of the Djungaro-Balkhash Province with adjacent territories is presented. The book is of interest to stratigraphers, paleontologists and geologists working in Kazakhstan and Central Asia.</ABSTRACT>

34471 <TITLE>Types of interactions in consortia of Baikalian sponges.</TITLE>
34472 <SOURCE>Bolletino Mus. Inst. Biol. Univ. Genova 68 [M. Pansini, R. Pronzato, G. Bavestrello & R. Manconi (eds): Sponge Science in the New Millennium]: 655-663.</SOURCE>
34473 <ABSTRACT>The composition of invertebrate communities inhabiting Baikalian sponges was studied. All the sponges examined were inhabited by invertebrates. Their number varied from 80 to 280 individuals per 100 cm³ of sponge, the biomass was found to be from 200 to 1020 mg per 100 cm³ of sponge. Twelve taxa: Turbellaria, Hirudinea, Nematoda, Oligochaeta, Polychaeta, Copepoda, Ostracoda, Isopoda, Amphipoda, Trichoptera, Chironomidae, Mollusca were found. There are two distinctive sets of species within the sponge consortia, which we designate as "specific" and "non-specific" ones. The latter differs in sponges sampled in different parts of the lake. The specific set consists of species, which are typical of all the sponge species sampled in different parts of the lake. The interaction between the sponges and the inhabiting invertebrates includes topic and trophic links. For most of sponge-dwelling invertebrates their interaction with the sponge is most likely to be as proto-cooperation (non-obligate co-existence), and for some species like Brandtia parasitica and Acanthocyclops spongicola as mutualism (obligate co-existence). 34484 <TITLE>Investigations on the endemic freshwater Porifera of Lake Baikal (Lubomirskiidae): status and perspectives.</TITLE>
34485 <SOURCE>Terra Nostra 2000, 9: 49-59.</SOURCE>
34486 <ABSTRACT>The endemic Porifera of Lake Baikal constituting the family Lubomirskiidae are comparably well investigated, but still there are many "white spots". This group is unique in its adaptation, both with respect to nutrition and reproductive strategies and also regarding its synecological significance. Particularly the genus Baikalospongia exhibits remarkable flexibility of its endosymbiotic relations, from autotrophic eucaryotes in the littoral to methanotrophic bacteria at thermal vents, and the role of these different symbiotic strategies are poorly investigated. So far, only one genetic analysis of Baikal sponges has been published, and the resulting phylogenetic tree rises more questions than answers. To clarify the phylogenetic relationships within the Lubomirskiidae, further genetic sequencing as well as intensive palaeoecological research of fossil spicule assemblages from drilling cores are necessary. First investigations of oxygene isotopes on spicules from recent Lubomirskiidae show the perspectives for a broader use of freshwater sponge spicules as a paleoclimatological indicator in limnic sediments.</ABSTRACT>

34497 <TITLE>Morphologie einiger Suesswasserporifera (Baikalospongia bacillifera, Lubomirskia baicalensis, Swartschewskia papyracea) des Baikal-Sees (Sibirien, Russland).</TITLE>
34498 <SOURCE>Berliner geowissenschaftliche Abhandlungen E13: 507-525.</SOURCE>
34499 <ABSTRACT>During a 9-day excursion at the beginning of September 1993 to Lake Baikal (Siberia) several samples of the endemic Baikal-sponges (Lubomirskiidae) Swartschewskia papyracea, Lubomirskia baicalensis, and Baikalospongia cf. bacillifera were collected and afterwards examined at histological and ultrastructural level. Special interest was focused on the morphology of choanocyte chambers and choanocytes, embryonal stages, larvae, spicules, and the contact between the substrate and the sponge. All choanocytes of the examined lubomirskiid species showed similar morphological patterns. The flagellum is located in a little pit and the kinetosome anchored with microtubules. In September Baikalospongia contained already fully developed parenchymellae, while Swartschewskia exhibited cleavage stages and Lubomirskia large oocytes only. Between sponge and substrate a biofilm-layer was detected.

34614 <TITLE>Cambrian anemones with preserved soft tissue from the Chengjiang biota.</TITLE>
34615 <SOURCE>Lethaia 38, 3: 193-203.</SOURCE>
34616 <ABSTRACT>The group Cnidaria includes 'jellyfish'; soft-bodied anemone and anemone-like forms and calcified corals. These diploblastic organisms have a fossil record extending back to the earliest metazoans of the Neoproterozoic; however certain cnidarians of the subclass Zoantharia, characterized by soft-bodied anemone-like forms, are absent or poorly represented in the fossil record. Despite the paucity of fossils, it is thought that calcification by soft anemone-like animals was responsible for producing the skeleton that allowed the preservation of the first corals. We report discovery of an abundant assemblage of in situ soft-bodied polyps with tissues. They are preserved in exquisite detail and come from the well-known Lower Cambrian Chengjiang biota of Yunnan, China. The soft-bodied polyps display a simple anatomy that is comparable to some extant anemones of the order Actinaria. The new fossils are assigned to Archisaccophyllia kunmingensis n.gen. et n.sp. Their simple and conservative form suggests that these fossils may represent some kind of ancestral rootstock. The preserved life assemblage provides a unique snapshot of Lower Cambrian anemone life and provides clues for relationships with extant actinarians as well as calcified corals.</ABSTRACT>

34627 <TITLE>Tiny sea anemone from the Lower Cambrian of China.</TITLE>

- 34628 <SOURCE>PLOS ONE 5, 10: e13276.</SOURCE>
- 34629 <ABSTRACT>Abundant fossils from the Ediacaran and Cambrian showing cnidarian grade grossly suggest that cnidarian diversification occurred earlier than that of other eumetazoans. However, fossils of possible soft-bodied polyps are scanty and modern corals are dated back only to the Middle Triassic, although molecular phylogenetic results support the idea that anthozoans represent the first major branch of the Cnidaria. Because of difficulties in taxonomic assignments owing to imperfect preservation of fossil cnidarian candidates, little is known about forms ancestral to those of living groups. * We have analyzed the soft-bodied polypoid microfossils Eolympia pediculata gen. et sp.nov. from the lowest Cambrian Kuanchuanpu Formation in southern China by scanning electron microscopy and computer-aided microtomography after isolating fossils from sedimentary rocks by acetic acid maceration. The fossils, about a half mm in body size, are preserved with 18 mesenteries including directives bilaterally arranged, 18 tentacles and a stalk-like pedicle. The pedicle suggests a sexual life cycle, while asexual reproduction by transverse fission also is inferred by circumferential grooves on the body column. * The features found in the present fossils fall within the morphological spectrum of modern Hexacorallia excluding Ceriantharia, and thus Eolympia pediculata could be a stem member for this group. The fossils also demonstrate that basic features characterizing modern hexacorallians such as bilateral symmetry and the reproductive system, have deep roots in the Early Cambrian. 34720 <ABSTRACT>The archaeocyath fauna collected in the lower Cambrian of
Yang Chang section (Yunnan) is studied in the light of a recent
revision of the Chinese collections. The composition of the fauna shows
that: 1) the two fossiliferous levels belong to one assemblage; 2) the
distribution of species is homogenous through SW and Central China; 3)
the archaeocyaths are Botomian in age, and no Tommotian archaeocyaths
are known in China to-date; 4) palaeogeographic relationships exist
between China, Altay Sayan, South western Europe and possibly Australia.

</TITLE>
34732 <SOURCE>Tikhookeanskaya Geologiya 14, 2: 62-67.</SOURCE>
34733 <ABSTRACT>Analysis of time of appearance and disappearance of
morphological characters of Siberian and Far-East archaeocyaths
establishes that their rate of evolution is significantly different.
The first stages were slower in Far-East paleobasins and continued up
to the Early Botomian, while the acme was short and limited to the
Middle Botomian. Nevertheless most of the morphological characters
chosen have no systematic significance; the problem of heterochrony
between Siberia and Far-East, a very interesting problem, was neither
well explained nor interpreted properly, even in the two following
abstracts presented at the International Symposium "Ecosystem
Evolution" Moscow, RAS, 1995 and in Madrid at the Cnidaria
Symposium, 1995, in which Belyaeva put forward the action of
environment and particularly volcanism as factors influencing the rate
of archaeocyath morphological evolution.</ABSTRACT>

34836 <SOURCE>Acta Palaeontologica Sinica 28, 1: 17-32.</SOURCE>
34837 <ABSTRACT>The sponges of the Lower Cambrian Chiungchussu Formation in Chengjiang, Yunnan are of unique importance in early history of sponges. At least 11 genera and 20 species have been found, forming the second most diversified metazoan group in Chengjiang. A majority of the sponges belong to the Demospongiae with a broad spectrum of morphological variation and sizes.- They were embedded in the mudstone layers of the lower part of the Yuanshan Member. This member is the unit representing the upper part of the Chiungchussu Formation. Stratigraphically the fossils in our study range in a narrow interval dated as the lowest Eoredlichia Zone in the trilobite sequence. [fragment of extensive summary]</ABSTRACT>

34848 <TITLE>New Lower Cambrian Demosponges - Quadrolaminiella gen. nov. from Chengjiang, Yunann.</TITLE>
34849 <SOURCE>Acta Palaeontologica Sinica 29, 4: 402-414.</SOURCE>
34850 <ABSTRACT>Although isolated spicules of sponges are known, virtually in all continents with greatly abundant Lower Cambrian rocks, the preservation of verified articulate skeletons is extremely rare in the past records. The Chengjiang Lagerstätten is of special importance in fossil sponge studies for the record of its older age and the excellent preservation. Because of the biased preservation, the knowledge of Lower Cambrian sponges has been heavily dependent on the isolated spicules which are largely known as isolated stauractines, and which have led to assumption by various authors that sponges in Early Cambrian had a limited diversity, consisting largely of Hexactinellid protosponges with a few rare demosponges. On the contrary, a supported evidence from Chengjiang Lagerstätte suggest that the sponges, particularly Demospongiae in the Early Cambrian Chiungchussu stage underwent very rapid diversification which led to many indefinite morphologic types, with an evolutionary complexity which might stand comparison with those of the Middle Cambrian Burgess Shale. The striking similarity of the sponge fauna between the Chengjiang Lagerstätten and the Burgess Shale suggest that sponges have retarded their evolutionary pace from the Chiungchussu stage for at least a period of 30 Ma. Among the demosponges, Leptomitus has a simple and thin double-layered skeleton and stratigraphic lowest occurrence which have led to assumption as the central stock of the Demospongiae. Fossil evidences indicate that many elements of demosponges have adopted from Leptomitus a virtually unchanged pattern of double-layered skeleton. None of multiple-layered skeletons have been known among the Cambrian sponges apart from the present new genus Quadrolaminiella. This new form is characterized by a unique four-layered and double-netted skeleton. The outer net consists of the 1st (outermost) and the 2nd layers of oxeads, which extend parallel and vertical to the length of the sponges respectively; inner net formed by the 3rd and 4th layers, extending upward diagonally clockwise and counter clockwise respectively. Quadrolaminiella might have derived from Leptomitus as if it had development a thicker skeleton with an additional inner net. All the specimens available for the present studies were collected from Quarries M3 and CF5 on the W and NW slopes of the Maotian hill, about five km SE of Chengjiang. They were embedded in the mudstone layers in the lower part of the Yuanshan Member, a unit representing the upper part of the Chingchussu Formation. Biostratigraphically the specimens under study range within a narrow interval dated as the lower Eoredlichia zone. [fragment of extensive original summary]</ABSTRACT>

34861 <TITLE>Hexactinellid Sponges from the Early Cambrian Black Shale of South Anhui, China.</TITLE>
34862 <SOURCE>Journal of Paleontology 79, 6: 1043-1051.</SOURCE>

- 34863 <ABSTRACT>Three new and one completely preserved species of hexactinellid sponges are described from Early Cambrian black shales of South Anhui, China. The sponges occur in the middle part of the Huangboling Formation, which is assigned to the early Canglangpuian based on trilobite biostratigraphy. *Metaxyspongia skelidata* n.gen. and sp. and *Hexatractiella dongzhiensis* n.sp. are subcylindrical thin-walled Protospongiidae. *Ratcliffespongia multiformina* n.sp. is assigned to the Hintzespongiidae. With these new sponges, the first occurrences of the Protospongiidae and Hintzespongiidae, and of *Hexatractiella* Mehl, 1996, can be traced back to the Early Cambrian. *Solactiniella* cf. *plumata* Steiner et al., 1993, with irregular rossellimorph skeletal architecture and regular spicular organization, is found here associated with the above species. Thus, the Anhui assemblage can be considered as intermediate between Atdabanian shallow-water communities of hexactinellids with irregular skeletons and the Middle Cambrian deepwater sponge facies characterized by regularly organized Hexactinellida.</ABSTRACT>

- 34876 <ABSTRACT>The assemblage of demosponge and hexactinellid sponges described here was collected from the Lower Cambrian, Atdabanian, Yu 'anshan member of the Chiungchussu Formation, at the Maotianshan and Xiaolantian sections in Chengjiang County, Yunnan Province, 70km southeast of Kunming. The sponges occur in relatively massive to weakly graded-bedded, grayish-yellow mudstone and silty mudstone. They are associated with other soft-bodied and skeletonized fossils. The new demosponge species and genera *Choiaella radiata*. *Allantospongia mica*, and the questionable sponge *Parvulonoda dubia* are described, along with new specimens of *Leptomitrus teretiusculus* Chen, Hou & Lu 1989, the hexactinellid sponge, *Triticispongia diagonata* Mehl and Reinter 1993 and the probable hexactinellid sponge. *Saetaspongia densa* Mehl & Reinter 1993. The sponges occur in what may be distal turbidite deposits, and they may have been buried essentially in situ by these argillaceous accumulations.</ABSTRACT>

- 34900 <TITLE>Early Cambrian Medusae from Chengjiang, Yunnan, China.</TITLE>
- 34901 <SOURCE>Acta Palaeontologica Sinica 26, 3: 257-270.</SOURCE>
- 34902 <ABSTRACT>This paper presents a preliminary report on the highly diversified and beautifully preserved medusoid fossils recently discovered from the Lowermost Cambrian Yuanshan Member of the Chungchussu Formation at Mt. Maotian-shan, Chengjiang County, eastern Yunnan, southwestern China. The specimens are moulds and casts of medusa body impressions, which were compressed into very thin discs or completely flattened into films between the bedding planes of shales and mudstones. They are accompanied by abundant and varied, soft-bodied and also shelly metazoans including sponges, annelids, brachiopods, gastropods, hyolithids, bradoriids, trilobites and other arthropods, etc. in the same assemblage, i.e. the Chengjiang fauna. The rock sequence of this fauna is marked by the Parabadiella Zone just at the bottom and bracketed within the lower part of the succeeding Eoredlichia-wutingaspis Zone. These two trilobite zones represent the very early Cambrian Chungchussu Stage, which was immediately predated by the Precambrian-Cambrian transition of the Meishucun Stage. * The medusoid fossils constitute a prominent part of the Chengjiang fauna. Four new genera and species are described here, including the hydrozoan *Heliomedusa orientalis* gen. et sp.nov., the chondrophoran *Rotadiscus grandis* gen. et sp.nov. and the scyphozoan *Stellostomites eumorphus* gen. et sp.nov. and *Yunnannomedusa elegans* gen. et sp.nov. * The medusae in the Chengjiang fauna represent the genuine medusoid fossils first discovered in China and the only known medusae occurring in the basal Cambrian of the world. The diversification of these new medusae can be traced back to their ancestors in the latest Precambrian Ediacara fauna in South Australia, providing remarkable evidence for a continuous metazoan evolution across the crucial Precambrian (Proterozoic) - Cambrian (Phanerozoic) boundary [fragment of extensive summary].</ABSTRACT>

- 34914 <SOURCE>Geological Society of America, Abstracts with Programs 37, 7: 486.</SOURCE>
- 34915 <ABSTRACT>The celebrated Early Cambrian Chengjiang biota of southwestern China has yielded some exquisite and extraordinary

fossils. These fossils have provided important and unparalleled insights into the biology, taxonomic diversity and nature of the Cambrian explosion. While arthropods and other hard-shelled fossils are well known, considerable soft-bodied components of this biota also have been discovered. Among these newly discovered taxa are a whole assemblage of in situ anemones preserved on the bedding surface, replete with attachment disc, column, tentacles and crown. Also found are an abundance of possible hydroids on the bedding planes. Extremely fragile gelatinous taxa belonging to the phyla Cnidaria and Ctenophora are present as well. Pelagic taxa among the gelatinous biota include a possible jellyfish-like siphonophoran with tentacles and gonozooids and also several examples of ctenophores. The ctenophores are the oldest yet known. They are easily recognized as ctenophores because they still retain their eight comb-rows, cilia plates and associated gelatinous soft tissues. Compared to some other soft-bodied taxa, they are unique in preserving details of the delicate soft tissues and gelatinous material of the original living organisms. These fossils also provide valuable information on anatomy and body organization, connecting these 530 million-year old organisms with their distant living relatives. The striking degree of anatomical similarity at high taxonomic levels between some of these Early Cambrian taxa and their extant counterparts, hints at a much older origin in the late Precambrian for the ancestors of these groups.

34926 <TITLE>Sponge fossil assemblage from the Early Cambrian Hetang Formation in southern Anhui.</TITLE>

34927 <SOURCE>Chinese Science Bulletin 49, 15: 1625-1628.</SOURCE>

34928 <ABSTRACT>Abundant well-preserved large articulated sponge fossils and isolated spicules have been reported from Early Cambrian Hetang Formation, southern Anhui Province. This unique epifaunal fossil assemblage dominated by articulated sponge fossils is called the Xidi Sponge Fauna. The sponge fauna lived in a quiet oxygenic environment below the storm wave base. Bloom of phytoplankton and rapid sedimentation rate resulted in the deposition of the black shales. Sufficient food supply, lack of other competitors, abundant ecological niches, and demand for oxygen during early Cambrian were in favor of the diversification and evolution of large sponges in the Early Cambrian.</ABSTRACT>

34939 <TITLE>Middle and Late Cambrian sponge spicules from Hunan, China.</TITLE>

34940 <SOURCE>Journal of Paleontology 70, 2: 173-184.</SOURCE>

34941 <ABSTRACT>Abundant and well-preserved assemblages of disarticulated sponge spicules occur in Middle and Late Cambrian platform carbonates

of western Hunan, China. Assemblages recovered from 11 stratigraphic horizons include calcisponges, demosponges, and hexactinellids. Hexactinellida, in particular, are both abundant and diverse in Upper Cambrian carbonates. Comparison with spicule assemblages from Australia indicates that many of these taxa have long stratigraphic ranges, limiting their use in correlation. The morphological diversity of these spicules exceeds that known for living siliceous sponges, supporting the observation that during the Cambrian radiation, sponges, like other metazoans, evolved a variety of architectural forms not observed in later periods. Like conodonts, individual sponges can produce more than one spicule form; thus, an *apparatus* genus concept based on multiple cooccurring elements may eventually prove useful in the biostratigraphic and paleobiological interpretation of disarticulated sponge spicules. Four distinctive forms are recognized as new taxa. *Australispongia sinensis* new genus and species, *Flosculus gracilis* new genus and species, *Pinnatispongia bengtsoni* new genus and species, and *Nabaviella paibiensis* new species.

 34953 <SOURCE>Berliner geowissenschaftliche Abhandlungen E09: 293-329.</SOURCE>
 34954 <ABSTRACT>A facies reconstruction and correlation of Upper Sinian - Lower Cambrian strata of the Yangtze platform (South China) is presented. Protected basin, uplift and deep basin development may be distinguished. The Lower Cambrian black shale transgression, the *Badaowan* Event, is characterized as diachronous. As a result of these investigations of lithology and geochemistry of the Lower Cambrian sediments (mainly black shales of the Sansha section, near Dayong, N. Hunan), sediments deposited under partially anoxic conditions or in a stagnant basin have been recognized. * Sponge spicules are widely distributed in the lowermost Lower Cambrian of Central China. Recently discovered more or less complete sponges, including *Sanshadictya microreticulata* gen. et sp.n., *Triticispongia diagonata* gen. et sp.n., *Solactiniella plumata* gen. et sp.n., *Huanospongia* sp. Qian & Ding 1988, Hexactinellida indet., a questionable demosponge, *Saetaspongia densa* gen. et sp.n., and the Malacostraca *Perspicaris* sp., and an unnamed alga are described. Sponge spicules additionally were found in rocks of the Shibantan Mb. (Dengying Fm., Upper Proterozoic) from the road section of Liantuo (near Yichang, S. Hubei province). The fauna of mainly hexactinellid poriferans from Sansha is discussed with regard to the similar taphonomy of the sponge faunas from the Red Hills Quarry (Middle Devonian of Nevada) and from the Arnagar limestone (Cretaceous, Bornholm).</ABSTRACT>

34966 <SOURCE>Journal of Paleontology 64, 1: 26-30.</SOURCE>
34967 <ABSTRACT>Blastulospongia is an enigmatic siliceous fossil with affinities proposed amongst both the sphinctozoan-grade sponges and radiolarians. Blastulospongia polytreta n.sp. extends the record of this genus into the Lower Cambrian (Shuijingtuo Formation) and represents its first occurrence in China (Taishanmiao section, Hubei Province). It differs from previously described species in size and pore spacing. The first evidence for benthic attachment is presented. A relationship with sphinctozoan-grade sponges is considered unlikely, but firm support for a place in the radiolarians is lacking.</ABSTRACT>

35096 <SOURCE>Science Press, Beijing; xvii + 391 pp., 41 figs., 67 t'bls., 81 pls. [in Chinese, with English summary]</SOURCE>
35097 <ABSTRACT>This book is an outcome of a collective research on the subject of the authors. The contents include two parts. Part I contains nine chapters and deals mainly with the skeletal structures and classification of the Palaeozoic corals. The first chapter is introductory. The main theme of this work is to investigate the minute skeletal structures and to attempt a revised classification on that basis, especially of rugose corals. This forms the content of chapter 2. Two different kinds of primary skeleton, the lamellar skeleton characterized by calcite flakes and the fibrous skeleton dominated by calcite needles or fibres, may be distinguished in Rugosa, Tabulata and also in Heterocorallia. The skeletal structure of the Rugosa is the most interesting and complicated. Altogether 75 genera of Rugosa, 24 of Tabulata and one of Heterocorallia are studied by SEM method, and the photographs are illustrated in 73 plates out of the 81 in total. [introductory part of the extensive English summary]</ABSTRACT>

35108 <TITLE>Additional list of Palaeozoic corals from Middle Asia and bibliography.</TITLE>
35109 <SOURCE>FC&P 24, 1: 42-47.</SOURCE>
35110 <ABSTRACT>My recent paper (Leleshus 1994: Fossil Cnidaria & Porifera 23, 1.1: 42-46), contains a list of Palaeozoic corals of Middle Asia and the names of paleontologists who studied these corals during the second half of the 20th century. I am very sorry, that the names of paleontologists G.M. Gataulina, V.V. Ogar, M.G. Sladkovskaya and Wu Din Li are missing. * This report gives the names of the missing genera, the corrections of mistakes and a bibliography. Here, only those publications are given, which are not present in the Bibliographical Guidebook by A.B. Ivanovskiy (editor-in-chief), 1973, History of investigation of Palaeozoic corals and stromatoporoids (286pp; Nauka, Moskva), as well as in the informational report (Leleshus 1994: The Study of Fossil Cnidaria and Porifera in Tajikistan.- Fossil Cnidaria & Porifera 23, 1.1: 38-41).</ABSTRACT>

- 35162 <ABSTRACT>Stromatoporoids are described from Middle Ordovician, Upper Ordovician, Middle-Upper Silurian, Middle Devonian, and Lower Carboniferous rocks. New species of the following genera are described: Amphipora (2), Clathrodictyon (2), Cliefdenella (6), Ecclimadictyon (2), Intexodictyon (1), Labechia (12), Paramphipora (1), Plectostroma (1), Pseudolabechia (7), ?Stictostroma (1), Syringostromella (1), Tuvaechia (3). The new genus Tianshanostroma of the Idiostromatidae is described. 31 other species are also described. The Carboniferous species of Pseudolabechia is listed as of Visean age.</ABSTRACT>

- 35187 <SOURCE>Contributions to Geology of the Qinghai-Xizang (Tibet) Plateau 16: 107-114.</SOURCE>
- 35188 <ABSTRACT>The Palaeozoic tabulate Corals of Qinghai Province can be subdivided into 5 assemblage zones as follows: (1) Foerstephyllum golmudense - Rhabdotetradium qinghaiensis - Neoplasmoporella golmudensis assemblage zone; (2) Agetolites - Wormsipore - Plasmoporella assemblage zone; (3) Fistulimurina compacta - Cladochonus - Kueichowpora assemblage zone; (4) Cystomichelina qilianensis assemblage zone; (5)

Qinghaipora titnjunensis - Sinopora dendroides assemblage zone. Zones 1 and 2 are of Late Ordovician; zone 3 is of Late Early Carboniferous; zones 4 and 5 are of Early Permian. The descriptions of 5 species collected from upper part (Visean) of Lower Carboniferous near Mahai of Da qaidam are given: Multithecopora ? qinghaiensis Lin, sp.nov., Syringopora pseudodistans Lin, sp.nov., Cladochonus socialis Sokolov, Fistulimurina compacta Sokolov, Pentaphyllia gracilis Lin, sp.nov.

35199 <TITLE>Some Palaeozoic Tabulate corals from Northern Xinjiang.</TITLE>

35200 <SOURCE>Palaeozoic Fossils of Northern Xinjiang, China [Nanjing University Press]: 187-269, 15 figs, 26 pls.</SOURCE>

35201 <ABSTRACT>Northern Xinjiang is subordinate to Palaeozoic Tianshan-Hinggan geosynclinal area. Coral faunas, especially those of Palaeozoic. Are well-developed in many rock formations. The Ordovician to Devonian tabulate corals from northern Xinjiang represent the geosynclinal faunas in North China, which are different from the faunas from South China in their assemblages and some structural features of corallites. In general, wall and septal component of corallites from geosynclinal faunas in North China are more varied than those of corallites from platform faunas in South China. The species of tabulate corals described in this paper amount to 58 species, including 21 new ones, which belong to 28 genera (3 of them are new). Their geographical and stratigraphical distributions are indicated, and features of some tabulate corals from Northern Xinjiang are briefly discussed.</ABSTRACT>

35278 <SOURCE>Neues Jahrbuch fuer Geologie und Palaeontologie, Abhandlungen 233, 3: 351-368.</SOURCE>
35279 <ABSTRACT>The Paleozoic sequences of the Padaukpin area of the Northern Shan States (Union of Myanmar)and the Baoshan region in Western Yunnan (P.R. of China) are compared. They show many similarities. A hiatus in sedimentation during the Carboniferous is developed in both regions and is therefore of regional importance. The Middle Devonian rugose coral fauna of both regions are typical for the Old world Faunal Realm and especially corals from the Padaukpin area (Northern Shan States), show strong affinities to the Rhenish faunas from the German Eifel Mountains. while the "pebbly mudstones" of Lower Permian age from the Baoshan region are usually discussed in the literature as glaciomarine deposits, similar strata in the Shan States are described as oligomictic conglomerate facies at the base of the Thitsipin Limestone Formation.</ABSTRACT>

35330 <SOURCE>Science Press: 454 pp., 66 figs, 202 pls; Beijing.</SOURCE>
35331 <ABSTRACT>This monographic treatment in the Chinese language of Cambrian through early Jurassic stratigraphy and paleontology provides illustrations and terse descriptions of more than 1,000 genus-group taxa (121 new) and nearly 1,500 species-group taxa (682 new). Newly named genus-group taxa were proposed for the archaeocyathids (Chengkoucyathus), graptolites (Hunanodendrum, Paraorthograptus, Pararetiograptus, Retioclimalis, Sinoretiograptus), and corals (Antheria, Densiphyllodes, Digonoclisia, Dushanophrentis, Nephelophyllum, Ningqiangophyllum, Pilophylloia, Qianbeilites, Shensiphyllum, xystiphyllodes). * Among the Archaeocyatha 1 of 11 genera is listed as new and 7 out of 11 species are considered new. Among the Graptolites 5 of 56 genera and 33 out of 106 species are considered new; for stromatoporoids the numbers are 10 genera (none new) and 4 out of 11 species considered new; for corals 10 out of 110 genera and 63 out of 126 species are presented as new. [this volume has been reviewed by Jeffords & Wilde in Journal of Paleontology 50]</ABSTRACT>

35343 <SOURCE>Academia Sinica Press, Nanjing: 423 pp., 175 pls.</SOURCE>
35344 <ABSTRACT>China is one of those countries that are extremely rich in stromatoporoids fossils in the world and has a history of over 60 years in the study of stromatoporoids fossils although there are only very few scholars engaged in the research on them. In this book a thorough, systematic, and intensive summary of the stromatoporoids found in China is made and serious and systematic amalgamation and revision of over 1100 species of stromatoporoids which have been described are also made. A total of 726 species and 97 genera are described herein, of which 78 genera and 675 species are of Paleozoic age and 19 genera and 51 species are Mesozoic in age. [first part of extensive summary presented on-line at <http://www.hceis.com/book.asp?ID=0818> by vendor of this book]</ABSTRACT>

35395 <SOURCE>Nanjing Institute Geology Paleontology, Academia Sinica 8: 305-322.</SOURCE>
35396 <ABSTRACT>This paper deals with Middle-Upper Ordovician corals collected in 1977 from the marginal areas of the Ordos Platform, mainly in Mt. Zhuozi of Nei Mongol, Long Xian and Yao Xian of Shaanxi province. The corals were found in association with brachiopods, trilobites, conodonts and graptolites. They include Rugosa, Tabulata and Heliolitida, 9 genera and 18 species in all, occurring in the following formations: Mt. ZhuoziThe Sheshan Formation (O3): Amsassia sheshanensis sp.nov.; Long XianThe Beigoushan Formation (O3 + O1): Catenipora distincta sp.nov., C. sp., Palaeophyllum thomi simplex subsp.nov.;The Longmendong Formation (O1 + O3): Catenipora inclinata sp.nov., Favistina midiana sp.nov., F. longxianensis sp.nov., F. pachythea sp.nov., F. sp.; Yao XianThe Taoqupo Formation (O3): Favistina formasa sp.nov., F. dybovskii Soshkina, F. sp., Catenipora subovata C.M.Yu, Plasmoporella convexotabulata maxima C.M.Yu, P. arcatabulata Bondarenko, P. affff. granulosa Bondarenko; JingyangThe Taoqupo Formation (O3): Rhabdotetradium jingyangense sp.nov., Heliolites aff. tashanensis Lin et Chow, Hormsipora simplex sp.nov., Favistina arcata sp.nov., F. strigosa sp.nov., F. ssp.Among corals, Agetolites, Amsassia, Rhabdoterium, Catenipora, Heliolites, wormsipora and Plasmoporella are characteristic forms in the Middle-Upper Ordovician of South China. Most remarkably, Favistina is very abundant in these areas but entirely absent in South China.</ABSTRACT>

35434 <SOURCE>Acta Palaeontologica Sinica 26, ??: 616-625.</SOURCE>
35435 <ABSTRACT>The coral-bearing strata from Shiyanhe of Xichuan county, Henan, are grey, thick-bedded limestones of the Shiyanhe Formation, and the coral assemblage contains such species as *Agetolites rariseptatus* Lin et Chou, A. cf. *raritabulatus* Lin, *Agetolitella tashanensis* henanensis subsp.nov., *Lyopora blanata* sp.nov., *Calapoecia anticostiensis xichuanensis* subsp.nov., *Paracorrugopora shiyanheensis* gen. et sp.nov. and *Favistina* aff. *shifosiensis* Cao. Correlation of the coral assemblage with those from southeast China leads to the conclusion that the coral-bearing horizon should belong to the Late Ordovician, approximately corresponding to the early Ashgillian stage of Europe. 35499 <SOURCE>Izvestiya Akademii Nauk Tadzhikskoy SSR, otdieleniye biologicheskikh Nauk 72, 3: 85-93.</SOURCE>
35500 <ABSTRACT>Separation of the family Plasmoporellidae is precisely evidenced. The appertaining genera, one of which is new, are characterized. The phylogenetic relation of the family Plasmoporellidae with other groups of the Heliolitoidea could be revealed. The following genera are described: Granulina Leleshus 1975; Voruporella Ospanova n.gen.; Plasmoporella Kiaer 1899; Proporella Leleshus 1975; Acdalopora Bondarenko 1958 - these order agrees with the phylogenetic development [?]. Diagnosis of Voruporella: corallum spherical, boil-shaped.

- Corallite walls thick, consisting of twelve closely adjacent trabecula-like vertical small columns. If wall thickness is uniform, the trabeculae appear slightly conical or rectangular in transverse section; if thickness changes, the trabeculae show a conical or oval shape. Trabeculae are also found in the coenenchyme. The vesicles of the coenenchyme are elevated. *Plasmoporella crassa* Kovalevskiy 1964, from the Upper Ordovician (Ashgill) from Kazakhstan and Central Asia is the type species.

35526 <ABSTRACT>From the Upper Ordovician beds of the Zeravshan-Gissarskye area the new genus *Acdalina* with the type species *A. mutata* n.sp. is described as well as the new species *Propora ornata* n.sp.. Biostratigraphic characteristics of Upper Ordovician corals from Central Asia are discussed. The new genus shows great affinities to *Acdalopora* but can be distinguished by the presence of interrupted walls, strongly developed coenenchyme, existence of vertical rods and short coenenchymal tubes. A difference between these two genera is very great in the early stages of growth but there is a great affinity of *Propora* to *Acdalina*. But in *Propora* convex dissepiments and other characteristics have developed.</ABSTRACT>

35589 <TITLE>Lower Ordovician Lithistid Sponges from the Eastern Yangtze Gorge Area, Hubei, China.</TITLE>
35590 <SOURCE>Journal of Paleontology 71, 2: 194-207.
<http://www.jstor.org/pss/1306456></SOURCE>
35591 <ABSTRACT>A moderately diverse assemblage of anthaspidellid demosponges has been recovered from reef-bearing carbonate platform deposits of Early Ordovician, Tremadoc to early Arenig age, in Hubei Province. The sponges occur, in part, in the Tremadoc Fenxiang Formation and, in part, in the lower Arenig Honghuayuan Formation at several localities near Yichang, Xintan, and Liujiachang. Archaeoscyphia nana Beresi and Rigby 1993, Archaeoscyphia pulchra (Bassler 1927), and Archaeoscyphia minganensis (Billings 1859) occur with the new genera and species, Jianghaniania yichangensis and Velellospongia adnata, and the new species Rhopalocoelia sanxiaensis and Anthaspidella lamellata. This is the first reported occurrence of Anthaspidella in Ordovician rocks of China. Great numbers of these species of fossil sponges have been found in Lower Ordovician outcrops, particularly in the eastern Yangtze Gorge area of Hubei Province.</ABSTRACT>

35615 <TITLE>New material of rugose corals from the uppermost Ordovician (Hirnantian) in northern Guizhou and their geological significance.
</TITLE>
35616 <SOURCE>Acta Palaeontologica Sinica 45, 3: 293-310.</SOURCE>
35617 <ABSTRACT>The latest Ordovician (Hirnantian) rugose coral fauna from the Guanyinqiao Beds in Bije, Remhuai and Shiqian districts of northern Guizhou are studied in detail, and some genera and species are reviewed. 4 genera and 2 species of rugose corals are reported from the Guanyinqiao Beds in northern Guizhou for the first time, they are Axiphora, Bodophyllum, Dalmanophyllum, Leolasma, Brachyelasma unicum (Neuman), and Grewingkia anguinea (Scheffen). In the past, quite a number of rugosan taxa, including the genera Borelasma, Kenophyllum and Ullernelasma, etc. had been discovered in the Guanyinqiao Beds (He 1978, 1985). The present new material thus further enriches the content of the latest Ordovician (Hirnantian) rugosan fauna in the Upper

Yangtze region and indicate the close affinities of the late Ordovician rugosan faunas in the Yangtze region to those of the Scandinavia and central Asia. Up to now, totally 39 species of 18 genera have been found from the Guanyinqiao Beds (tab. 1). Among them, 12 species of 10 genera of rugosa are described in this paper, including *Amplexobrachyelasma* He et Chen gen. nov., *Grewingkia densicolumna* He et Chen sp.nov., *Kenophyllum fossulatum* He et Chen sp.nov. and *Leolasma qianbeiense* He et Chen sp.nov.

35628 <TITLE>Late Ordovician mass extinction of rugose corals in the Yangtze region. [in Chinese, with English abstract]</TITLE>

35629 <SOURCE>Biotic Mass Extinction and Recovery of the Paleozoic in South China [Rong Jiayu & Fang Zhongjie (eds)]: chapter 2, part 6, pp 167-183; Hefei Science and Technology Press.</SOURCE>

35630 <ABSTRACT>Two phases of the latest Ordovician rugosan mass extinction are recognized based on the study of rugose coral fauna from the Sanjushan Formation (middle Ashgill) in the Lower Yangtze region and the Guanyinqiao Beds (late Ashgill) in the Upper Yangtze region integrated with modification as well as statistical analysis of range and distribution of the genera and species. The first phase took place during the end of Rawtheyan Stage. The Late Ordovician (middle Ashgill) rugosan fauna of Lower Yangtze region contains 16 genera, among which 6 genera (*Cystocantrillia*, *Hillophyllum*, *Bowanophyllum*, *Parastreptelasma*, *Favistina* and streptelasmatic one new genus) (37.5%) became extinct in the end of Rawtheyan Stage. The second phase happened during the latest Himantian. The rugose coral fauna from the Guanyinqiao Beds of Upper Yangtze region contains 15 genera, among which 9 genera (*Sinkiangolasma*, *Lambeophyllum*, *Kenophyllum*, *Borelasma*, *Salvadorea*, *Ullernelasma*, *Siphonolasma*, *Pycnactoides*, *Bodophyllum*) (60%) became extinct. The present paper deals with the controlling factors of two extinction events and their differences. The global sea-level decline caused by the Southern Hemisphere glaciation of the Late Ordovician and climatic deterioration are the main factors, which resulted in the first phase of rugosan mass extinction during the end of Rawtheyan. In the Lower Yangtze region, because of the beginning time of the first phase of rugosan mass extinction was earlier than brachiopods and graptolites, the authors concluded that the factors of the first phase may be also connected with the Guanxian Orogeny. The second phase of the extinction again related to a rise of global temperature and a sharp rise of sea-level with oceanic water anoxia which caused the demise of the shallow, bottom-living and cool / cold water rugose coral fauna at the late Himantian (latest Ashgill) and the earliest Silurian. The two phases coincided with the start of the Gondwana Supercontinental glaciation and its melting respectively. [original abstract]</ABSTRACT>

35642 <SOURCE>Paleontologicheskii Zhurnal 1978, 3: 39-44.</SOURCE>
35643 <ABSTRACT>The new genus Tchingizophyllum is described from the Upper Ordovician (Upper Caradoc) of the Chingiz ranges. Evolution of microstructure and morphology of the skeleton in representatives of this genus are investigated. The older representatives are related to Primitophyllum, whereas the younger ones show relations to the Lower Silurian genera Cysticonophyllum Zaprudskaya & Ivanovskiy 1962, and Cantrillia Smith 1930. A close genetic relationship between the genera Tchingizophyllum. Cysticonophyllum and Cantrillia allows to combine them into the family Tchingizophyllidae. The new species T. primitivum and T. perplexum, both from the Upper Caradoc, and the new species Cantrillia orientalis from the lower Upper Llandovery, as well as Cysticonophyllum tchingizicum are described. Diagnosis of Tchingizophyllum: solitary, conical to cylindrical. The wall consists of lamellar sclerenchyma with fine holacanthic trabeculae; septal spines are sometimes developed. Tabulae absent or rare, horizontal or deeply inclined. Elongated dissepiments sometimes are developed at the wall.</ABSTRACT>

35667 <TITLE>Concerning: High-Mg calcite in Ordovician stromatoporids (?)</TITLE>
35668 <SOURCE>FC&P 29, 1: 5.</SOURCE>
35669 <ABSTRACT>I received today on interlibrary loan, a copy of the following article: Chan Min YOO and Yong II LEE, 1993. Original mineralogy of Ordovician stromatoporoids. Carbonates and Evaporites, 8(2):224-229. In this paper Chan and Yong claim to have shown that Ordovician stromatoporoids were originally high-magnesium calcite, rather than the aragonite that others have proposed (at least for labechiids). They called their specimens Labechia regularis. * what is interesting is that the korean specimen they illustrated looks very much like Cliefdenella, with relatively straight laminae and tubelike pillars. Cliefdenella is now considered a sphinctozoan sponge. The end product of this is that they apparently did not work with labechiids (or clathrodictyids), and the most useful information we have is a new occurrence of Cliefdenella. [comment and correction to a paper by Yu Changmin & Lee Yongil, 1993]</ABSTRACT>

35680 <TITLE>Fluorite cement in Ordovician stromatoporoid skeletons.</TITLE>
35681 <SOURCE>Boletin de la Real Sociedad Espanola de Historia Natural, Seccion Geologica 92, 1/4: 067-076.</SOURCE>
35682 <ABSTRACT>Fluorite crystals have been found within the skeletons of a Middle Ordovician (Llanvirn) stromatoporoid, *Labechiella regularis* (Yabe & Sugiyama), from peritidal carbonates of the Youngwol area, Southern Korea. Observation of sedimentary and diagenetic characteristics indicates that the carbonates were deposited and buried in an evaporitic, very shallow water environment, with some dolomite also formed. Occurrence fluorite is most common within the stromatoporoid skeletons. The fluorite occurs in pillars, galleries, and within dolomitic sediment between the latilaminae. In normal optical view, the pillars seem to exhibit a tube-like structure. However, the walls of the tubes are composed of fine-grained calcite crystals representing the earliest stage of cementation, and appear to have a different refractive index to the fluorite crystals occurring in the centre of the pillars. Formation of the fluorite clearly postdates and may be related to the dolomitization, consuming the magnesium ion and releasing the fluoride to the reacting fluid. Diagenesis of the stromatoporoids does not resemble the diagenesis of aragonitic (molluscan) or high-Mg calcitic (echinoderm) skeletons. However, the selective occurrence in the stromatoporoid is probably related to the textural or mineralogical characteristics of the stromatoporoids.</ABSTRACT>

35746 <SOURCE>Carbonates and Evaporites 8: 224-229.</SOURCE>
35747 <ABSTRACT>Stromatoporoids in the Middle Ordovician Yeongheung Formation show delicate reticulate structure of persistent laminae and discontinuous pillars. Abundant microdolomite inclusions are found in the stromatoporeid skeletons. Coexisting aragonite precursor grains, such as those of gastropods and cephalopods, preserve no internal microstructures due to extensive dissolution and subsequent filling by low-magnesian calcite. Brachiopods (low-magnesian calcite precursor)

show well preserved skeletal microstructures but do not contain any microdolomite inclusions. Stromatoporoids were not dissolved as completely as original aragonitic shells but recrystallized more than shells with low-magnesian calcite precursor. The similarity of the stromatoporoid preservation pattern to that of echinoderm grains (high magnesian-calcite precursor) and the widespread occurrence of microdolomite rhombs in the stromatoporoid skeletons indicate that the Middle Ordovician stromatoporoids were originally composed of high-magnesian calcite. [original abstract; Stock, 2000, states the specimens described in the present paper are in fact sphinctozoan sponge Cliefdenella]

35811 <SOURCE>Bulletin Chinese Academy geological Sciences 12: 127-144.
</SOURCE>
35812 <ABSTRACT>The materials described here were collected from the Upper Ordovician (Ashgill Stage), the Bulongor Formation in Hobuskar county of the Xinjiang Uighur Autonomous Region and the Belguoshan Formation in Guyuan County of the Ningxia Hui Autonomous Region by Cao Xuanduo and Huang Hongping in 1983. Described are 13 genera (3 of them are new ones) and 20 species and subspecies (19 new ones). The taxa mentioned belong to the Agetolitidae (herein also Hemiagetolitella n.gen., characterized by mural pores besides corner pores), Sarcinulida (herein Cystosarcinula n.gen., having cystose tabulae), and Heliolitida. The new genus Sinolites is assigned to the family Palaeoporitidae. The main characters are tabulae and diaphragms, thick columella and absence of perforate wall.</ABSTRACT>

35825 <ABSTRACT>The Tabulata here described were collected from the Upper Ordovician Bulunggor Formation in Hoboksar County of Xinjiang Uygur Zizhiqu. The collections contain 18 genera and 47 species including 30 new species. The mentioned taxa belong to the Sarcinulida, Favositida, Halysitida, and most of them to the Heliolitida [part of summary].

35838 <ABSTRACT>The tabulate corals dealt in this paper were collected from Late Ordovician in the northern side of Borohoro Mountain, Xinjiang. They contain six genera and eleven species, of which seven species are new, as follows: Agetolites jingheensis Lin et wang, sp.nov., Mesofavosites jingheensis sp.nov., M. dualis var. mutabilis Sokolov, M. sokolovi Barskaya, Eofletcheria xinertaiensis sp.nov., Reuschia kasakhstanica Kovalevskiy, Rhabdotetradium huochengense sp.nov., R. tianshanense sp.nov., R. borohoroense sp.nov., R. quadratum (Zhizhina), Paratetradium reticulatum sp.nov.</ABSTRACT>

35914 <TITLE>Ordovician reef systems and settings in South China before the Late Ordovician mass extinction.</TITLE>
35915 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 205, 3-4: 235-254.</SOURCE>
35916 <ABSTRACT>Ordovician reefs of the South China Block occur chiefly in three stratigraphic units: (1) the middle Tremadoc Fenhsiang Formation and the upper part of the Lunshan Formation; (2) the late Tremadoc Hunghuayuan Formation; and (3) the middle Ashgill Xiazhen, Sanjushan and Daduhe Formations. The region therefore records part of the Early Palaeozoic reef expansion episode and permits a broader assessment of change in Ordovician reef facies. During middle Tremadoc time, lithistid sponge-bryozoan-Calathium-calcimicrobially dominated patch

reefs of the Fenhsiang Formation occur in the high-energy belt of the central Yangtze Platform. Columnar nonskeletal stromatolites of the Lunshan Formation (coeval with Fenhsiang Formation) occur on the southeastern margin of the platform, where low diversity reef-attached organisms, and the generally fine-grained character of the sediment, are consistent with a depth below normal wave base. Calathium and lithistid sponges were the principal reef builders of late Tremadoc reefs and were widespread in the areas of Yichang (Hubei Province) and Dongzhi (Anhui Province), from the platform centre to its margin settings. Bryozoan reef builders occur only in the platform centre with a high diversity of reef dwellers such as brachiopods, trilobites and nautiloids. However, during the same time, at the platform margins, microbes played an important part in reef building together with Calathium and lithistid sponges. The middle-late Tremadoc lithistid sponge-bryozoan-Calathium-microbial community was replaced by a middle Ashgill coral-stromatoporoid community and shows that the succession of community replacement during the Ordovician took a relatively long time. Restricted by the black shales of the main part of the Yangtze region, middle Ashgill reef complexes can be found only on the northeast platform of Cathaysian Land, between the Yushan (Jiangxi) and Changshan (Zhejiang) regions. Carbonate mudmounds are present on the western margin of the Yangtze Platform. On the northeast platform of Cathaysian Land, patch reefs (some higher relief) with talus and biostromes of the Xiazhen Formation consist of high-diversity biotas of corals, stromatoporoids, calcimicrobes, brachiopods and gastropods. The Sanjushan Formation is age-equivalent to the Xiazhen Formation and contains carbonate mudmounds that are composed of abundant calcareous algae and calcimicrobia. Uplift forced a northward extension of Cathaysian Land and caused a regional relative sea-level fall, eliminating this reef complex prior to the first extinction event of the Late Ordovician. The Daduhe Formation carbonate mudmounds occur in the nearshore belt of Kangdian Land (western margin of the Yangtze Platform) and are paraconformably overlain by the Hirnantian Nancheng Formation. In total, the Ordovician reefs of south China show a range of habitats and controls on growth and demise. [original abstract]

35953 <TITLE>The distribution and features of reef in Tazhong Area of Tarim Basin, Northwest China. [in Chinese]</TITLE>
35954 <SOURCE>Petroleum exploration and development 30, 2: 33-36.</SOURCE>
35955 <ABSTRACT>There are many different kinds of reef in Tazhong Area of Tarim Basin, Northwest China in age of Medium-Upper Ordovician. The main reef-building organisms are sponges, Calathium, stromatoporoids, corals, Crytalgaes, bryozoans, blue-green algae, chorophyte and rhodophyte in solenoporaceae. The reef can be divided onto calcilutite mound, framework reef and baffle reef. The analyzing on the reed encountered during the drilling shows that the calcitite mound is mainly formed in continental shelf are mainly in the shelf and the shelf margin. And by studying the sedimentary facies and the features of seismic reflection in this area, it can be predicted that reef with the distribution shapes of belt and discontinuous belt can be found in the shelf margin area of Tazhong Uplift and in the middle area of northern slope of Tazhong area. Especially, the areas at the west end of No. 1 fracture of Tazhong in west Shutuoguole block, up to now six anomaly reflection bodies have been found. Depending on the characters of environment and features of interior reflection they are very likely the reef mounds. It will have great effects on the oil and gas exploration of this area in case of that more play would have been processed. [original abstract]</ABSTRACT>

36005 <TITLE>Origin, dispersal and biogeographic affinity of the Middle-Late Ordovician and the Llandovery rugose corals in the Yangtze Region.</TITLE>
36006 <SOURCE>Acta Palaeontologica Sinica 43, 2: 179-191.</SOURCE>
36007 <ABSTRACT>The Middle Ordovician - Llandovery rugose corals are abundant in the Yangtze region, especially in the Early Silurian. Altogether 123 genera of Rugosa, which contain 4 genera of Middle Ordovician, 25 genera of Late Ordovician, and 94 genera of Llandovery respectively, have been reported from this region, of which 30 genera first appeared in the Yangtze region and then dispersed to Europe and North America and other adjacent regions. The following may represent the earliest occurrence age of the referred genera: Calostylis in the Middle Ordovician (Llandeilo) of southern Sichuan; Aphyllum and Cantrillia in the middle Ashgill of western Zhejiang; the streptelasmataceae Briantelasma, Pycnactis and Tunguselasma in the late Rueddian of northeastern Guizhou; the columnariids Ceriaster, Stauria, Amplexoides and Synamplexoides, and the cystiphyllids Maikottia, Rhizophyllum among others in the Middle Llandovery of northeastern Guizhou, South China. Based on these data, we may regard that the Yangtze region may have

been one of the origin centers for the Ordovician and Silurian rugose corals. This paper deals with the Middle Ordovician to Llandovery rugose coral faunas in the Yangtze region, especially with their palaeobiogeographic affinities. The Middle Ordovician Rugosa of this region are characterized by the calostylids *Calostylis* and *Yohophyllum*. The Late Ordovician (mid-Ashgill) rugosan fauna from the Sanjushan Formation of western Zhejiang Province contains some Australian elements (*Hillophyllum*, *Bozoanophyllum*), while the late Ashgill rugose fauna from the Guanyinqiao Bed in the Upper Yangtze region shows a high degree of similarity to that of North Europe, indicating that Yangtze and Europe have a close palaeobiogeographic affinity with each other. The Llandovery rugose fauna in the Yangtze region is much closer with that of Siberia, Kazakhstan and Australia. </ABSTRACT>

36045 <SOURCE>Acta Palaeontologica Sinica 42, 2: 174-188.</SOURCE>
36046 <ABSTRACT>7 genera of rugose corals are reported from the middle Llandovery in northern Guizhou Province of China for the first time. They are *Cantrillia*, *Neocantrillia*, *Prototryplasma*, *Pycnostylus*, *Dalmanophyllum*?, *Rhegmaphyllum* and *Schlotheimophyllum*. In addition, two species [*Grewinkia* cf. *bilateralis* (Neuman) and *Brachyelasma* cf.

- medioseptatum (Neuman)] collected from the late Ashgill Guanyinqiao Beds in the Shiqian County of northern Guizhou Province, and one species (*Crassilasma* sp.) from the early Ashgill Jiancaogou (Jiantaoshou) Formation in the same area are described. These data enrich further the content of the Late Ordovician and Early Silurian rugose coral fauna in Yangtze region, and are considerably significant for study on origin, evolution and disperse of some Early Paleozoic rugose corals. Altogether 18 species assigned to 13 genera are described. Among them 6 species are new. They are *Crassilasma fenggangense* sp.nov., *C. crebrumseptatum* sp.nov., *Dinophyllum insolitum* sp.nov., *Neocantrillia* sp.nov., *Prototryplasma guizhouense* sp.nov. and *Schlotheimophyllum regeneranum* sp.nov. - 36058 <SOURCE>Acta Palaeontologica sinica 25, 6: 648-656.</SOURCE>
- 36059 <ABSTRACT>Three early palaeozoic coral species are described in this paper. The Ordovician rugose coral *Favistina* was not known in southeast China before. A fragment to be designated under the name of *Favistina* cf. *burksae* Flower (Brown, 1965) was collected for the first time from the Sanjushan Formation of Late Ordovician in Yushan area of Jiangxi, southeast China. This species is significant to indicate that the Ordovician coral fauna of southeast China corresponds roughly to that of North America. Two tabulate corals were collected from the Guandi Formation of Late Silurian in Qujing of Yunnan, southwest China, namely *Parastriatopora rhizoides* Sokolov and *P. guandiensis* sp.nov. The ramose corallum of the latter shows a clearly lamellar microstructure as pointed out by Plusquellec (1976). [part of original summary] </ABSTRACT>

36083 <TITLE>Silurian Tabulata from Tadjikistan.</TITLE>
36084 <SOURCE>Akademiya Nauk SSSR; 85pp [in Russian].</SOURCE>
36085 <ABSTRACT>In this monograph Lower Silurian and some Upper Ordovician Tabulata are described. New data on the morphology of Tabulata is exposed, notably on the numerical criteria of morphological features. Based on detailed paleontological and stratigraphical research, carried out by a team of geologists and paleontologists, the stratigraphical outlines of the Ordovician and Silurian of Tadjikistan are sketched out. The chapter "Paleozoogeography" gives the geographical distribution of Tabulata and Heliolitida. A paleozoogeographic regional zonation of the Ordovician, Silurian and Lower Devonian is obtained by aid of Ch. Lang mathematical formula.</ABSTRACT>

36098 <ABSTRACT>The sarcinulid fauna, described herein, contains two genera: Calapoecia and Lyopora, with the following species: Calapoecia anticostiensis Billings 1865, C. anticostiensis mediana n.ssp., C. condensa n.sp., C. kanini n.sp., Lyopora spongiosa n.sp., L. coxi Bassler 1950). * The age of this fauna is Upper Ordovician, with the exception of the last mentioned lower Silurian species. Concerning the problems of systematics, the author refers to Preobrazhenskiy & Klaamann 1957 (see Fossil Cnidaria 6-2: 21. Moreover, he mentions the genus Coxia that he believes to be a synonym of Lyopora.</ABSTRACT>

36135 <TITLE>Reef reconstruction after extinction events of the latest Ordovician in the Yangtze Platform, South China.</TITLE>
36136 <SOURCE>Facies 48, 1, 269-284.</SOURCE>
36137 <ABSTRACT>Carbonate sediments gradually developed into beds rich in brachiopods and crinoids in the lower part of Xiangshuyuan Formation, middle Rhuddanian. In the middle part of Xiangshuyan Formation, biostromes, containing abundant and high diversity benthic faunas such as corals, crinoids and brachiopods, show beginnings of reconstruction of reef facies. Substantial reef recovery occurred in the upper part of Xiangshuyuan Formation, lower Aeronian, as small patch reefs and biostromes. During the late Aeronian, carbonate sediments, especially reefs and reef-related facies, expanded on the upper Yangtze Platform, and radiation of reefs occurred in Ningqiang Formation, upper Telychian. The long period of reef recovery, taking several million years, remains difficult to explain, because redistribution of any refugia faunas would be expected to take place soon after the extinction. Reefs and reef-related facies subsequently declined after Telychian time due to regional uplift of the major portion of the Yangtze Platform. Carbonate facies are therefore uncommon in South China during the rest of Silurian time. [last part of an extensive abstract]</ABSTRACT>

36240 <SOURCE>Izvestiya Akademii Nauk Tadjikskoy SSR, otdieleniye biologicheskikh Nauk 71, 2: 49-54.</SOURCE>
36241 <ABSTRACT>Four new species of Heliolitidae are described from silurian deposits of Tadjikistan and are assigned to the genera Thaumalolites Yanet in Sokolov 1955, and ? Bogimbailites Bondarenko 1966. The new species are: Th. cylindricus, Th. turkestanicus, Th. relictus and B. tangisaicus. The diagnosis concerning Thaumalolites is amended and precisely defined. Diagnosis (Thaumalolites): coralla small, pear-, bowl-shaped or cylindrical. Corallites either without own or with interrupted walls. In the first case they are confined by coenenchymal vesicles which sporadically show vertical orientation in the area of the corallites though forming a corallite tube. In the second case the walls appear interrupted or as an almost closed, compact line which stands out against the remaining skeletal elements due to thickening. Tabulae horizontally and only rarely emanating from each other. Coenenchyme consisting of convex, frequently merging vesicles of different size and shape. Thorns may be recognized in the coenenchyme. These are absent in corallites.</ABSTRACT>

36253 <SOURCE>Paleontologicheskij Zhurnal 1979, 2: 16-22.</SOURCE>
36254 <ABSTRACT>The new genus Helioplasmolites takes an intermediate position between the Proporida and Heliolitida. During the initial growth stage and locally as well as zonally it shows a proporid coenenchyme which is replaced by a heliolitid coenenchyme during further growth of colony. This indicates that the Heliolitida are derived from the Proporida and not from the Protareida as was presumed before. New informations are presented regarding morphology, phylogeny and systematics of the family Plasmoporidae. The new species H. communicata from the Silurian (Lower Wenlockian) of Central Asia (Zeravshan mountains) is described being the type species of the new genus. Diagnosis of Helioplasmolites: corallum semi-globular to bowl-shaped; corallites closely situated, in places touching each other; connecting canals may develop between the corallites; tabulae horizontal, bent or emanating from each other; septal formations absent or thorn- or tubercle-shaped; around the corallites there is an aureole consisting of 12 coenenchymal tubes, polygonal in outline and differing in size; diaphragm horizontal, oblique, conical or vesicular; during initial stage of colony and locally, e.g. in some zones, there is a proporid (vesicular) coenenchyme which leads to a typical heliolitid one during further growth of the colony, showing zigzag-shaped, bent walls; walls of coenenchyme and corallites thick. H. communicata Ospanova n.sp.: corallum 30 to 150 mm; corallites rounded, 0.8 to 1.3 mm in diameter, distance between corallites 0 to 1.0 mm; distance of tabulae 0.1 to 0.9 mm; thickness of wall 0.0? to 0.05 mm; between the corallites 1, rarely 2 to 3 rows of polygonal coenenchymal tubes of 0.1 to 0.6 mm in diameter, arranged in an aureole of 12 coenenchymal tubes; distance of their diaphragms 0.015 to 0.02 mm; the new species differs from H. regularis (Dun, 1927), the diameter of which is also 0.8 to 1.3 mm, by the greater numbers of connecting canals and a lesser development of coenenchyme (H. regularis is found in the Silurian of New South Wales, Australia).</ABSTRACT>

36317 <TITLE>Late Silurian rugose coral fauna from the Qujing District, East

- Yunnan.</TITLE>
36318 <SOURCE>Acta Palaeontologica Sinica 43, 3: 303-324.</SOURCE>
36319 <ABSTRACT>Late Silurian (Late Ludlow - Early Pridoli) rugosa coral fauna from the Qujing district, east Yunnan are studied in detail, and some rugosan genera and species are reviewed, especially the coral faunacharacters and their distribution of the Guandi Formation and Miaogao Formation are discussed. Altogether 22 genera and 44 species of rugose occurred in Late Silurian (including Guandi, Miaogao and Yulongsi Formation) of Qujing, east Yunnan (see table I, II). Among them, cystiphylloids Holmophyllum, Cystiphyllum and Kytophyllum are dominant. The columnariidskyphophyllum, Micula and Pilophyllum and others are present. Only three genera Brachyelsma, Rukhinia and Phaulactis have been found for the first time from east Yunnan. As a whole, the Late Silurian rugosan coral fauna of east Yunnan has an affinity with contemporary west Qinling forms, and shows to a certain extent similarity to those of contemporaneous beds of Ural. Altogether 23 species comprising 17 genera of Rugosa are described, among them 3 species are new, namely Cystiphyllum minutum sp. nov., Ketophyllum qujingense sp. nov. and Phaulactis vesicularis sp. nov.</ABSTRACT>

36330 <TITLE>Early Silurian (Telychian) Rugose coral fauna of Dagan Area, Northern Yunnan.</TITLE>
36331 <SOURCE>Acta Palaeontologica Sinica 44, 2: 229-246. [English translation]</SOURCE>
36332 <ABSTRACT>The late Early Silurian (Telychian) rugose coral fauna from Dagan area, northeast Yunnan is studied by the present authors. The Lower Silurian Series in the Dagan region may be divided into the following units: overlaying strata: Lower Devonian Cuifengshan Formation disconformity Telychian-Rhuddanian, Lower Silurian: Caitianwan Formation (mid-late Telychian) Daluzhai Formation (mid-late Telychian) Sifengya Formation (early Telychian) Huanggexi Formation (mid-late Aeronian) Longmaxi Formation (Rhuddanian-early Aeronian) conformity Upper Ordovician: Guanyinqiao Formation Wufeng Formation. In the Huanggexi Formation rugose corals are scarce, but the Sifengya Formation (early Telychian) yields numerous rugosans. Up to now, 18 genera and 34 species are reported in the Sifengya Formation, while the Daluzhai Formation merely contains rugosans including 9 genera and 11 species (Table 1). Altogether 9 species assigned to 12 genera are described in this paper, among them 1 genus and 5 species are new. They are: Protoketophyllum daganense gen. et sp. nov., Crassilasma huanggexiense sp. nov., Pseudophaulactis heae sp. nov., P. convolutus sp. nov. and Shensiphyllum minor sp. nov. In addition, the coral fauna characters of the Sifengya and Daluzhai are briefly discussed.</ABSTRACT>

36356 <TITLE>On the genus Idiophyllum.</TITLE>
36357 <SOURCE>Acta Palaeontologica Sinica 25, 5: 525-530.</SOURCE>
36358 <ABSTRACT>In this paper, the morphological features of the rugose coral genus Idiophyllum Cao 1975 are discussed in detail. The generic diagnosis is emended and its systematic position revised. Idiophyllum may be referred to the rugose family Arachnophyllidae Dybowski 1873 on the basis of its morphological characteristics. This genus is probably affined to Sumsarophyllum Lavrusevich 1971 and Nanshaaphyllum Yu 1956, but all the three are independent genera. The diagnosis for the genus Idiophyllum is emended as follows: Corallum solitary or fasciculate-massive. Septa displaying pinnate arrangement with continuous chain-like or reticulate structure; tertiary septa incomplete; all septa including second and tertiary ones serial in arrangement. Four new species are described from the Middle Silurian Hingqiang Formation in Dazhuba and Erlangba, Hingqiang County, Shaanxi, namely: Idiophyllum massulatum Chen (sp.nov.), I. tenuiseptatum Chen (sp.nov.), I. major Chen (sp.nov.) and I. shaanxiense Chen (sp.nov.).</ABSTRACT>

36369 <TITLE>New information on Silurian Rugosan genus Pilophyllia Ge et Yu, 1974 in northeastern Guizhou.</TITLE>
36370 <SOURCE>Acta Palaeontologica Sinica 46, 1: 98-112.china.jst.go.jp/D/C2080A/07A0904646.html</SOURCE>
36371 <ABSTRACT>Rugosan genus Pilophyllia Ge et Yu, 1974 possesses typical amplexoid septa belonging to the Family Amplexidae. This genus is widespread in Llandovery strata in the upper Yangtze region, China. Numerous specimens of Pilophyllia collected from the Xiangshuyuan and Leijatun formation (Aeronian) in the Shiqian area, northeastern Guizhou are studied in the present paper. The diagnosis of this genus is emended, and its geological distribution are discussed in detail. Nine species are described and illustrated here for the first time. Among them, 6 species are new. They are: Pilophyllum vesiculosa Tang sp. n., P. conica Tang sp.nov., P. ultima Tang sp.nov., P. stylaris Tang sp.nov., P. raritabulata Tang sp.nov. and P. leijatunensis Tang sp.nov. In addition, the characteristics of the Pilophyllia species population from the Xiangshuyuan and Leijiatun formations in the Shiqian district are briefly discussed and compared with those of the Nngqiang Formation (Telychian), southern Shaanxi and northern Sichuan.</ABSTRACT>

36447 <TITLE>Early Silurian rugose coral fauna of Tewa Area, West Qinling.
[in Chinese, with English summary]</TITLE>
36448 <SOURCE>Acta Palaeontologica Sinica 38, 4: 423-434.</SOURCE>
36449 <ABSTRACT>The Early Silurian rugose coral fauna of Tewa area, West
Qinling was first reported in 1990. Recently, the fauna has been
researched in detail, including 9 families, 13 genera and 18 species.
In this paper 11 genera and 12 species (of which 5 are new) are
described. They are: Brachyelasma sp., Paramplexoides sp.,
Kodonophyllum cf. leijiatusensis Ge et Yu, Eostauria minor (Chen),
Amplexoides chaoi (Grabau), Tryplasma cf. multitabulata Nikolaeva, T.
sp., Aphyphyllum tewoense sp.nov., Cystocantrillia silurica sp.nov.,
Cystiphyllum yiwaense sp.nov., Gyalophylloides simplex sp.nov., and
Pseudamplexus intermedius sp.nov. All the specimens are collected from
the upper member of Lalong Formation (M. Llandovery) in Tewa area, West
Qinling. This fauna may be correlated with the Leijiatus Formation (M.
Llandovery) of northeastern Guizhou, indicating the Early Silurian
rugosan fauna from West Qinling to be close to those of Yangtze region
in biogeographical affinity, and it may belong to the Yangtze Province.

36460 <TITLE>Early Silurian (Llandovery) rugose coral recovery and radiation
in the Upper Yangtze region. [in Chinese, with English abstract]</TITLE>
36461 <SOURCE>Biotic Mass Extinction and Recovery of the Paleozoic in South
China [Rong Jiayu & Fang Zhongjie (eds)]: chapter 2, part 7, pp
185-205; Hefei Science and Technology Press.</SOURCE>
36462 <ABSTRACT>Upper Yangtze region contains many complete sections through
the Upper Ordovician and Lower Silurian (Llandovery). Three
macroevolutionary stages, including survival interval (early and middle
Rhuddanian), recovery interval (late Rhuddanian to early Aeronian), and
radiation interval (mid-to late Aeronian), are recognized based on
rugose coral data, with the redefinition and modification of some

genera and statistical analysis of the range and distribution of the rugosan genera, including rugose coral 44 genera, assigned to 3 orders and 13 families from the Lower Silurian (Llandovery) of the Upper Yangtze region. It is discussed that the feature, pattern, and control factors of the macroevolutionary stages and their fauna. The rugose coral fauna of the survival interval are composed of 6 genera, assigned to 2 orders and 3 families, and are characterized by a few survival and Lazarus genera. During the recovery interval the rugose coral fauna are possessed of 15 genera from 3 orders and 8 families, and are dominated numerically by the small, solitary Streptelasmata (10 genera: 61%), with first appearing abundance debutantes taxa and endemic forms. Forty-two rugose coral genera are recorded from the radiation interval. Some genera in the radiation interval extended up from the recovery interval, whereas many genera occur first in the form of the debutantes taxa and radiation taxa. One of the most striking differences between the recovery and radiation interval is a rapid generic increase of the Cystiphyllida (13 genera; 31%), the Streptelasmata (19 genera; 45%) and the Columnariida (10 genera; 24%), with 14 new genera first appearing from the radiation interval. In addition, the radiation interval is of many colonial forms (12 genera: 29%) and occur the small reef composed of the rugose corals, tabulate corals and stromatoporoids. It should be emphasized that typical Silurian rugose corals are known to occur during the recovery interval and the radiation interval in Yangtze region. They include representatives of the crisis progenitor taxa, debutantes taxa and radiation taxa. It is recognized that the beginning of the 3 orders (Cystiphyllida, Streptelasmata, Columnariida), with differential recovery and radiation rates for each group, were different respectively. In the recovery interval and radiation interval, the beginning of Cystiphyllida and Streptelasmata were earlier than the order Columnariida. It is indicated that the conditions of the ecological environments or ecosystem during the Early Silurian were more adaptable for diversity of the Cystiphyllida and Streptelasmata which were more primitive rugose corals than the Columnariida which was more advanced group with rapidly development after Silurian. The debutantes taxa are subdivided into three kinds of the endemic-debutantes, the emigrant-debutantes and the immigrant-debutantes. [original abstract]

36512 <TITLE>Continental island from the Upper Silurian (Ludfordian Stage) of Inner Mongolia: implications for eustasy and paleogeography.</TITLE>
36513 <SOURCE>Geology 29, 10: 955-958.</SOURCE>
36514 <ABSTRACT>An unconformity between the Silurian Xibiehe Formation and Ordovician igneous rocks marks the perimeter of a small paleoisland near Bater Obo in north-central Inner Mongolia, 180km northwest of the provincial capital of Hohhot. The stratigraphic position of the lower part of the Xibiehe Formation is correlated by means of conodonts with the upper part of the Ancoradella ploeckensis Zone in the basal Ludfordian Stage (corresponds to mid-Ludlovian Epoch, ca. 421 Ma). Elongate in plan (610m x 200m), the exhumed diorite core rises 30m above the lowest elevations of surrounding Silurian strata. Paleoshores along the principal axis of the inlier delineate contrasting facies. Robust stromatoporoids are in growth position within silty limestones, some directly encrusting the unconformity surface of the sheltered southeast margin. A basal conglomerate of diorite cobbles and boulders characterizes the high-energy northwest margin. The depositional constraints and timing of transgressive facies associated with this continental paleoisland have implications for the eustatic and paleogeographic history of the parent Sino-Korean plate. Burial of the island corresponds to the beginning of a global rise in sea level that peaked in late Ludlovian time. Our interpretation of windward and leeward facies requires an approximate 90° clockwise rotation of the parent plate to accommodate the dominant pattern of low-latitude trade winds and storms. 36551 <TITLE>Continental island from the Upper Silurian (Ludlow) Sino-Korean plate.</TITLE>
36552 <SOURCE>Chinese Science Bulletin 46, 3: 238-241.</SOURCE>
36553 <ABSTRACT>Recent field studies on Upper Silurian stratigraphy and paleontology in the Inner Mongolia Autonomous Region (for short, Inner Mongolia) near Bater Obo (=Bateaobao) resulted in the discovery of a small continental island with fossil invertebrates preserved as encrusters (stromatoporoids and corals) attached directly to a rocky shore surface and buried by silty clay mud. The Bater Island (named herein) is 610 m x 200 m in size and is composed of Ordovician diorite. Limestone strata dating from the Ludlow epoch (about 420 Ma) surround

the island and dip away from the igneous core in a radial pattern. The encrusting fossils occur on the sheltered (south and southeast) side of the island, whereas the north side was exposed to stronger wave activity based on a basal conglomerate unit composed of diorite boulders. This is the first record of an ancient island in China and the first report worldwide of stromatoporoids as members of a rocky shore community. The island clearly shows distinct windward and leeward deposits comparable to geologically younger islands from the Mesozoic and Cenozoic outside China. (original abstract)The taxa mentioned in the text are: unidentified species of Plexodictyon, Actinostromella slitensis, Hexastylstroma sp., Syringostromella sp., and Clathrodiction? microstriatellum.</ABSTRACT>

36578 <SOURCE>Acta palaeontologica Sinica 23, 1: 1-19.</SOURCE>
36579 <ABSTRACT>The Silurian tabulate corals in the Huanggexi range of Dagan from Early Silurian Huanggexi and Sifengya Formations to Middle Silurian Hangjiadian and Daluzai Formations are recorded. Four tabulate assemblages in descending order are established and are as follows: * 4. Erlangbapora-Carneiea assemblage in the Daluzai Formation contains Favosites, Pachyfavosites, Alveolites, Marginofistula, Fletcheriella, Acanthohalysites, Heliolites, Ningguangolites and Propora. * 3. Mesofavosites, assemblage in the Hanjiadian Formation bears Mesofavosites jiunguanensis, M. angustus irregularis, M. confertus, M. maowenensis and M. daganensis. * 2. Multisolenia-Subalveolites assemblages in the Sifengya Formation yields Laceropora, Palaeofavosites, Parastriatopora, Halysites and Propora. * 1. Palaeofavosites-Mesofavosites assemblage in the Huanggexi Formation contains Halysites and Propora.</ABSTRACT>

36629 <TITLE>Sponges and Receptaculitids from Ningqiang Formation (Late Llandovery) of Guangyuan, Sichuan.</TITLE>
36630 <SOURCE>Acta Palaeontologica Sinica 29, 5: 581-591.</SOURCE>
36631 <ABSTRACT>The present study is based on the materials collected from Xuanhe, a small village in Guangyuan County, NW Sichuan by the writer in 1987. The collection contains sponges (a new subspecies Calyco-coelia profunda sichuanensis) and receptaculitids (Calathium sp. indet). According to their restudy of the biostratigraphy of Ningqiang and Guangyuan in recent years, the Chinese geologists suggested a late Early Silurian (Telychian) age for the Ningqiang Formation. In the past, Silurian sponges and receptaculitids have not yet been reported

- in Chinese palaeontological literature. It is interesting that the Silurian sponges and receptaculitids from the Yangzi Platform are used as supplementary evidence for Silurian biostratigraphic correlation between East Asia and North America.</ABSTRACT>

- 36656 <SOURCE>Facies 46, 1: 133-148.</SOURCE>
- 36657 <ABSTRACT>Ningqiang Formation (late Telychian, Llandovery, Silurian) characterized by nearly 3000 m of shales intercalated with carbonates, is situated between Ningqiang (S. Shaanxi Province) to Guangyuan (N. Sichuan Province) adjacent to the northwest margin of the Yangtze Platform. The high diversity "Xiushan Fauna", and abundant reef development, illustrate a relatively warm and persistent shallow marine environment in these early Silurian sediments. The sequence shows reef radiation after recovery from the end of Ordovician mass extinction events. Multiple horizons of reef-building occurred within a relative short geological interval and resulted in more than 30 patch reefs up to 2000 m in diameter and 1-50 m vertically, composed of abundant fossils. Reef biota include frame-building corals, stromatoporoids, bryozoans, and microbiolites, and reef-associated organisms such as crinoids, brachiopods, trilobites, gastropods, nautiloids and ostracods. Three reef-related biotic associations are recognized: a) reefs dominated by framework with crinoids and microbiota; b) crinoid-dominated facies. Seven representative reef examples illustrate different morphologies and growth styles. A high terrigenous debris input and shallow epicontinental ramp, which lacked obvious topographic variation, were major controls which resulted in rather simple reefs; sedimentation was apparently the main constrain on lateral and vertical extension of reefs, and prevented large-scaled reef complexes developing.</ABSTRACT>

36722 <ABSTRACT>The following species of heliolitoid corals are described: Heliolites kuznetskiensis, H. subdecipiens and H. balkhashensis. The latter one is a nomen novum and was formerly named H. lindstromi by Kovalevskiy in 1960. But this name was [pre]occupied already by H. porosus var. lindstromi Angelin 1901. * In chapter III of this work evolutionary trend – concerning especially the coenenchyme, the thickness of the vertical skeletal elements etc. – of the late silurian and lower Devonian heliolitoid corals of Central Kazakhstan are discussed.</ABSTRACT>

- 36812 <SOURCE>Acta Palaeontologica Sinica 38, 2: 155-167.</SOURCE>
- 36813 <ABSTRACT>There are some peculiar calceoloid corals appeared in the Siluro-Devonian. Corallum is semicircular in transverse section and the calyx is with an operculum of one or four plates of dense sclerenchyme. The nomenclature of actual systematics is as follows (Weyer, 1996): Family Calceolidae King, 1846, Subfamily Calceolinae King, 1846, Genus Rhizophyllum Lindstrom, 1866, Genus Calceola Lamarck, 1799, Genus Goniophyllum Milne-Edwards & Haime, 1850. * Among these three genera, Goniophyllum is pyramidal in shape and has four plates of operculum. It is very easy to distinguish it from the two other. Rhizophyllum differs from Calceola in its lumen which is filled with numerous cystose dissepiments, but the latter is completely filled by sclerenchyme. * There exist also some differences on their geological ranges between Rhizophyllum and Calceola. The former appears from Llandovery (Lower Silurian) to Emsian (Lower Devonian) and the latter occurs only in the Lower and Middle Devonian. Moreover, Rhizophyllum has a global geographical distribution. It is found in Europe, Asia, North America and Australia (Hill, 1981), but Calceola is not known from North America up to now (Oliver, 1964). * Some geologists used to consider the genus Rhizophyllum as a typical silurian coral. However, its real geological range is from Llandovery (Early silurian) to Emsian (Early Devonian). [introductory part of the original summary]</ABSTRACT>

36852 <ABSTRACT>Silurian-Devonian rocks of Central Inner Mongolia are mainly exposed in Darhan Mumingan Joint Banner. The rocks consist of neritic clastolites and carbonatites and bear numerous zoolites. Recently the junior writer and his colleagues collected a number of tabulate corals and heliolitids from the Bateaobao Formation (S2-S3), the Xibiehe Formation (S3), the Qaganhebu Formation (D1?), and the Alugong Formation (D1). The collections described in this paper contain 19 genera and 58 species (including 1 new genus and 17 new species). Stratigraphical range and geographical distribution of the species studied are indicated in Table 7 of the Chinese text. According to the characteristic features of the tabulate corals and heliolitids from the Xibiehe Formation, the Silurian faunas have affinities with those of Kitakami, Jilin, Altai, Sayan, Tien Shan, Kazakhstan, Podolia and Estonia.</ABSTRACT>

36876 <TITLE>Silurian and Devonian Tabulate coral assemblages in the Beishan area, Gansu province. [in Chinese, with English abstract]</TITLE>
36877 <SOURCE>Acta Palaeontologica Sinica 22, 1: 71-81.</SOURCE>
36878 <ABSTRACT>Six Silurian and Devonian tabulate coral assemblages are

recognized in the so-called Beishan area which covers the vast territory north to the Hexi Corridor and west to the weak Stream in Gansu Province. (1) Paleofavosites-Hexismia Assemblage (Lower Silurian Xieshan Group); (2) Favosites-Multisolonia-Halysites Assemblage (Middle Silurian Gongpoquan Group); (3) Hemithecia-Romingerella-Alveolites Assemblage (Upper Silurian Salinhaolai Formation); (4) Parastriatopora-Favosites-Squameofavosites Assemblage (Upper Silurian-Lower Devonian Shuishishan Group); (5) Neoyacutiopora-Squamites Assemblage (Late Lower Devonian Qinghegou Formation); (6) Thamnopora-Parastriatopora Assemblage (Early Middle Devonian Hazhu Formation). * The first two assemblages are distributed in the southern Beishan while the other four are in the northern Beishan. The genera Hemithecia, Romingerella, Rachopora, Crenulipora and Squamites found in the northern Beishan are known to be restricted to a belt extending from Kazakhstan, Beishan, Inner Mongolia to Heilungjiang. In the southern Beishan, however, most genera are cosmopolitan and similar in specific composition to those in the Qilianshan. It seems that there exist two different biogeographic provinces in this area, the Kazakhstan-Xingan Province in the North and the Qinling-Qilian Province in the South. [original summary] </ABSTRACT>

36928 <TITLE>The sequence and distribution of Devonian coral assemblages in South China II.</TITLE>
36929 <SOURCE>Pap. Int. Symp. Devonian System 1978: 7 pp; Nanjing Institute Geology Paleontology, Academia Sinica.</SOURCE>
36930 <ABSTRACT>The paper summarizes the sequence and distribution of the Devonian coral faunas in South China. Corals are proliferated and very diversified in the shallow sea which, during Devonian time, covered major parts of South China. They may roughly be divided into two faunas, namely the western and the eastern fauna. In the early Devonian they differ considerably from each other. The western fauna mainly developed in the miogeosynclinal region of western Yunnan, western Szechuan and west Tsingling. Regarding this fauna, Tabulata are prevalent. Five rugose complexes are established ranging from Upper Lochkovian to Zlichkovian (see Yu & Liao 1978). The eastern part of South China is characterized by a sedimentary prevailing system of platform type (nearshore shallow water environment). Corals, for the first time, appeared in the transgressive marine carbonate deposits and continued to develop until the Late Devonian. Both, Rugosa and Tabulata are abundant in this sequence. From this type, rich in corals, the faunal sequence of the Lower and Middle Devonian may be taken as a standard of reference. The following [assemblages] are recognized in ascending order: the Nahkaoling fauna (Upper Lochkovian / Lower Pragian), the Yukiang fauna (Middle / Upper Pragian), and the Ertang fauna (Zlichovian); the Beiliu fauna of the early Middle Devonian (Dalejan / Eifelian) probably equivalent to the Szepai and the Yingtang faunas, the Tungkangling fauna of the late Middle Devonian (Givetian), and the Shetienchiao fauna of the early Late Devonian (Frasnian). Representatives of the successive faunas are listed in two tables, and their characteristic features are briefly discussed.</ABSTRACT>

36942 <SOURCE>Paleontologicheskii Zhurnal 1982, 3: 3-8.</SOURCE>
36943 <ABSTRACT>Living conditions of early Devonian corals from Shishkata are described. It is observed that in "polycarpic" species almost all coral polyps are not dying of natural ageing but of hostile ecological living conditions. In some species of colonial corals the surviving curve of the polyps is in analogy with the living curves of non-ageing organisms. Between the Tabulata "monocarpic" species occurred in edition, the natural life-span of which did not outlive one year. A. WEISSMANN's theory is confirmed herewith.</ABSTRACT>

</TITLE>
36955 <SOURCE>Acta Palaeontologica Sinica 39, 1: 126-135.</SOURCE>
36956 <ABSTRACT>It is generally recognized that there were three first-level
marine, biographic divisions of the Devonian world:1. The Old world
Realm, which includes Eurasia, Australia, North Africa and western and
Arctic North America.2.The Eastern Americas Realm (or Appalachian
Realm), which includes most of eastern North America and northern South
America.3. The Malvinokaffric Realm, which includes southern South
America, southern Africa and Antarctica.The Old world Realm occupied
the ancient tropics, the Malvinokaffric Realm was located near the
ancient South Pole and the Eastern Americas Realm was situated
probably in the southern temperature zone. [first part of extensive

36981 <SOURCE>Journal of Stratigraphy 11, 2: 77-90 [in Chinese, with English
summary].</SOURCE>
36982 <ABSTRACT>The Qiziqiao (Chitzechiao) limestone widely distributed in
Hunan is a diachronous lithostratigraphic unit. It extends from the
Dunggangling stage to the top of Shetianqiao stage in stratigraphic
range. Its upper boundary lies below the Shetianqiao stage in the
typical section located in Qiziqiao of Xiangxiang, Hunan. It is
possibly changed into the Shale, Dinghechong, Xinshao, Longkouchong
formations and "Shetianqiao bed"; in the horizontal direction.
Sinodisphyllum and Pseudozaphrentis occur in the late middle Devonian
rather than the early upper Devonian. The Grypophyllum mackenziense
zone is regarded as belonging to the middle Devonian.</ABSTRACT>

- 37060 <ABSTRACT>A detailed taxonomic study on the Devonian rugose corals in Guilin resulted in the description of 20 genera and 51 species, based on more than 1100 thin sections, and in the recognition of four rugose coral assemblages in the interior-platform subfacies, including the Temnophyllum waltheri-Sunophyllum assemblage, the Pantophyllum-Disphyllum liumaense assemblage and the Cystophrentis assemblage. Four rugose coral assemblages in the platform margin subfacies also can be recognized as the Disphyllum-Argutastrea assemblage, the Spinophyllum-Kwangxiastraea assemblage, the Pseudozaphrentis assemblage and the Caninia-Dorlodotia assemblage. - 37098 <SOURCE>Acta Palaeontologica Sinica 19, 3: 175-181</SOURCE>
- 37099 <ABSTRACT>Rugose corals have been reported for the first time from the Ertang Formation of Central Guangxi. Here described and illustrated are Lyrielasma guangxiense sp.nov., L. guangxiense crassum sp. et subsp.nov., L. guangxiense gracile sp. et subsp.nov., Xiangzhouphyllum minor gen. et sp.nov. Besides this, the species of Tryplasma, Heterophrentis, Zonophyllum, Pseudomicroplasma and "wedekindophyllum " are only identified. The Ertang Formation, about 433m in thickness, is composed of thin-layered limestones intercalated with shales, calcareous mudstones and argillaceous limestone. This formation occurs over a large expanse of area, extending from south of the Wuxian district northward to the north of the Xiangzhou district. It is overlain by the Sipai Formation and underlain by the Yukiang Formation respectively, with the poorly fossiliferous dolomite beds in between. Known as the Lyrielasma guangxiense fauna, the new assemblage is found at the base of the upper member of the Ertang Formation and is considered to be Lower Devonian in age. The established sequence of Lower to early Middle Devonian coral faunas in central Guangxi is shown in Table 2 of the Chinese text.</ABSTRACT>

- 37112 <ABSTRACT>Late Middle Devonian deposits containing faunas of distinct palaeoecological character are well developed in Liujiing, Heng Xian of Central Guangxi. These are called Mintang Formation, about 112m in thickness, lying above the Najiao Formation and ranging from Early Devonian to early Middle Devonian in age. Overlying the Mintang Formation is a limestone bed of Late Devonian, Frasnian, with conodonts that belong to the upper hermanni-cristatus Zone and lower asymmetricus Zone. Rugose corals are associated with tabulate corals, brachiopods, crinoid stems and stromatoporoids in the Mintang Formation. * The rugose corals, described in this paper, include 30 species referred to 17 genera and subgenera. Among them two subgenera and 22 species are new. * The new subgenera are: Temnophyllum (Truncicarinulum) and Haplothecia (Kuangxiastraea).</ABSTRACT>

37162 <TITLE>Rugose Korallen aus dem Givetium von Dushan, Provinz Guizhou, S-China. 3: Einzelkorallen und einige Koloniebildner.</TITLE>
37163 <SOURCE>Senckenbergiana lethaea ...</SOURCE>
37164 <ABSTRACT>With the present third part, a preliminary completion of our investigations on rugose corals of the Tushan Formation of Dushan

County, Province Guizhou in the People's Republic of China is attained. This part deals with descriptions and illustrations of solitary corals of the Cyathophyllina and Ptenophyllina which are very abundant in that region, and also with some colonial species of the same suborders. 27 species and subspecies have been recognized within our material, in which we refer to 17 different genera. The following species and subspecies are described by us as new: *Dendrostella tunshangensis* n.sp., *Jipaolasma sinense* n.sp., *Tabulophyllum quasiexpansum* n.sp., *Grypophyllum convolutum dahekouense* n. ssp., *Sociophyllum ? guizhouense* n.sp., and *Sociophyllum jumuwanense* n.sp. Furthermore a new genus, *Jipaolasma*, with the type species *Jipaolasma sinense*, is established.- with the exception of some species which are known up to now only from S.China, there are also many in our present fauna which have been recorded at a lot of localities in the world, especially from the Givetian of Europe (together with the Russian Platform), of the Urals, and even of N. America.- In the Tushan Formation of the Dushan Section as a whole we find the following characteristic reference genera: *Dendrostella* in the lower part (Tunshang Member), *Endophyllum* and *Spinophyllum* in the upper part (Chiwochai Member), whereas *Tenophyllum* is present in the middle (Chipao Member) as well as at the top of the Givetian where it reaches its acme.-Some Chiwochai Member species as *Mictophyllum shawoziense*, *Tabulophyllum quasiexpansum*, and perhaps also *Spinophyllum hejiazhaiense* suggest already remarkable Upper Devonian elements in our coral fauna.</ABSTRACT>

37188 <TITLE>Rugose corals from the Arpishmebulaq Formation (Early Devonian, Lochkovian) of South Tianshan in Xinjiang.</TITLE>

37189 <SOURCE>Acta Palaeontologica Sinica 43, 3: 366-376.</SOURCE>

37190 <ABSTRACT>The Arpishmebulaq Formation is exposed at the eastern South Tianshan of Xinjiang and was originally proposed by E. Norin (1937, 1941), a Swedish geologist. It consists mainly of limestones and shales with a thickness about 400 m and yields abundant corals, brachiopods, ostracods, stromatoporoids and conodonts. Norin subdivided it into 6 divisions (A, B, C, D, E, F). There are some different opinions about the geological age of the Arpishmebulaq Formation: 1. Norin (1941) and Regnell (1941) first regarded most of formations (division A to division E) of Late Silurian age, while the top part (division F) of possibly Early Devonian age; 2. Zhang, Yu et al (1959) as well as Hou, Wang and al. (1988) recognized it as of the Lower Devonian; 3. Wang

(1988) and Wang (1990) considered it as belonging to the Late Silurian; 4. Liao and others (1990, 2001), Liao and Xia (1996), Xia (1997), Deng (2001), Soto and Liao (1998, 1999, 2001) believed that it (from division B to division F) would be the age of late Lochkovian (Early Devonian) in the light of some index conodonts *Amydrotaxis praejohnsoni*, *Pandorinellina optima*, *Ozarkodina remscheidensis remscheidensis*. The rugose corals described and illustrated comprise 17 species within 7 genera: *Cystiphyllodes corniculum* (Regnell, 1941), *C. cf. laticystis* (Regnell, 1941), *C. cf. macrocystis* (Schlüter, 1889), *Tryplasma cf. tomtchumyshensis* Zheltonogova, 1961, *T. hercynica* (Peetz, 1901), *T. aequabile* Lonsdale, 1845, *Pseudotryplasma sp. A*, *Dubrovia sp. A.*, *D. sp. B.*, *D. aff. dubroviensis*, *Salairophyllum cf. angustum* (Zheltonogova, 1961), *Neomphyma sp.*, *Rhizophyllum hedinii* (Regnell, 1941), *R. cf. enorme* Etheridge, 1903, *R. extensum* Soto and Liao, 1998, *R. sp. A.*, *R. sp. B.* Among these rugose corals, *Tryplasma cf. tomtchumyshensis*, *T. hercynica* and *T. aequabile* closely resemble some Lower Devonian forms from the Urals, Salair and Altay Mountains. Although genus *Rhizophyllum* is usually recorded from Silurian but *R. cf. enorme* is somewhat related to *R. enorme* from the Lower Devonian of eastern Australia, Salair, Altai and the Urals. *Dubrovia aff. dubroviensis* and *Salairophyllum cf. angustum* closely resemble their holotypes from the Lower Devonian of the Salair, Russia respectively. Besides, the tabulate corals *Dictyofavosites multitabulata* Dubatolov, *D. nagorskyi* Mironova, *Favosites terrejaensis* Tchernychev and *Cladopora rectilineata* Simpson have also been recorded from the Lower Devonian of Salair. Taken as a whole, they all indicate an Early Devonian age (Lochkovian), obviously bearing a much closer relationship with those of Salair, Altay and the Urals of Russia. </ABSTRACT>

37201 <TITLE>A new species of *Aphraxonia* from the Upper Middle Devonian of the South Tianshan Area, Xinjiang, China.</TITLE>

37202 <SOURCE>Acta Palaeontologica Sinica 41, 3: 118-123.</SOURCE>

37203 <ABSTRACT>*Aphraxonia*, a rare Middle-Late Devonian rugosa coral genus with columella structure, was previously only known from two localities: Upper Devonian of Anatolia area, Turkey and the Qiziqiao Formation (Givetian) of Hunan Province, China (Ünsalner 1951; Jia et al. 1977), including two species: *Aphraxonia salaner* and *Aphramonia zhuzhouensis* (Jia). *Aphraxonia zhuzhouensis* (Jia) was originally described by Jia (see Jia et al. 1977) under the genus *Hunanaxonia*. After comparing the main features of *Aphraxonia* Ünsalner 1951 and *Hunanaxonia* Jia 1977, Hill (1981) thought that [there are] no basic differences between the two genera and, thus, she put *Hunanaxonia* under the subjective synonyms *Aphramonia* Ünsalner 1951. In this paper, we report a new species of the genus, namely *Aphraxonia wuqiaensis* sp. nov., collected from the Middle Devonian of the South Tianshan area, Xinjiang. This new species represents an intermediate form between *Aphraxonia taurenensis* Ünsalner and *Aphramonia zhuzhouensis* (Jia) in the internal morphological features. It is the first to confirm the existence of *Aphraxonia* outside the Anatolia area of Turkey and Hunan Province of China. This discovery demonstrates that *Aphraxonia* has wide geographical distribution during the Middle to Late Devonian period although it is rare in the fossil record. It also suggests that the South Tianshan area had close biogeographical relationship with both Turkey and Southern China during the Devonian. [first part of extensive

- 37228 <SOURCE>Earth Science Frontiers 13, 6: 234-246.</SOURCE>
- 37229 <ABSTRACT>Eastern Yunnan, southwest China, especially the Panxi (Poshi) area, has been one of the most important areas for the study of the neritic Devonian in south China. Fossiliferous Devonian deposits in the Panxi region have been well known for a long time. The Devonian in the Panxi section is mainly composed of carbonate rocks, which contain abundant benthic fossils (rugose corals, stromatoporoids and brachiopods). Significant biostratigraphic works on these Devonian rugose corals have been made by Wang Hong-zhen, who assigned them to 36 species in 19 genera, including 19 new species. He subdivided them into 7 horizons (in ascending order: G, C, K, E, T, P, D). The rugose corals described and illustrated in this paper comprise 15 species within 14 genera: *Cystiphyllodes tungshanensis* (Wang), *Mesophyllum panxiense* (Yu, Liao Deng), *Dendrostella trigemme*, *Neosyringaxon huaningense* sp.nov., *Endophyllum panxiense* sp.nov., *Grypophyllum tenue* wedekind, *Disphyllum* sp., *Spinophyllum hejiazhaiense* (Kong in Kong Huang), *Temnophyllum waltheri* Yoh, *Truncicarinum temeniophylloides* (Wang), *Pseudozaphrentis* cf. *difficile* Sun, *Thamnophyllum sinense* Yu, Liao Deng, *Mictrophyllum intermedium* Liao, *Axophyllum vauhani longiseptatum* Wu Zhao, *Axophyllum zhanyiense* Wu Zhao. Among them, *Grypophyllum tenue*, *Temnophyllum waltheri*, *Thamnophyllum sinense*, *Cystiphyllodes tungshanensis* and *Spinophyllum hejiazhaiense*, the species in the Kutsing and Poshi Formations, as well as the genera *Endophyllum* and *Neosyringaxon* are characteristic of the Givetian in South China, Russia and Germany. *Pseudozaphrentis difficile* and *Mictrophyllum intermedium*, the former is from the upper part of the Itate Formation and the latter is from the Zaijie Formation, usually recorded from the Frasnian of South China. *Dendrostella trigemme*, from the Nanpanjiang Formation, is commonly found in the upper Eifelian to lower Givetian. The overlying strata yield Lower Carboniferous corals *Axophyllum zhanyiense* and *Axophyllum vauhani longiseptatum*. Both species were originally reported from the Lower Carboniferous of western Guizhou and eastern Yunnan. The boundary between Carboniferous and Devonian in Panxi area may be disconformable. 37240 <TITLE>Devonian Biostratigraphy of Dushan, Southern Guizhou and its coral Extinction events. [in Chinese, with English abstract] </TITLE>
37241 <SOURCE>Acta Palaeontologica Sinica 42, 3: 417-427. </SOURCE>
37242 <ABSTRACT>The shallow marine Devonian is well developed in Dushan, southern Guizhou and rich in fossil corals. The Devonian corals in Dushan flourished in a nearshore shallow water environment and all coral communities fall in the range of BA3 and BA4 (equivalent of the upper part of subtidal) in the Pedder and McLean's benthic assemblage scale. * On the basis of study of the Devonian rugose corals in Dushan section, 7 assemblages have been established. (1) Of which the Utaratuia-Sociophyllum Assemblage of Longdongshui Member is correlated with the coral assemblage of Hume Formation (Eifelian) from northwestern Canada. (2) The Columnaria-Dendrostella Assemblage from Tunshang Member may be correlated with the late Eifelian coral assemblages in Germany. (3) The Paramixogonaria-Jipaolasma Assemblage from Chipao Member together with the (4) Endophyllum-Sunophyllum-Argutastraea Assemblage from Chiwochai Member should be equivalent to European Givetian coral assemblages. (5) The Sinodisphyllum-Pseudozaphrentis-Mictophyllum Assemblage from Hejiazhai Member and the (6) wapitiphyllum-Pseudozaphrentis-Disphyllum Assemblage from Lujiazhai Member are approximately equivalent to the Frasnian coral assemblages in northwestern Canada. (7) The Cystophrentis Assemblage in Kolaoho Formation should be approximately contemporaneous with the European Strunian (latest Famennian) coral assemblages. * Four-times bio-events have been found from the Devonian in Dushan recently. (I) The first occurred at the top of the Longdongshui Member, in which all of Favosites disappeared, it may be correlated with the mid-Eifelian event (Oliver and Pedder, 1994). (II) The second appeared at the top of Chiwochai Member, in which a lot of cystimorph corals and Stringocephalus died out, it is approximately equivalent to the end-Givetian event (Oliver and Pedder, 1994). (III) The third happened at the bed about 80m above the lower boundary of Yaoso Formation, a large number of shelly benthos, such as tentaculites, Atrypacea, the characteristic Devonian corals, stromatoporoids, bryozoans and reefs were killed, it should be equivalent to the F-F mass extinction (Kellwasser event in Germany). (IV) The fourth found near at the top of Kolaoho Formation, many Strunian (latest Devonian) fauna were replaced by the Tournaisian (earliest Carboniferous) taxa. It should be equivalent to the D-C extinction (Hangenberg event in Germany). [original summary] </ABSTRACT>

37253 <TITLE>A restudy of Cystophrentis Yu, 1931 (Rugosa) from the uppermost Famennian (Strunian) of South China. </TITLE>
37254 <SOURCE>Geobios 36, 4: 407-419. </SOURCE>
37255 <ABSTRACT>The genus Cystophrentis, first described by Yü, 1931 occurs

in South China, Tibet, Viet Nam and Armenia. Its geological age is Strunian (latest Fammenian). It forms the basis for the order Mesocorallia Yü, 1963, regarded as intermediate between the Rugosa and the Scleractinia based on the presence of metasepta between the counter septum and the counter-lateral septa. The genus Kailingophyllum Yu and Lin, 1984 was described as being similar to Cystophrentis, but the apparent differences between these genera are no more than ontogenetic variations. Consequently, Kailingophyllum is regarded here as a synonym of Cystophrentis. Three species from six localities in South China and Tibet are described: Cystophrentis kolaohoensis Yu, 1931; Cystophrentis simplex (Yu and Lin in Yu, Lin and Fan, 1984) and Cystophrentis grandis Kuang in [Jia et al., 1977]. Serial sections and external septal grooves of the corals studied show no insertion of metasepta between the counter septum and the counter-lateral septa in Cystophrentis. Thus there is no basis for the recognition of the order Mesocorallia Yü, 1963. [original abstract]

37267 <SOURCE>Revista Espanola de Paleontologia 13, 2: 197-206.</SOURCE>

37268 <ABSTRACT>En el presente trabajo se describen varias especies del género Rhizophyllum Lindström, procedentes de la Formación Arpishmebulaq (Lochkoviense), en el SE de las Montañas de Tian-Shan (provincia de Xinjiang, NO de China). Las descripciones realizadas comprenden cinco especies, de las cuales Rhizophyllum extensum se propone como nueva, R. sp. A y R. sp. B son también, probablemente, nuevas, pero la falta de material más abundante y mejor conservado hace que las mantengamos, por el momento, en nomenclatura abierta. R. hedinii (Regnell) era conocida solo por su morfología externa y ahora se describen por primera vez sus estructuras internas. Finalmente, R. cf. enorme (Etheridge) no había sido citada nunca en China y su presencia en el área de Arpishmebulaq confirma relaciones biogeográficas durante el Lochkoviense con los Montes Urales, Salair, Asia Central (Altai) y Este de Australia. 37279 <TITLE>Corales rugosos (Tryplamatidae, Mucophyllidae y Cystiphyllidae) de la Formación Arpishmebulaq (Lochkoviense) en el SE de las Montanas de Tian-Shan (NO de China).</TITLE>

37280 <SOURCE>Revista Espanola de Paleontologia 16, 2: 255-268.</SOURCE>

37281 <ABSTRACT>In the present paper seven species of the rugose coral genera Tryplasma Lonsdale, 1845, Pseudotryplasma Ivaniya, 1958 and Mesophyllum Schlüter, 1889 {subgenus Mesophyllum (Cystiphyllodes) Chapman, 1893, sensu Birenheide, 1974} from the Arpishmebulaq Formation (Lochkovian) in the south east of the Tian-Shan Mountains (Xinjiang province, NW

China) are described. With the exception of the species *Mesophyllum* (*Cystiphyllodes*) *corniculum* (Regnell, 1941) and *M. (C.) cf. laticystis* (Regnell, 1941), which are known up to now only in the SE of the Tian-Shan Mountains (NW China), the other described species/subspecies, *Trylasma aequabile* Lonsdale, 1845, *T. hercynica* (Peetz, 1901), *T. cf. tomtchumyshensis* Zheltonogova, 1961, *Pseudotryplasma* sp. A and *Mesophyllum* (*Cystiphyllodes*) *macrocystis* cf. *macrocystis* (Schlüter, 1889) have been recorded at several localities, specially in the Russian Federation. Thus, the geographical and stratigraphical distributions of the mentioned species confirm strong biogeographical relationship during the Lochkovian age with the Ural Mountains, Altay and Salair, as well as with NE China (Jilin province). Also, such relationship, in a less degree, could have existed among NW China (Tian-Shan Mountains) and Tadjikistan, Kazakhstan, eastern Australia and E of North America (Nevada and Yukon). This relationship was previously confirmed by the authors (Soto y Liao, 1998, 1999) in relation to different taxa of rugose corals from the same formation and locality.

37293 <SOURCE>Geobios 33, 5: 527-541.</SOURCE>

37294 <ABSTRACT>Famennian rocks with deep water facies are very well developed in the northern part of Junggar Basin, Northern Sinkiang (NW China). The Hongguleleng Formation yields abundant rugose corals of the "Cyathaxonia fauna"; associated with a lot of brachiopods, some ammonoids (Clymenids) and some conodonts. The assemblages of these fossils indicate a Famennian age for the Hongguleleng Formation. The descriptions herein include fifteen species, among them two are new, belonging to ten genera. Some genera such as *Amplexus*, *Guerichiphyllum*, *Hebukophyllum*, *Nicholsoniella*, *Cyathaxonia*, *Ufimia*, *Caninia* and *Petraia* are common in north Sinkiang and they show a close relationship during the Famennian with those of the NE of Siberia (Omolon Region), E of Inner Mongolia (Central Great Hinggan Mountains, NE China), Kazakhstan (Russian Federation), the Urals (Russian Federation), Holy Cross Mountains (Poland) and Thuringia Mountains (Germany).

37345 <SOURCE>Bulletin Nanjing Inst. Geol. Palaeont. 5: 41-82.</SOURCE>
37346 <ABSTRACT>Devonian rugose corals including 34 species assigned to 21 genera are described from the Beiliu Formation, typically exposed in Beiliu, Guangxi, South China, where the formation is about 475 m thick and composed mainly of thick carbonate layers. One new genus is established: Beiliucyathus, which is characterized by two new species: the type species B. gracilis as well as B. carinatus. The other new species are as follows: Siphonophrentis asperetus, Sinospongophyllum undulatum, S. giganteum, S. beiliuense, Heliophyllum beiliuense, Dohmophyllum beiliuense, Xystriphyllum densum, Embolophyllum infundibulare, E. intortum, E. beiliuense, Grypophyllum psilatum, Stringophyllum beiliuense, Sociophyllum crassum, and Atelophyllum crasseptatum. Representatives of the genera Heliophyllum and Siphonophrentis indicate a remarkable mixture of taxa belonging to the eastern North America realm in the Beiliu fauna. 37371 <SOURCE>Courier Forschungsinstitut Senckenberg 92: 123-159.</SOURCE>
37372 <ABSTRACT>The well exposed Devonian rocks along the Da-yao-shan Mountains in central Guangxi yield abundant fossil corals and other benthic organisms. Especially the Upper Lower Devonian (Emsian) and Middle Devonian Subdivisions in Dale section, Xiangzhou and adjacent regions have been selected as the standard exposures of marine Devonian in South China, of which some massive rugose corals of Emsian and Upper Eifelian age are systematically described herein. The descriptions include the following 12 new or revised species belonging to 6 different genera: *Xystriphyllum daleense* n.sp., *Xystriphyllum guangxiense* n.sp., *Xystriphyllum* sp., *Disphyllia xiangzhouensis* n.sp., *Disphyllia regularis* n.sp., *Disphyllia* ? sp., *Gaynaphyllum sinense* n.sp., *Columnaria* ? *zhonpingensis* n.sp., *Spongonaria simplex* (Yoh 1937), *Spongonaria daleensis* (Yoh in Yoh et Bai 1978), *Spongonaria gracilis* (Yu et Liao 1974) and *Exilifrons varians* n.sp. The genera *Exilifrons* Crickmay 1968 and *Gaynaphyllum* Pedder 1980 are reported for the first time from South China. The definition of *Disphyllia* He 1978 is revised. A biostratigraphical division framework by means of Devonian corals and its correlation with the brachiopod and conodont successions in central Guangxi is presented; two assemblage zones, indicated as S and X, are recognized as new.</ABSTRACT>

37384 <SOURCE>Journal of Stratigraphy 11, 2: 120-125 [in Chinese, with English summary].</SOURCE>
37385 <ABSTRACT>Cystophrentis Zone has been considered by all the Chinese geologists to be Early Carboniferous since it was established in 1931. But Cystophrentis was commonly associated with *Icriodus costatus*, *I. raymondi*, *Polygnathus obliquicostatus* (conodonts), *Quasiendothyra kobeitusana*, *Q. radiata*, *Q. communis*, *Q. konensis* (foraminifers),

- Valliatisporites pusillites, Retispora lepidophyra (spores). All the fossils listed above indicate that the Cystophrentis Zone is undoubtedly Late Devonian. </ABSTRACT>

- 37423 <SOURCE>Acta Palaeontologica Sinica 27, 3: 269-277.</SOURCE>
- 37424 <ABSTRACT>The Famennian rugose corals described in the present paper were collected from the Yishan county of Guangxi, comprising 7 species in 6 genera, namely: Neaxon cheilos Weyer 1984, N. longiseptatum sp.nov., Kielcephyllum guangxiense sp.nov., Ufimia xiakouensis sp.nov., Prosmilia? yishanensis sp.nov., Yishanophyllum bellum gen. et sp.nov. and Zaphriphyllum sp. Although a majority of the above-mentioned corals are new species, however, they all bear obviously a much closer relationship with those of the Holy Cross Mountains of Poland and the Thuringian Mountains of GDR. Since the latest Devonian (Famennian) corals have rarely been reported in China, a brief description of these fossils seems desirable. [Kielcephyllum guangxiense ?] Corallite solitary, about 11-18 mm in diameter. In adult stage, major septa long, extending to the centre, numbering 24-30; minor septa short or rudimental; dissepiments variable in cross section. In later stage, major septa withdrawing from the centre, about half as long as the radius; cardinal septum shortened with cardinal fossula clear. Tabulae incomplete and cystose, dissepiments elongate or semiglobular. Remarks: Kielcephyllum cupulum Rozkowska differs from the present new species in its wider peripheral cystose [zone] and differentiated tabulae.</ABSTRACT>

37448 <TITLE>Colonial Rugosa from the Early Devonian (Pragian) of the Zeravshan Range, Tajikistan.</TITLE>
37449 <SOURCE>Alcheringa 31, 2: 121-151.</SOURCE>
37450 <ABSTRACT>The colonial rugose corals of the Shishkat fauna (Pragian, Kshtut Formation) from the Zeravshan Mountains are compiled and redescribed according to current taxonomic standards. The fauna can be categorized as a so-called *Carlinastraea*-Fauna, and a generally comparable generic composition is recognized on a global scale. Some Silurian relictual genera such as *Maikottia* or *Pycnostylus* are recorded. Of the 15 taxa discussed, *Australophyllum soghdianum* sp.nov. is described. All other specimens are assigned to known species or discussed in the context of open nomenclature. The Shishkat-fauna is clearly dominated by the Ptenophyllina (especially *Carlinastraea* and *Spongophyllum*), and Ptenophyllidae (*Australophyllum*, *Xystriphyllum* and in particular *Lyrielasma*). A remarkable occurrence of *Vepresiphyllum* indicates a weak faunal relation to eastern Australia. All other taxa show close affinities to coeval associations in the Urals, but especially to those from the Turkestan Range and the south Fergana Valley. The treatment of the Fasciophyllidae is supplemented by a short redescription of the Turkestan *Fasciophyllum maikottaense* Lavrusevich, 1972 because its type material is lost.</ABSTRACT>

37462 <SOURCE>Courier Forschungsinstitut senckenberg 110: 81-103.</SOURCE>
37463 <ABSTRACT>The present paper deals with descriptions and illustrations of 12 species of 8 genera of the rugose coral family Cyathophyllidae, subfamilies Columnariinae and Zaphrentinae sensu Birenheide 1978. Their reference material is taken from collections of the localities

Lujiazhai and Balhupo, near the county town Tushan, Province Guizhou, People's Republic of China. Geologically it was taken from beds of the Lujiazhai Member of the Wangchengpo Formation. The Frasnian of the Lujiazhai Member is concluded by means of brachiopods and the corals described herein; its proof by means of conodonts is not yet executed. The following two compound rugose coral species are new *Wapitiphyllum balhupoense* n.sp., and *Spongonaria frechi* n.sp. The stratigraphical and facial sequence of the Upper Devonian part of the Tushan Section are described and illustrated. The relations between the Givetian and Frasnian coral faunas of the Tushan section, as described by Liao & Birenhelde 1984, 1985, this paper, and that of the Rhenish Realm are discussed by comparison of the respective genera and species.

 37474 <TITLE>Early and Middle Devonian rugose corals from Toudaoqiao district of Central Da Hinggan Ling (Mts.).</TITLE>
 37475 <SOURCE>Bulletin Shengyang Inst. Geol. Min. Res., Chin. Acad. Geol. Sci. 18: 25-36.</SOURCE>
 37476 <ABSTRACT>The Devonian strata are widespread with numerous fossil corals in the central Da Hinggan Ling (Mts.). In 1979, the author took a field trip in the Toudaoqiao district, about 150 km south of Hailar City of Inner Mongolia (see the locality map), and collected abundant fossil corals and stromatoporoids from the Wunur formation. 16 genera with ... species, including 1 new genus, 5 new species and 1 new subspecies, of the Wunur formation studied in the present paper are as follows: - *Calceola sandalina weinaheensis* (subsp.nov.), *Cystiphyllodes robertense* (Stumm), *Siphonophrentis elongata* (Rafinesque & Clifford), *Briantelasma brevisseptata* (sp.nov.), *Metriophyllum* sp. indet., *Acanthophyllum* 1 sp. indet., *Leptoinophyllum* sp., *Grypophyllum* cf. *carinatum* (Soshkina), G. cf. *graciliseptatum* Pedder, *Lyrielasma chapmani* Pedder, *Hinganophyllum polygonalis* (gen. et sp.nov.), *Fasciphyllum obesum* (sp.nov.), *Chalcidophyllum* cf. *recessum* (Hill), *Exilifrons hinganesis* (sp.nov.), *Hexagonaria toudaoqiaoensis* (sp.nov.), *Thamnophyllum* cf. *stachei* Penecke, *Glossophyllum* sp. indet. Obviously, the genetic group of the fauna is composed mainly of the common genera of Eurasian continent added with some North American types and an endemic genus, and the species is also a mixture of the European and Australian species with the North American forms, except the endemic one. The age of the coral fauna is considered to be early Middle Devonian that may be correlated with the Heitai formation in eastern Heilong-jiang province and with the Wendurobot formation of central Inner Mongolia, and furthermore, may be corresponding to the Shandin-Mamontov formations of Salair of USSR, with which together to construct the Late Paleozoic folded belt in the southern margins of the Siberian plate. A few beds of gray-yellow and gray-green siltstone containing some small solitary corals is bound by fault with the Wunur formation in the stratigraphic section. These corals are identified as to be *Neaxon curta* (Pocta) which is very common in the Lower Devonian (Lochkovian to Pragian stage) in our region. The new genera *Hinganophyllum* and its type species *H. polygonalis* are described in the English abstract.</ABSTRACT>

37487 <TITLE>Frasnian-Famennian extinction and late Devonian rugose corals from Great Xing'an ranges, NE China.</TITLE>
37488 <SOURCE>Acta Palaeontologica Sinica 29, 4: 427-446.</SOURCE>
37489 <ABSTRACT>Data on occurrences of Late Devonian rugose corals suggest a major worldwide extinction of platform- and reef-dwelling corals occurring near the end of Frasnian time. The basin-dwelling corals, however, were virtually unaffected by the Late Frasnian event. The Daminshan district in the central Great Xing'an Ranges of NE China is one of the very rare localities in the world, where the Frasnian shallow-water corals and the Early Famennian basinal corals were well-developed. The Frasnian sediments called the Lower Daminshan Formation containing the corals Hexagonaria zambinskiensis (Ivania), Temnophyllum rectum (Walther), T. densum sp.nov., and Hinganastreaa daminshanensis gen. nov., while in the Famennian strata called the Upper Daminshan Formation, the corals are small and solitary with thin and simple skeletal elements, reflecting a semipelagic basinal environment, such as Petraiella sp., Barrandeophyllum zhaduenheense sp.nov., Guerichiphyllum daminshanense (Guo), Friedbergia sinensis sp.nov., Amplexocarinia sp., Gorizdronia simplex (Guo), G. minor sp.nov., Kozlowskinia sinensis sp.nov., Tabulophyllum tenuis sp.nov., Famennelasma sinensis sp.nov., etc. Their age may be bounded by the associated ammonoids corresponding to the Cheiloceras and Platyclymenia zones. The collisional suture between the Sino-Korean and the Siberian plates extends roughly along the border line of China with Mongolia, about 350 km south of the Daminshan district. In the author's (1986) interpretation, the convergence of the two paleoplates in Late Devonian, and so the orogenic movement and volcanic activities caused by the collisional process might be the direct reason of the Late Frasnian extinction in this region. Of course, this requires further study on the stratigraphic sections to find the iridium anomaly and determine the isotopes. [original summary] The following new genera and species are described in the English abstract: Barrandeophyllum zhaduenheense sp.nov., Friedbergia sinensis sp.nov., Gorizdronia minor sp.nov., Kozlowskinia sinensis sp.nov., Tabulophyllum tenuis sp.nov., Temnophyllum densum sp.nov., Hinganastreaa n.gen. (type species Billingsastreaa daminshanensis Guo 1980), Famennelasma sinensis sp.nov.</ABSTRACT>

- 37541 <ABSTRACT>Three species referred to Smithiphyllum are described for the first time from the Devonian reef complexes in Guilin. The species with well developed dissepiments and presepiments has been found in a

Frasnian bafflestone constituting a small patch reef; whereas the species in the back reef or platform margin facies are commonly represented by small colonies with slender corallites and less development of the dissepiments and presepiments. A revision of the Chinese species formerly referred to Smithiphyllum is made; only 5 species including those from Guilin are accepted.</ABSTRACT>

37552 <TITLE>Devonian tetracoral assemblages and their distribution in Guangxi, China.</TITLE>

37553 <SOURCE>Courier Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, vol. 2]: 7-13.</SOURCE>

37554 <ABSTRACT>within the Devonian rocks of Guangxi Province 17 tetracoral assemblage biozones can be recognised, which are very important for the subdivision and correlation of Devonian strata in that area. The development and evolution of the tetracoral assemblages varies with changes in sedimentary environments and can be divided into two main stages. 1. From the Lianhuashan to Yujiang epochs (Pragian - early-middle Emsian), a shallow shelf environment without obvious facies differentiation developed and very similar tetracoral assemblages occur in different areas of the Guangxi Devonian. 2. In the second stage, post-Yujiang to Rongxian epoch (late Emsian - Famennian), a carbonate platform developed in Guangxi. With the accompanying differentiation of sedimentary environments, two distinct tetracoral communities developed. In the open platform facies the tetracoral faunas are characterized by dense phaceloid and massive colonies. Eight assemblage biozones can be distinguished, represented by Spongonaria, Brevisseptophyllum, Disphyllum, Hexagonaria, etc. In the platform margin facies tetracorals are solitary or loose fasciculate colonies. Six assemblage biozones can be recognised, represented by taxa such as Grypophyllum, Stringo-phyllum, Temnophyllum, Sociophyllum, Neocolumnaria, etc. They form reefs in association with tabulates and stromatoporoids or algae.</ABSTRACT>

37565 <TITLE>Distribution of rugose corals in Devonian reef complexes in South China.</TITLE>

37566 <SOURCE>Courier Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, vol. 2]: 77-86.</SOURCE>

37567 <ABSTRACT>An attempt is made to determine the environments of the Pragian to Givetian rugose corals of the South China carbonate platform. Six different facies have been recognized in which Devonian rugose corals occur. Evidently most of the Devonian rugose corals in South China can be found in argillaceous limestones and marls containing terrigenous material; this facies indicates a nearshore

shelf or a protected open shelf environment. Late Emsian and Eifelian corals show a greater diversification of taxa and distribution than Pragian coral faunas. The maximal diversification of rugose corals was attained in Givetian time, corresponding with maximum reef development. There were no deep water corals in the Devonian sea of South China.

37578 <TITLE>The rugose coral fauna from the upper part of the Heyuanzhai Formation in western Yunnan, China.</TITLE>

37579 <SOURCE>J. Fac. Sci. Hokkaido Univ. IV, 23, 3: 343-552.</SOURCE>

37580 <ABSTRACT>The material studied here is from the Malutang-Heyuanzhai region of Shidian County, Yunnan Province, China. In this region Devonian is well developed and may be divided into eight formations. They include the Lower Devonian Xiangyangsi Formation, the Wangjiacun Formation, the Shabajiao Formation, the Middle Devonian Xibiantang Formation and Malutang Formation, the upper Middle to lower Upper Devonian Heyuanzhai Formation and the Upper Devonian Dujiacun Formation. Rugose corals are known from the Malutang Formation and the Heyuanzhai Formation. The Malutang Formation yields abundant brachiopods and a few rugose corals, while the Heyuanzhai Formation is rich in both rugose corals and brachiopods. This paper only deals with the rugose corals of the Heyuanzhai Formation. [part of extensive summary]</ABSTRACT>

37631 <SOURCE>Acta Palaeontologica Sinica 20, 1: 1-14.</SOURCE>
37632 <ABSTRACT>The corals described in the present paper were chiefly collected in 1976 and 1977 from the Shaodong formation in Central Hunan, northern Guangdong and northern Guangxi. Consisting of seven genera and fifteen species, they may be differentiated into two assemblage zones: the lower one is called the Ceriphyllum elegantum assemblage zone, dominated by such endemic forms as Ceriphyllum and Complanophyllum; and the upper one, the Caninia dorlodoti assemblage zone, characterized by the presence of Caninia patula Michelin, Diphyphyllum antiquatum (sp.nov.) and Dematophyllum hunanense (gen. et sp.nov.), etc. * The Shaodong formation with Caninia dorlodoti and Zaphrentoides delanouei may correspond to the Etroeungt limestone of western Europe, which is generally believed to be of early Lower Carboniferous age. Caninia dorlodoti, reported from Novaya Zemlia is also of Lower Carboniferous age. * Three new genera, each with a new species, are described: Ceriphyllum Wu & Zhao (C. elegantum n.gen. et n.sp.), Complanophyllum Wu & Zhao (C. compressum n.gen. et n.sp.); Dematophyllum Wu & Zhao (D. minor n.gen et n.sp.). 37644 <SOURCE>Acta Palaeontologica Sinica 22, 1: 66-70.</SOURCE>
37645 <ABSTRACT>In the present paper two new genera of Middle Devonian Rugose corals including six new species are described. They were collected by

the writer in 1963 from Dushan and Puan, Guizhou Province. Puanophyllum (gen. nov.) was found in the Middle Devonian at Guanziyan of Puan, western Guizhou, and forms a characteristic assemblage along with Calceola in the Lijiawan Formation. Jiangzhaiphyllum (gen. nov.) occurs in the limestone of the Bongzhai Formation and in the lower part of the Dushan Formation of Dushan, southeastern Guizhou. * The dilated septa and the presence of cystose dissepiments in the peripheral zone are of special interest in regard to the origin and evolution of the latter genus. 37656 <TITLE>On the Occurrence of Aulacophyllum and Hallia (Rugose corals) in Western part of Southern Qinling Range. [in Chinese, with English abstract]</TITLE>
37657 <SOURCE>Acta Palaeontologica Sinica 22, 2: 163-169.</SOURCE>
37658 <ABSTRACT>Aulacophyllum and Hallia described in this paper were found in the Early Devonian Emsian deposits in the western part of southern Qinling Range. These rugose corals are recorded for the first time in China; but outside this country more than 30 species of Aulacophyllum and about ten species of Hallia, so far known to the writer, have been described mainly from Onesquethawan stage in the central-eastern part of the USA, occasionally from the Devonian in England, Germany and Spain of West Europe, Sahara and Mauritania of N Africa, Ural, Russian platform and Armenia of USSR, Northern Shan State of Burma and NSW of Australia. * The Early Devonian Emsian deposits in this area may be compared with the Onesquethanwan stage of the USA in the abundance of fossils. Nevertheless, the coral-bearing beds are thought to be lower in stratigraphic position than those at other places of the world. [original summary]</ABSTRACT>

37696 <SOURCE>Acta Palaeontologica Sinica 49, 1: 29-43.</SOURCE>
37697 <ABSTRACT>The Devonian rugose coral genus Heterophaulactis from Lower Emsian Yujiang Formation in Guangxi, previously not fully described, is thoroughly examined and described in this paper. The main characteristics of this genus are also diagnosed. Based on the characters displayed in the holotype and additional type materials, the description of its type species, Heterophaulactis semicrassa is made in detail with full illustrations. A new species of this genus, Heterophaulactis yujiangense sp.nov. is erected with detailed description and full illustration. The genus is compared with other relevant genera in different aspects. It is interesting to note that a number of genera from the Lower Devonian in western Qinling mountainous region are of close affinity to Heterophaulactis. Some species referred to those genera may be assigned to Heterophaulactis, indicating that the distribution of Heterophaulactis is not restricted in south China, but extended to northwest China. The family assignment of Heterophaulactis is discussed and concluded that Heterophaulactis may be derived from Silurian Pycnactis - Phaulactis evolutionary lineage. The Subfamily Miroelasmatinae Cao 1983 is emended to include Heterophaulactis and its relevant genera and the family assignment of this subfamily is herein switched from Family Halliidae Chapman 1893 by Cao et al. (1983) to Family Lykophyllidae wedekind 1927. [original abstract] </ABSTRACT>

37709 <SOURCE>Global Geology 22, 4: 313-318.</SOURCE>
37710 <ABSTRACT>Some coral fossils newly collected from Lower Devonian Daerdong Formation of Xainza, Tibet have been systematically described. There are 7 species of Rugosa including one new species, 4 species of tabulatomorphic corals including 2 new species. The three new species are Hunanaxonia xizangensis sp.nov., Pachycanalicula sparcula sp. Nov. and Paraheliolites zakangensis sp.nov. The discovery of these corals in this area is beneficial for more understanding the symbiotic assemblage, evolution of the corals and their biogeography in Early Devonian. 37721 <TITLE>Rugose corals and brachiopods across the Frasnian-Famennian boundary in centre Hunan, South China.</TITLE>
37722 <SOURCE>Acta Palaeontologica Polonica 47, 2: 373-396.</SOURCE>
37723 <ABSTRACT>we present taxonomic revision of rugose corals and brachiopods from several Frasnian-Famennian (F-F) boundary sections in central Hunan Province, China. Diversity of shallow-water rugose corals gradually increased during the Frasnian, but ended with sudden extinction near the end of Frasnian. Ostracods were abundant during the Frasnian; their extinction coincided with anoxic deposition of the end-Frasnian black shale deposits. The early Famennian ostracod fauna is of low diversity. The brachiopod fauna of the late Frasnian (Palmatolepis rhenana and Pa. linguiformis zones) is dominated by atrypids, small-sized cyrtospiriferids, and the rhynchonellid Hunanotoechia. All atrypids disappeared before the F-F boundary with highest rates of extinction below the boundary (probably low in the Pa. linguiformis Zone). The Frasnian cyrtospiriferid fauna is also of low diversity and dominated by small taxa. All but one of the cyrtospiriferid taxa crossed the F-F boundary. The early Famennian post-extinction recovery brachiopod fauna was the result of rapid radiation of new forms shortly after the terminal Frasnian event. The early Famennian fauna is characterized by diverse cyrtospiriferids, abundant Yunnanellina and productoids. Above the early recovery fauna another fauna was recovered, with brachiopods Hunanospirifer and Yunnanella and is correlated with the late or latest Pa. crepida Zone. Sinalosia rugosa gen. et sp.nov. (Productida) is erected.</ABSTRACT>

37762 <ABSTRACT>In the present work the stratigraphical and geographical distributions of the cystimorph rugose corals (Cayugaea Lambe, Mesophyllum Schlueter and Mesophyllum (Cystiphyllodes) Chapman) coming from the SW of the Qingling Mountains (Tewo District, Gansu province, Central China) are studied in detail; the material belongs to the Dangduo (Upper Emsian) and Lure (Eifelian) Formations. The results of this study let us to reach a series of conclusions. On one hand the presence of the Cayugaea genus is reaffirmed in Central China. On the other hand, and on the basis of the analysis of the geographical distribution of the cystimorph taxa, new data are given supporting the paleobiogeographical hypothesis proposed by other authors. Finally, a relationship among Central China, NW Canada, W and E Europe and S China, during the Upper Emsian-Eifelian, is evidenced.</ABSTRACT>

37775 <ABSTRACT>In this work different species and subspecies of cystimorph Rugose corals coming from the lower half of the Dangduo Formation (Upper Emsian) and Lure Formation (Eifelian), Tewo District (Gansu Province, Central China), are described in detail. Five taxa, Cayugaea aff. gansuensis Cao, C. aff. cylindrica (Bulvanker), Mesophyllum (Cystiphyllodes) secundum ssp. A, M. (C.) secundum ssp. B and Mesophyllum (Mesophyllum) aff. arrectum (Yu & Cai) probably correspond to new forms. Regarding the rest of the species and subspecies, Mesophyllum (Cystiphyllodes) fongi (Yoh), M. (C.) caespitosum (Schlueter) and M. (C.) cf. macrocystis macrocystis (Schlueter), the stratigraphical range in China is extended. The rest of the species had been cited and described before by other authors from the same district. Finally, on the basis of the analysis of the stratigraphical and geographical distribution of the taxa studied, new data are given which support the paleobiogeographical hypothesis proposed by other authors. A relationship among Central China, NW Canada, Europe and S China, during the Upper Emsian-Eifelian, is shown.</ABSTRACT>

37799 <TITLE>Laccophyllidae Grabau 1928 (Rugosa) from the Hongguleleng Formation (Devonian, Lower Famennian) at the northwestern margin of Junggar Basin (Northern Xinjiang, NW China).</TITLE>
37800 <SOURCE>Coral Research Bulletin 7: 209-220. [Dieter weyer's 65th birthday commemorative volume; S. Schröder, H. Löser & K. Oekentorp (eds)]</SOURCE>
37801 <ABSTRACT>The Famennian Laccophyllidae (rugose corals) described in the present paper were collected in the Hongguleleng Formation, at Hoboksar (northwestern margin of Junggar Basin, Northern Xinjiang Uygur Autonomous Region, NW China). They are represented by six species, referred to three genera, some of them are redescribed in this paper after their original description in Liao & Cai (1987). Neaxon kullmanni and Guerichiphyllum hebukeense are new, Amplexocarinia tenuiseptata Liao & Cai 1987 is reassigned to the genus Catactotoechus Hill 1954 and Guerichiphyllum sinense Liao & Cai 1987 is described, refigured and its diagnosis amended. Finally, Catactotoechus sp. A and C. sp. B are considered also as new, but the scarcity of specimens does not allow the establishment of new species at the present time. This rugose coral assemblage and, especially, the presence of conodonts could be stratigraphically correlated with those of the Lower Famennian from the Holy Cross Mountains in southern Poland. The geographic distribution of the genera mentioned for the Junggar Basin during the Famennian confirms a close relationship with Inner Mongolia (Grand Khingan Mountains Range), Germany (Variscan Thuringian Mountains), Western Australia (Canning Basin) and Poland (Holy Cross Mountains). 37812 <TITLE>Ptenophyllidae (Rugosa) solitarios de la Formacion Arpishmebulaq (Lochkoviense) en el SE de las Montanas de Tian-Shan (NO de China).</TITLE>
37813 <SOURCE>Trabajos de Geologia 21: 353-362; Oviedo.</SOURCE>
37814 <ABSTRACT>En el presente trabajo se describen los corales rugosos

pertenecientes a la familia Ptenophyllidae de la Formación Arpishmebulaq (Lochkoviense), en el SE de las Montañas de Tian-Shan (provincia de Xinjiang, NO de China). Se han reconocido tres géneros y cinco especies, de las que *Dubrovia* aff. *dubroviensis* Zheltonogova, D. sp. A y D. sp. B son, probablemente, nuevas, pero se mantienen en nomenclatura abierta dada la escasez de ejemplares, mientras que *Salairophyllum* cf. *angustum* (Zheltonogova) y *Neomphyma* sp. se citan también ahora por primera vez en esta región. La distribución geográfica de estos taxones permite afirmar la existencia de relaciones paleobiogeográficas durante el Devónico Inferior (Lochkoviense) entre el SE de Tian-Shan y otras regiones asiáticas (Kazakhstan, parte E de los Urales, Altai y Salair). Estas relaciones son apreciables asimismo con el E de Norte América (Nevada y Yukón). [original abstract]

37942 <TITLE>Devonian Stromatoporoids of Eastern Yunnan.</TITLE>
37943 <SOURCE>Bulletin Nanjing Institute Geology and Palaeontology, Academia Sinica 4: 1-40.</SOURCE>
37944 <ABSTRACT>The purpose of this paper is to describe the stromatoporoids collected from the lower Middle Devonian Gumu and Qingmen Formations in Wenshan and Zhaotong, the upper Middle Devonian Donganling, Huaning or Zhaotong Formations in Wenshan, Huaning and Zhaotong, the Upper Devonian Mage or Zaijie Formations in Wenshan and Huaning. After identification they contain 19 genera and 76 species, in which 3 genera (Eostachyodes, Taeniosstroma and Columdictyon) 27 species and 3 subspecies are recognized as new taxa. By judging from the stromatoporoid aspects, some forms are very similar to those from the equivalent deposits in central and eastern Guangxi, southern Guizhou and northern Sichuan, some elements have been reported to occur in the

- contemporaneous deposits of Europe and Russia, and a few species have been known in North America. But it is to be noted that the new genera (Eostachyodes, Taeniosstroma and Columdictyon) are evidently endemic forms, which have so far not been found elsewhere. [from original summary]

37983 <ABSTRACT>This paper applies the guild concept extended by Bambach (1983) to the study of the level-bottom community. The organisms of the residual fossil communities - for example the Stromatopora-Scoliopora community - are assigned to 15 guilds. For correctly understanding the functions and trophic structures of organisms in a community, the concept of biovolume is used. Since the volume-sample method is not suitable to limestone, we have compared the dominance of each species by determining the volume of each population in the same bedding plane.

38033 <TITLE>Stromatoporoids from the Late Devonian (Strunian) Menggongao Formation, China.</TITLE>
38034 <SOURCE>Memoires Institut Geologique de l'Universite Catholique de Louvain 36: 141-152.</SOURCE>
38035 <ABSTRACT>Five species of labechiid Stromatoporoids are studied from the Late Devonian (Strunian) Menggongao Formation of central and south-central Hunan. This fauna from the Hunan province much resembles that described by Dong Deyuan (1964) from Guangxi and Guizhou. It also typically corresponds with the cool water, labechiid-rich assemblage 2 of Stearn (1987) and does not present any relation with the Strunian stromatoporoid fauna of western Europe.</ABSTRACT>

38124 <TITLE>Devonian Pseudofavosites in Northern Xinjiang.</TITLE>
38125 <SOURCE>Acta Palaeontologica Sinica 22, 6: 701-705.</SOURCE>
38126 <ABSTRACT>Pseudofavosites (Tabulata), as one characteristic genus of the Permian, was first reported by Gerth (1921) who described only one species from Timor. Since then, Yakovlev (1939) and Sokolov (1955) have described two species of the genus from the Lower Permian from the Ural in the USSR. In recent years, Pseudofavosites has also been found in the Carboniferous and Devonian of Guangxi and Xinjiang. Lin Bao-yu, for instance, described two species of the genus from the Carboniferous in Guangxi. Six new species of Pseudofavosites: *P. giganteus* sp.nov., *P. kakesuensis* sp.nov., *P. longispinus* sp.nov., *P. transitorius* sp.nov., *P. barkolensis* sp.nov. and *P. rarus* sp.nov. are described from the Lower Devonian in Barkol of Xinjiang. They are preserved in bioclastic limestone (Dananhu formation and Taheier-basitao formation). These species are associated with other Tabulata (Squameofavosites, Favosites, Steatothamnopora, Striatopora), Rugosa (Syringaxon, Barrandeophyllum), brachiopods (Mucrospirifer), and trilobites (Odontochile), indicating an early-middle Early Devonian age (Gedinnian and Siegenian).</ABSTRACT>

38137 <TITLE>The Devonian tabulate coral assemblages of Northern Xinjiang with remarks on subdivision of the Lower Middle Devonian.</TITLE>
38138 <SOURCE>Journal of Stratigraphy 01, 1: 34-40.</SOURCE>
38139 <ABSTRACT>During the past two decades, a large number of Devonian tabulate corals were gathered from many localities in northern Xinjiang. On the basis of study on these corals, five Devonian coral assemblages of northern Xinjiang are established as follows: Upper Devonian: Aulopora-Striatopora Assemblage; Middle Devonian: Alveolites-Trachpora Assemblage, Pachyfavosites polymorphus-Tyrganolites-Xinjiangolites Assemblage; Lower Devonian: Squameofavosites-Placocoenites-Pseudofavosites Assemblage, Aulocystis-Steatothamnopora-Pleurodictyum Assemblage. In the light of the tabulate coral assemblages mentioned above, the author suggests that the Lower Devonian of marine facies may be subdivided into two parts, namely, the Utubulake (including Mengeer) and Taheierbasitaw (or Asushan) Formations in the lower part; the Mongkelu, Zuomubasitaw (or

- Tuoranggekuduke) and Dananhu Formations in the upper. The Middle Devonian may be also subdivided into two parts, namely, the Kulumudi (or Sawuershan), Altai, Wulusubasitaw (or Beitashan) and Baixinde Formations in the lower part; the Zhifang Formation in the upper. The author also suggests that the first occurrence of Pachyfavosites polymorphus, Tyrganolites, Xinjiangolites is considered as the beginning of the Middle Devonian.

 38164 <SOURCE>Acta Palaeontologica Sinica 40, 2: 219-223.</SOURCE>
 38165 <ABSTRACT>In eastern South Tianshan, the age of the Arpishmebulaq Formation with Tabulata is defined again as Late Lochkovian, Early Devonian. The corals from the Arpishmebulaq Formation differ from those of equivalent horizons in the Junggar-Hingan biogeographic region but are similar to those from the Shanjiang Formation in Lijiang County, Yunnan, the Xiaputonggou Formation in Zoige County, Sichuan, the Alugong Formation in Darhan Mumingan Joint Banner, Inner Mongolia and the Erhtaokou Formation near Jilin City, Jilin. During early Early Devonian in China, a big biogeographic region is situated to the south of the Junggar-Hingan biogeographic region, and this region, including South Tianshan, Central Jilin, south Inner Mongolia, west Qiling Mountains and northwest Yunnan etc., should belong to the Palaeotethyan Province of the Old World Realm.</ABSTRACT>

38204 <ABSTRACT>The present paper deals with the tabulate corals collected from the late Middle Devonian in the Baijingshan district of Dahinganling (Mts. greater Khingan). Among them are six genera and eleven species (including four new species) as listed below: Favosites aff. intermedius Stewart, Thamnopora aff. reticulata (Blainville), T. absurda Yanet, Alveolites levis Chernyshev, Crassialveolites mirus Dubatolov, Coenites tenella Guerich, C. dubatolovi Yanet, C. lunatus sp.nov., Tyrganolites fungosus sp.nov., T. mixtus sp.nov., and T. extensus sp.nov. * In accordance with these elements, the tabulate coral-bearing rocks may be assigned to the late Middle Devonian, approximately corresponding to the Givetian Stage in the Kuznetsk Basin and the Urals of the USSR and in North America as well. 38242 <SOURCE>Acta Palaeontologica Sinica 18, 2: 131-160.</SOURCE>
38243 <ABSTRACT>This paper deals with the tabulate corals and chaetetids collected from the Longdongshui Member of the Houershan Formation in Dushan of Guizhou. The collections contain 19 genera and 30 species (including 12 new species and 3 varieties) of tabulate corals, 2 genera and 2 species of heliolitids and 2 genera and 4 species (including 2 new species) of chaetetids. The new species are: Roemerolites dushanensis, R. polymorphus, Parastriatopora jumuwanensis, P. jumuwanensis var. varia (var.nov.), P. jumuwanensis var. thamnopoidea (var.nov.), Thamnopora tersa, T. longdongshuiensis, Gracilopora spina, Alveolites convolutus, A. inconstans, Crassialveolites yunnanensis var. dushanensis (var.nov.), Caliapora mixta, Placocoenites elasmatus, Aulopora mixta, Syringoporella convexotabulata, Chaetetes raritabulatus and Cyclochaetetes distortus. The tabulate corals, heliolitids and chaetetids were found together with rugose corals (Utaratuia sinensis, Sociophyllum minor and Brevisseptophyllum kochanensis etc.) and Brachiopods (Acrospirifer houershanensis, Eospiriferina lachrymosa, Athyrinsina squameosaeformis, Acrospirifer fongi, Gypidula biplicata and Kwangsia perfecta etc.). * Accordingly, the tabulate coral-bearing deposits may be assignable to the early Middle Devonian stage, approximately corresponding to the Eifelian stage in Europe. Based upon the characteristic features of the tabulate corals and chaetetids, two coral assemblages may be recognized in the Longdongshui Member of the Houershan Formation, the upper assemblage is characterized by the presence of Parastriatopora jumuwanensis, Favosites clarus and Roemerolites dushanensis, while the lower assemblage is represented by Pachyfavosites nilella, Favosites multiplicatus and Pachycanalicula barrandei.</ABSTRACT>

38254 <TITLE>Lower and Middle Devonian Tabulate and Heliolitida from Alengchu of Northwestern Yunnan.</TITLE>

- 38255 <SOURCE>Bulletin Nanjing Institute Geology and Palaeontology, Academia Sinica 7: 287-310.</SOURCE>
- 38256 <ABSTRACT>The Lower and Middle Devonian marine deposits well developed in Alengchu of Lijiang N.W. Yunnan contain tentaculites, conodonts, brachiopods and corals. The tentaculites collected from there have been identified in 1975 by Mu Dao-cheng and the rugose corals in 1978 by Yu Chang-min and Liao Wei-hua. Here described which are Tabulata and Heliolitida belong to 14 genera and 35 species including 12 new species and 7 new subspecies with their stratigraphical distribution given as follows. In China, the Devonian sea may be generally outlined by two paleobiogeographical districts, the North district and the South one. The Lower Devonian marine strata with coral faunas including Tabulata and Heliolitida are developed from West Sichuan, Northwest Yunnan, Central Guangxi and West Qinling in the South, from East Junggar and Central Da Hinggan Mountains in the North. Favositids, Thamnoporids, Heliolitids are abundant in the above areas, chiefly containing Favosites, Dictyofavosites, Squameofavosites, Pahcyfavosites, Thamnopora, Striatopora, Cladopora, Parastriatopora, Heliolites and Paraheliolites, among which Favosites, Dictyofavosites and Squameofavosites are predominant. On the whole, the Lower Devonian coral faunas with Tabulata and Heliolitida from either North and South China bear a resemblance to those of Kazakstan and Kuznetsk Basin.</ABSTRACT>

- 38269 <ABSTRACT>Givetian, Frasnian and Famennian limestones from southern China contain microfossils generally regarded as calcified algae and cyanobacteria. These are present in 61 out of 253 sampled horizons in four sections from three widely spaced localities in Guangxi and southern Guizhou. Three of the sections sampled are Givetian-Frasnian-Famennian, one section is Frasnian-Famennian. They include reef and non-reef carbonates of shallow marine platform facies. The following taxa are identified with differing degrees of confidence, and placed in algae, cyanobacteria or microproblematica. Algae: Halysis, 'solenoporaceans', Vermiporella. Cyanobacteria: Bevocastria, Girvanella, Hedstroemia, Subtifloria. Microproblematica: ?Chabakovia, Garwoodia, ?Issinella, Izhella, Paraepiphyton, Rothpletzella, Shuguria, ?Stenophycus, Tharama, Wetheredella. As a whole, the abundance of algae, cyanobacteria and microproblematica increases by 34% from Givetian to Frasnian, and declines by 63% in the Famennian. This secular pattern of marked Famennian decrease does not support recognition of them as "disaster forms" in the immediate aftermath of late Frasnian extinction. Nonetheless, their survival into the Famennian could indicate tolerance of environmental stress, independence of changes in food supply, morphologic plasticity, and ability to occupy a range of habitats and depths. Uncertainties concerning the affinities of the problematic taxa hinder assessment of their significance.</ABSTRACT>

38293 <TITLE>Famennian (Upper Devonian) calcimicrobial (Renalcis) reef at Miaomen, Guilin, Guangxi, South China.</TITLE>
38294 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 204, 3-4: 373-394.</SOURCE>
38295 <ABSTRACT>Famennian (Upper Devonian) reefs represent a calcimicrobial and stromatolitic reef framework with a few skeleton-dominated (stromatoporoid) examples after the skeletal metazoans in reef ecosystems were impacted on a global scale by the Frasnian-Famennian extinction event. Calcimicrobes, thrombolites, stromatolites, and biologically induced cement formed the major part of reef framework volume and contributed to rigidity of reefs. In this study, one example of Famennian non-skeletal carbonate buildups at Miaomen, Guilin, South China, has been documented in detail. Thick and massive limestones in the platform margin facies show a lateral transition to well-bedded fenestral and laminated limestone in the back-reef facies southeastward and to well-bedded intraclastic grainstone, mudstone, and shale with lithoclasts and breccias in fore-reef slope facies northwestward. The Miaomen reef is almost exclusively constructed by calcimicrobes and cement. Major reef builders are Renalcis, Izhella, Paraepiphyton, Garwoodia, and a Keega-like microbe. Other reef builders are Wetheredella, Rivularia, Rothpletzella, Ortonella, and Girvanella. Some less common algae and calcimicrobes also occur in the Miaomen reef, including Parachaetetes, Solenopora, Tharama-like objects, and unidentifiable microbes. Cavities are well developed in the reef limestone. The Miaomen Renalcis reefs developed along leeward platform margin settings adjoined by intraplatform depressions and rimmed Famennian carbonate platforms along with stromatolite reefs, ooid shoals, brachiopod-shell shoals, nautiloid shoals, and previously described Renalcis-Epiphyton and Renalcis-cement reefs. Miaomen reefs demonstrate the significant roles of calcimicrobes and microbial carbonates in the development of Famennian carbonate systems in South China. Famennian microbial reefs in Guilin represent an interval of profound biotic change in the style and extent of carbonate buildups and in the composition of buildup communities and indicate important environmental and ecological changes within the carbonate system. 38306 <TITLE>Astraeospongium (Porifera: Calcarea) from the Late Devonian of northwestern China, and the late ontogeny of the genus.</TITLE>
38307 <SOURCE>Memoirs of the Association of Australasian Palaeontologists 34: 331-342.</SOURCE>
38308 <ABSTRACT>Two species of sponges are reported from Famennian strata at the locality Aomuhu, north of Hoxtolgay, Xinjiang, northwestern China. Astraeospongium chenae sp.nov. differs from other species in lacking a dermal armour of heteracts on the concave surface. Preservation and weathering details of this species suggest that the life orientation of Astraeospongium (convex up) is the reverse of that generally accepted. A growth analysis of A. chenae indicates that definition of species of the genus on the basis of spicule size is invalid. The presence of an abraded astylospongiid accompanying A. chenae indicates an association enduring from Late Silurian to Late Devonian times.</ABSTRACT>

38345 <TITLE>Biogeografiya Kazakhstana v devonskiy period.</TITLE>
38346 <SOURCE>Trudy Instituta Geologii i Geofiziki AN SSSR (Sibirskoe Otdeleniye) 347 : 64-103</SOURCE>

- 38347 <ABSTRACT>Nach einer eingehenden Charakteristik der stratigraphischen Einheiten Kazakhstans werden die biogeographischen Zusammenhänge anhand der Korallen (Rugosa und Tabulata) und Brachiopoden des Dshungarskiy-Balkhash Meeres dargestellt und den Faunenprovinzen der übrigen Welt gegenübergestellt. Im tieferen Unterdevon finden sich noch verstärkt Relikte silurischer Gattungen und Arten (unter den Rugosa z.B. Schlotheimophyllum, Araeopoma, Pilophyllum, Ptychophyllum; unter den Tabulata Astrocenum, Pachyporid, Alveolites), die aber gegen Ende des Unterdevons verschwunden sind. Gleichzeitig treten aber neue Formen auf, die teils starken endemischen Charakter besitzen und im Kazakhian (Upper Emsium) den grossten Anteil der Fauna ausmachen. Favositidae spielen die bedeutendste Rolle. Das Dshungarskiy-Balkhash-Meeresbecken stellt somit im Unterdevon eine selbständige biogeographische Einheit dar. Die mit dem Ende des Kazakhian erfolgende Regression führt zu einem Aussterben der meisten Korallen und Brachiopoden. Im Mitteldevon, insbesondere im Givetium, wird die Isolierung Beckens beendet. Neue, teils kosmopolitische Faunenvertreter erscheinen. Unter den Tabulata herrschen die Thamnoporinae vor, aber auch Alveolitidae u.a. Ein Austausch mit benachbarten Provinzen findet statt, so können Einwanderer aus Westeuropa (z.B. Thamnopora cervicornis), aus der Mediterranean -, der Uralo-Tianshan -, der Altai-Sayan-Provinz festgestellt werden. Verbindungen nach Nordamerika und Australien fehlen. Im Oberdevon schreitet die Transgression fort. Gleichzeitig aber tritt, vor allem im Famennium, dem Hohepunkt der Transgression, eine Faunenverarmung ein. Herrschen zunächst in Frasnium noch Alveolitidae vor, so finden sich im Famennium in erster Linie Syringoporen und Auloporen, die zudem bereits Anklänge an die karbonischen Formen aufweisen. - 38360 <ABSTRACT>This paper deals with the litho- and biofacies, the division and correlation of the Devonian stratigraphy, as well as the Devonian fossil assemblages of South China. Species of stromatoporoids, tabulate and rugose corals are mentioned besides plants and other vertebrate fossils. Two major provinces are to be distinguished: the western province covers the Tsinling, the Tibet - western Yunnan region and parts of the Kunlun Mts with marine Lower Devonian of mainly miogeosynclinal type with abundant benthonic and planktonic faunas conformably situated on the Silurian while the eastern province occupies the vast region south of the Tsinling Mts, and the east of the Kongtian Massif, where the Devonian is of platform type with deposits yielding rich faunas of different phyla.</ABSTRACT>

38372 <SOURCE>Chinese Journal of Geology 39, 1: 92-97.</SOURCE>
38373 <ABSTRACT>The Devonian Buzhai reefs in southern Guizhou developed in the Jipao and Jiwozhai members of the Dushan Formation. The reefs distributed along the boundary between the platform and platform-basin and grew on a narrow elevated area, caused by a syn-sedimentary fault. They were mostly frame reefs, built mainly by Stromatopora-Almolites community, which was very important reef building community, characterized by the massive stromatoporoids and various tabulate corals. Some of them were baffle reefs, built mainly by blue-green algae community, which was dominated by columnar stromatolites. The reef complex could be divided into six facies, and four subfacies could be distinguished in the reef facies. The development of reefs was largely controlled by the sea transgression and regression and included two large cycles.</ABSTRACT>

38410 <TITLE>Biotic recovery from the Late Devonian F-F mass extinction event in China.</TITLE>
38411 <SOURCE>Science in China Series D: Earth Sciences 45, 4: 380-384.</SOURCE>
38412 <ABSTRACT>The Frasnian-Famennian (F-F) mass extinction is one of the five great extinctions of marine life during the Phanerozoic. The F-F event killed most of the Devonian reefs, the characteristic Devonian

corals, stromatoporoids, bryozoans, nearly all tentaculites, a few superfamilies of brachiopods, such as Atrypacea and Pentameracea and some important elements of goniatites, such as Manticoceras. * The end-Frasnian was a phase of mass extinction. A large number of shelly benthos were killed by the F-F event. Early and middle Famennian was the survival interval. The marine faunas were very rare at that time. The late Famennian was the recovery interval. There appeared to have many new taxa in the Strunian stage. It lacked a radiation interval in Late Devonian Famennian because another event (the D-C mass extinction) happened at the Devonian-Carboniferous boundary. * Several causes for the F-F mass extinction have been proposed by some geologists, which have been grouped into two broad types, terrestrial and extraterrestrial. The former is related to sea level changes, climate changes and anoxic water event. The latter is linked with some forms of meteorite impact. * A large-scale eustatic change of sea level and black shales representing an anoxic environment has been invoked to explain one of the causes for the F-F mass extinction. [original abstract; also reported in FC&P 30, 2: 11 - similar, Chinese version of this paper: Liao Wei-Hua 2001, Biotic recovery from the Late Devonian F-F mass extinction event - this could not be confirmed by our bibliographic query in June 2013] </ABSTRACT>

38450 <SOURCE>Acta Geologica Sinica 74, 4: 727-739. [English edition; Journal of the Geological Society of China]</SOURCE>

- 38451 <ABSTRACT>Three Devonian reefs (bioherms) from Yunnan and Guangxi, southern China, are studied in detail. Six microfacies types are differentiated. Colonial rugose corals (Columnaria, Disphyllum, and Hexagonaria) at Qujing, tabulate corals (Alveolites) with massive stromatoporoids (Actinostroma, and Stromatoporella) and sponges at Pauxi, and massive stromatoporoids (Actinostroma, Trupetostroma and Stromatoporella) at Yangshuo belong to the most important reef builders. All the three reefs studied clearly reveal a successive evolution history. They developed on carbonate banks, shallow carbonate platforms and platform margins in Late Givetian and terminated in the Frasnian due to sea-level falls related to local uplifts of platforms. This coincides with a eustatic fall of relative sea level at the Frasnian / Famennian transition.</ABSTRACT>

- 38475 <TITLE>Analysis of a Middle Devonian community from Panxi in eastern Yunnan, with notes on fossil counting in a quadrat.</TITLE>
- 38476 <SOURCE>Acta Palaeontologica Sinica 26, 1: 18-29.</SOURCE>
- 38477 <ABSTRACT>This paper discusses the fossil counting in a quadrat, with the recognition that it is appropriate and effective to use the alternate fossil counting method for diverse organisms which are individually different in size. From the consumption of food resources in an ecosystem, a colonial form with smaller individuals (e.g. bryozoans) may be equivalent to a larger solitary form (e.g. solitary tetracorals). Application of this method would precisely ascertain the relative importance of each population at the same trophic level. By using the quadrat method and based on the data from autecology and sedimentology, the authors have analysed the structures of the PM (Parasociophyllum isactis - Microplasma fungi) community from the Middle Devonian Huaning Formation of Panxi, Eastern Yunnan and reconstructed the general features of the living community (fig. 6). The PM community represents a living community dominated by benthic suspension feeders. Including at least 28 populations, with the dominant species Microplasma fongi (Yoh) and Cystiphyllodes kwangsiense Yoh, and rare species Stringocephalus obesus, Murchisonia, etc. The PM community has a high diversity (D=3.795), a high dominance (C=0.648) and a low equitability (E=0.286), at two trophic levels (producer level and primary consumer level). The spatial distribution of the community is characterized by a mosaic pattern with patch areas of high biomass and high density enclosed in scattered areas of low biomass and low density, on four levels in height. Probably the PM

- living community was developed in the tropic zone and on the upper part of a shallow-shelf (below the normal wave base).</ABSTRACT>

- 38489 <SOURCE>Canadian Society of Petroleum Geologists, Memoir 14 [McMillan N. J. et al. (eds): Devonian of the World], II: 649-658.</SOURCE>
- 38490 <ABSTRACT>Middle Devonian rocks in Southern China exhibit a variety of lithofacies and biotas. Three facies areas can be recognized, including four facies zones or belts. The distribution of various facies zones was only controlled by a basement fracture system but also by syndepositional faults. The reefs range in age from late Emsian to Eifelian and from Givetian to the end of Frasnian time. They are mainly distributed along the northwest-trending Nandan-Yadu fault zone and along the northeast-trending Yongfu-Tao-jiang fault zone. Some of the Givetian reefs in Southern China are laterally differentiated into fore-reef, reef-core and back-reef subfacies. In vertical section they exhibit in ascending order repeated cycles of reef basement, reef, dolomitized reef and biotrital limestones. Hematite ore deposition occurs preferentially in the transition zone between clastic rocks and argillaceous limestone in the central part of the littoral facies area. Siderite and its sister deposits typically occur in the transitional terrane between the reef platform and depressional facies so they, too, are related to the reef facies. The Devonian of South China was deposited in an epicontinental sea which overlapped paleo-landmasses. On the east the epicontinental sea was bounded by the Cathaysian landmass, on the north and northwest by the Jiangnan landmass and the Qianbei landmass respectively, and on the west by the Kongdian landmass. These paleo-landmasses were source areas for terrigenous material that was transported, respectively, from east to west, from north and northwest to south and from west to east during the Devonian marine transgression which advanced mainly from the southwest toward the northeast. The Middle Devonian of South China exhibits diverse lithofacies and biotas culminating in the development of reef complexes. Studying these rocks gives us a general understanding of the Devonian facies pattern and reef development in south China.</ABSTRACT>

38527 <TITLE>New thinking about research on Devonian reefs and oil exploration in Hunan, China.</TITLE>
38528 <SOURCE>Boletin de la Real Sociedad Espanola de Historia Natural, Seccion Geologica 92, 1/4: 015-021.</SOURCE>
38529 <ABSTRACT>Devonian reefs in Hunan were developed in the late Givetian and early Frasnian. Most reefs have been discovered in the area of carbonate platform facies and regarded as biostromes or patch reefs. Rare oil shows have been found in these kinds of reefs. Some so-called reef mounds have abundant oil shows, but they have been considered to have developed only on a few elevated blocks in the area of inter-platform depressional facies. Based on research on reef distribution and characters of sedimentography and paleoecology, this paper proposes that many so-called biostromes are not layered but instead are narrow [structures] along the edges of platforms [acting] as barrier reefs. Some reef mounds are only the upper parts of barrier reefs, which extended towards the depressional facies area and were broken by faults. If this is true, they will be found along the edges of platforms and are not restricted within narrow limits. Because these parts of the reefs are preserved in the black shales and have fine oil shows, great attention should be paid to them in oil exploration.</ABSTRACT>

38568 <ABSTRACT>A vast area of China is characterized by karst topography. The most beautiful karst landscapes are the Stone Forest in Yunan and the peculiar karst features of Kweilin in Kwangsi. Many of these features are developed in the Devonian carbonate rocks and are closely related with reef phenomena. * The distribution, depositional types and subdivision of the Devonian System of China are controlled by two major latitudinal structural belts, the Inshan-Tianshan mountains and Tsinling-Kunglung mountains respectively... 38579 <TITLE>Devonian reefs and reef complexes in Guilin, Guangxi, South China [in English].</TITLE>
38580 <SOURCE>Jiangsu Science and Technology Press, Nanjing: 168 pp., 57 text-figs, 27 pls.</SOURCE>
38581 <ABSTRACT>A professional volume contains rich data on Devonian reefs and reef complexes in Guilin, south China based on the result of as long term study under multidisciplinary principles of biology and geology, especially based on the result of paleobiologic study on many fossil groups, on the lithostratigraphic, biostratigraphic, sedimentology, microfacies analysis of carbonate rocks etc. It reveals that the region of present Guilin was covered by warm and shallow marine about 360 million years ago and was prosperous with the reef development. By the beginning of the geologic time interval approximately equivalent to the varcus conodont zone there started a record of carbonate deposition in Guilin. It was until the late Famennian and earliest Carboniferous that the reefs were intermittently developed along the margin of carbonate platform, and in places in the interior of platform. As a whole the marine Devonian form a megacycle mainly composed of the clastics at the base (pre-varcus zone), and of the carbonates at the above, where some hiatus of various scale caused by the bioevents and sedimentary events can be found. Some patch reefs, fringing reefs and algal mounds of smaller size occurred mainly in the earlier stage of the carbonate platform development in Givetian,

whereas the barrier reefs along the margin of platform and rare patch reefs behind them were growing in the late developmental stage mainly in Frasnian, locally in Famennian. * Beside the first chapter in which the regional geology and the Devonian stratigraphy including the biostratigraphic framework and lithostratigraphic sequences are introduced, there are descriptions and records of the characteristics of various parts of the reef complexes and different facies types outcropped from place to place in Guilin. these contents occupying the length of three chapters are appended with many photos in plates and text-figures made from the outcrops or under the microscopy, the fifth chapter deals with the aspects of diagenesis and in the sixth chapter there is discussion of the sea-level changes affecting the Devonian sedimentation and reef development, the conclusive parts issued that the special mode of Devonian reef development in Guilin is distinct from the contemporaneous reef development in western part of North America, northwestern Australia and western Europe. </ABSTRACT>

38606 <SOURCE>Journal of Xiangtan Mineralogical Institute 18, 3: 29-32.</SOURCE>

38607 <ABSTRACT>Devonian reefs in Buzhai of Guizhou developed in the Jipao Member and Jiwozhai Member of Dushan Formation. They are mostly frame reefs, built mainly by stromatoporoids and tabulate corals. Some are the baffle reefs, built mainly by dendroid tabulate corals or algae. Four communities and an association are recognized in the reef complex. The Ilmenia-Crassialveolites community is characterized by small brachiopods and dendroid tabulate corals and occupied in the lower-turbulent shallow sea. The Thamnopora-Stringocephalus community consists of the dendroid tabulate corals and big brachiopods and develops in the open shallow sea. The Stromatopora-Alveolites community is the very important reef-building community, characterized by the massive stromatoporoids and various corals. The blue-green algae community is the builder of the baffle reefs. The Cyclocyclicus-Clathrocoilona association is composed of the crinoids and thin-bed stromatoporoids and develops in bank facies. By the ecological analysis and comparison with the reefs in neighboring areas, the reef complex developed in a stable shallow marine environments, which was more suitable for growth of reef-building organisms.

38633 <ABSTRACT>Corals are generally common in the Devonian / Carboniferous boundary beds of the Nanbiancun sections although not the most common fossils. 23 species assigned to 11 genera belong to the rugose corals. Among them 11 species and 2 genera are new. The rest of them either remained as open species or genus or restricted the identification at a species level, 2 forms described as indeterminable. There is only one species belonging to the tabulate corals. The described corals occurring in the beds are dated by conodonts. [...] The existence of axial structures already in Famennian corals is discussed as well as the paleoecological aspects of the Nanbiancun fauna. The corals in Nanbiancun probably favour a deeper water environment. [taken from the abstract] </ABSTRACT>

38683 <TITLE>Distribution of Heterocorallia in China and Microstructure of Hexaphyllia.</TITLE>
38684 <SOURCE>Acta Palaeontologica Sinica 27, 4: 475-480.</SOURCE>
38685 <ABSTRACT>China yields the most abundant fossils of Heterocorallia in the world. However, so far only eight genera have been established, namely, Tetrphyllia, Oligophylloides, Pentaphyllia, Crepidophyllia, Longlinophyllia, Radiciphyllia, Heterophyllia and Hexaphyllia. Among them, Oligophylloides, is only found in Poland, Radiciphyllia only in Japan, while the others are all discovered from China, and can be classified into 3 families, 6 genera and 58 species. These Chinese taxa include not only the genera first identified in Europe, for example, Heterophyllia and Hexaphyllia, but also the endemic forms such as Tetrphyllia, Pentaphyllia, Crepidophyllia and Longlinophyllia. In China, Tetrphyllia is found from the Lower Devonian of wenshan, Yunnan, while the others are widespread in the strata of the Tatang Stage. The genus Hexaphyllia is much more abundant than others and together with Yuanophyllum may be regarded as zonal fossils for late Tatang Stage. It has been found that the microstructures of the skeleton of Hexaphyllia are all made up of fibrous elements, based on electron microscope observation of the specimens of Hexaphyllia floriformis wang et Ye from Majiaoba, Sichuan. These microstructures resemble the septal structure of advanced forms of Carboniferous tetracorals. The walls are made up of fibrous crystals which are mainly

composed of brachy-columns and needles, with rare crystal-granules, nearly in parallel arrangement and are perpendicular to the fibrolamellae. The fibrous elements in the septa are mainly brachy-columns and crystal-granules, with rare needles; they are arranged parallel to each other and are perpendicular to the mid-septal face. The tabulae are also mainly made up of brachy-columns and crystal-granules; they seem to be arranged in only one row and roughly perpendicular to the surface of tabulae.</ABSTRACT>

38710 <SOURCE>Memoires de l'Institut geologique de l'Universite de Louvain 36: 89-139.</SOURCE>

38711 <ABSTRACT>Rugosa were collected in four sections in Hunan, to determine precisely the biozonation of Famennian to upper Tournaisian strata and to attempt correlations with western Europe. 29 species (including two new ones), belonging to 16 genera (including three new ones), are described and compared with Rugosa from equivalent levels in Europe. Their stratigraphical distributions are documented. In systematics, Eocaninophyllum nov. gen. has been created for Famennian species previously assigned to Caninia, Parastelechophyllum nov. gen. for Tournaisian species resembling Stelechophyllum, previously assigned to Thysanophyllum, and Heterostrotion for Famennian to Visean species assigned to Donophyllum or to Stylostrotion. It is shown that Pseudoralinia is a junior synonym of Uralinia and is not close to Cystophrentis. The fauna, which developed during the Strunian, is totally different to that occurring at the same time in western Europe. It includes genera which are not known outside southern and central Asia, or in other levels than the Strunian, except one taxon (Smithiphyllum), and do not allow correlations. The Tournaisian strata yielded corals belonging to the Uralinia tangpakouensis and Keyserlingophyllum Zones, including some genera which are known outside China, or closely related to them. The base of the U. tangpakouensis Zone is correlated with the base of the RC1x, Zone of Belgium. The base of the keyserlingophyllum Zone corresponds closely with the base of the RC3 Zone.</ABSTRACT>

38723 <SOURCE>Courier Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, vol. 2]: 23-33.</SOURCE>
38724 <ABSTRACT>Study of the distribution of rugose corals from Frasnian to Tournaisian in South China permits recognition of seven rugose coral zones (including 3 assemblage zones, 2 interval zones, 1 acme zone and 1 range zone): I, Pseudozaphrentis-Hunanophrentis-Mictophyllum A.Z.; n, Smithiphyllum-Hebukephyllum A.Z.; III, First Interval Z.; IV, Ceriphyllum elegantum-Caninia dorlodoti A.Z.; V, Cystophrentis R.Z.; VI, Second Interval Z.; VII, Pseudouralinia Acme Z. The zones are represented by shallow-water coral faunas. In deep-water facies, three rugose coral zones are established: Neaxon-Kielcephyllum-Prosmilia A.Z. (equivalent to Cystophrentis Range Z.), Guilinophyllum A.Z. (equivalent to C-P Interval Z.) and Koninckolasma A.Z. (equivalent to the lower part of Pseudouralinia Acme Z.). Five main palaeontological events are distinguished: extinction of most Devonian-type rugose corals at the end of the Frasnian; development of a new rugose coral fauna in the early Famennian; increase and diversification of rugose corals during late Famennian (or Strunian); extinction of most Strunian rugose corals near the Devonian-Carboniferous boundary; diversification of the Tournaisian-type rugose coral fauna at the beginning of the late Tournaisian.</ABSTRACT>

- 38749 <SOURCE>Annales de la Societe geologique de Belgique 116, 2: 359-378.
</SOURCE>
- 38750 <ABSTRACT>In southern China, the Devonian-Carboniferous transitional strata are well exposed in several sections representative of different sedimentary environments. The siliciclastic-carbonate deposits have been investigated in the Oujiachong, Malanbian and Sujiaping sections situated in central Hunan. The Devonian-Carboniferous boundary coincides with the boundary between the Menggongao and the overlying Malanbian Formation. Study of different fossil groups (conodonts, foraminifera, ostracods, spores, brachiopods, rugose and tabulate corals) gives coherent biostratigraphical results which form the framework for reconstruction of the sedimentological evolution. Strong similarities are observed with southern Belgium allowing biostratigraphical and sequence stratigraphical correlations between the two distant sedimentary basins.</ABSTRACT>

- 38840 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 170, 3-4: 197-218.</SOURCE>
- 38841 <ABSTRACT>The Carboniferous and Permian of the Baoshan block consist of three major depositional sequences: a Lower Carboniferous carbonate sequence, a Lower Permian siliciclastic sequence, and a Middle Permian carbonate sequence. These three sequences were interrupted by two major regressive events: first, the Namurian Uplift ranging in age from

Serpukovian to Gzhelian, and second, the Post-Sakmarian Regression occurring probably at Artinskian time in the Baoshan block, although the precise time interval of the latter event is still unclear. The Baoshan block is characterized by warm-water, highly diverse and abundant faunas during the Early Carboniferous, by cold-water and low diversity faunas during the Early Permian, and by possibly warm-water but low diversity faunas during the Middle Permian. The *Sweetognathus bucaremangus* conodont fauna constrains the upper boundary of the diamictite-bearing siliciclastic deposits (Dingjiazhai Formation) to the Sakmarian to early Artinskian, as well as the eruption of the rifting basalts (Woniusi Formation) to, at least, the post-early Artinskian. Paleozoogeographically, affiliation of the faunas in the Baoshan block changed from Eurasian in the Early Carboniferous, to Peri-Gondwanan in the Early Permian, and to Marginal Cathaysian/Cimmerian in the Middle Permian. Cimmerian blocks have more or less comparable geohistory to one another in the Carboniferous and Permian. During the Middle Permian, the eastern Cimmerian blocks such as Sibumasu (s.s), Baoshan, and Tengchong are not far from the palaeoequator, but apparently more distant than the western Cimmerian blocks based on the presence or absence of some index taxa such as the fusulinaceans *Eopolydiexodina* and *Neoschwagerina*, and the corals *Thomasiphyllum* and *Wentzellophyllum persicum*. </ABSTRACT>

 38867 <ABSTRACT>The Carboniferous marine deposits are generally known to be extensively widespread and fairly well-developed in China. These deposits contain a great amount of corals. During the past two decades, knowledge regarding the Carboniferous corals of China has been increased considerably. In broad outline, three faunal regions may be [distinguished], based on the characteristics of Carboniferous coral fauna: the southern, northern and northwestern faunal regions. In this paper, accounts are given of the coral assemblages in each region, especially those in the southern region with their stratigraphical implications.</ABSTRACT>

</TITLE>
38892 <SOURCE>Bulletin Nanjing Institute Geology and Palaeontology, Academia
Sinica 1982, 4: 213-239.</SOURCE>
38893 <ABSTRACT>From uppermost Carboniferous deposits, the Kangkelin
Formation, consisting of light grey argillaceous limestone, a rich
coral fauna is described of which 29 species and subspecies are
belonging to ten genera. Among them one Family (Kepingophyllidae),
three genera (Cardiaphyllum, Paraduplophyllum, Anfractophyllum) and 20
species and subspecies are new. * Two coral assemblages can be
differentiated: the Cardiaphyllum elegans assemblage below and the
Kepingophyllum aksuense assemblage above. These are contemporaneous in
age with coral faunas in the Maping Formation of northern Guangxi and
western Guizhou, as well as with those faunas from the Upper Chuanshan
Formation of southern Jiangsu. * This is proved by the occurrence of
Lophocariphyllum, Caninia, Timania, Koninckocarinia and
Kepingophyllum in the Kangkelin Formation and the occurrence of
characteristic fusulinids in addition. Regarding the Upper Paleozoic
biogeographic provinces, it seem unlikely that the coral fauna of the
Kangkelin Formation belongs either to the waagenophyllidae or to the
Durhaminidae provinces. The Kepingophyllidae province thus is
established covering the western Guizhou, eastern Jizang and southern
Jiangsu areas as well as the Kalping area, Xinjiang. It approximately
corresponds to the Sakmarian in the Urals or the Wolfcampian of North
America. * Cardiaphyllum gen.nov. very closely resembles Palaeosmia
in the character of the tabulae and can easily be distinguished from
the latter by its longer minor septa, the concentric dissepiments, and
the absence of keyhole fossula. It also resembles Amandophyllum, but in
the latter the central column is distinct and the character of the
tabulae indistinct. The following [species] belonging to the new genus
are mentioned: Neokoninckophyllum dunbari Ross & Ross 1962, N.
cooperi Ross & Ross 1962, N. deciense Ross & Ross 1962,
Koninckophyllum oklahomense Rowett & Sutherland 1964, and probably
Dibunophyllum clari Felser 1937. * Paraduplophyllum gen.nov. is similar
to Duplophyllum with regard to the longer minor septa. It can be
distinguished from the latter by its developing carinae and the
incomplete tabulae. It also closely resembles Asserculina, but in the
latter the columella and fossula are developed. * Anfractophyllum
gen.nov. is similar to Szechuanophyllum in the shape of the corallites
and the character of the tabulae. The difference between these two
genera is the epitheca of the present genus being generally suppressed,

the septa being of three orders and the cystose zone rather developed.
* At first glance, the present genus shows a similarity to
Polythecalis, but differs from the latter in presenting tertiary septa.

38971 <ABSTRACT>The corals described in this paper were collected from the Heshilafu Formation at Aitegou section, southwestern margin of the Tarim Basin, southern Xinjiang [= Sinkiang), NW China in 1992. They comprise 29 species included in 24 genera. Three species are new: Fomichevella shacheensis, Auloclisia formosa and Caninostrotion xinjiangensis. The lower and middle parts of the Heshilafu Formation are attributed to the Eostafella mosquensis zone (Foraminifera, Fusulinida) and the upper part of the Heshilafu Formation belongs to the Pseudoendothyra directa zone. The former correspond to the Visean and the latter equivalent roughly to Serpukhovian.</ABSTRACT>

38983 <SOURCE>Journal of Stratigraphy 12, 2: 20-27 [in Chinese, with English summary].</SOURCE>
38984 <ABSTRACT>The marine Middle-Late Carboniferous strata are widely distributed in Liu-shugou, Qijagou and Jingjingzigou of Urumqi, Xinjiang. Strata under discussion may be divided into three formations, namely the Liushugou, Qijagou and Aoertu Formations. * The Liushugou Formation is subdivided into two subformations. The lower one is made up of grey-greenish, medium-bedded to massive interbeds, intermediate-acid tuff and volcanic rocks and a few siliceous rocks, totalling 1131m in thickness. The upper one is composed of green, grey-violetish volcanic breccia and agglomerate, intercalated with a few andesitic porphyrite, with a thickness of 894m. The modified Qijagou Formation, 189m thick, consists of carbonate and clastic rocks of normal littoral shallow water facies and contains abundant fusulinids, brachiopods, corals. In the present paper the volcanic and

volcaniclastic rocks in the lower part of the Qijiagou Formation have been incorporated into the Liushugou Formation. Thus, the contact between the Qijiagou and Liushugou Formations is conformable. The Aoertu Formation is also subdivided into two subformations. The lower one consists chiefly of carbonate rocks intercalated with a low calcium-bearing clastic rocks 66m thick, containing brachiopods, corals, etc. The upper one is made up of the normal clastic rocks intercalated with a few carbonate rocks 175-228m thick, yielding gastropods, cephalopods and a few corals. </ABSTRACT>

39021 <TITLE>Carboniferous corals from the lower Yangtze area.</TITLE>
39022 <SOURCE>Bulletin of Nanjing Institute of Geology and Mineral Resources 8, 2: 99-108.</SOURCE>
39023 <ABSTRACT>Carboniferous corals are abundant in the Lower Yangtze Area and mainly distributed in the carbonate facies of Jingling Formation, Hezhou Formation, Laohudong Formation, Huanglong Formation and Chuanshan Formation. The corals of the Gaolishan Formation occur in lenticular mudlimestone of littoral facies in Nanjing-Zhengjiang area and Caohu area. The majority of corals in this area is of Huanan type, and the minority is of European type. Besides, a quantity of them belongs to local type. * The tetracoralla from the Lower Carboniferous Jingling Formation is monotonic and undiversified, belonging to solitary Zweizoner. Pseudouralinia is a zone fossil of Jingling Formation. The corals of Gaolishan Formation differs from that of the

Jingling Formation. Dreizoner begin to appear but in small quantity. In Hezhou period, the Early Carboniferous corals flourished, solitary, compound Dreizoner and Zweizoner appeared in great number. Yuanophyllum kansuens - Aulina carinata are assemblage zone fossils of Hezhou Formation. In late Early Carboniferous Laohudong period fossils are rare. Aulophyllidae and Palaeosmiliidae which flourished in Hezhou period largely vanished. Lithostrotion mccoynum is the zone fossil of Laohudong Formation. The corals in Late Carboniferous Huanglong period is less flourishing than that in Early Carboniferous. Main Early Carboniferous species extinguished continuously. New elements such as Kionophyllum, Fomitchevella, Wentzellophyllum and so on appeared. In Chuanshan period developed solitary and compound Dreizoner corals with axial structure and clinotabulae. Some species resemble to Permian species. The coral group has a transitional nature of Carboniferous-Permian. (Original summary) The new taxa are: Dingshanophyllum minglingense n.gen. et n.sp., Chaohuphyllum anhuiense n.gen. et n.sp., Vesiculoamplexocarina yinpingensis n.gen. et n.sp.

39086 <TITLE>The Early Visean rugose coral communities in China.</TITLE>
39087 <SOURCE>J. Fac. Sci. Hokkaido Univ. IV, 23, 3: 329-342.</SOURCE>
39088 <ABSTRACT>within China six Early Visean rugose coral communities are recognized, they are: 1) the Siphonophyllia community, 2) the cool water Gangamophyllum community, 3) the Thysanophyllum community, 4) the Bothrophyllum-Zaphrentites community, 5) the island Humboldtia community and 6) the cold water Hapsiphyllum-Rhopalolasma community. In northwest China, the Siphonophyllia community is distributed along the northern margin of the Tarim-Qaidam Oldland. The Gangamophyllum community was widespread north of the region occupied by the Siphonophyllia community, including north Tianshan, central Tianshan and east Junggar. In South China there were three rugose coral communities. The Thysanophyllum community occurs on the margin of the Upper Yangtze Oldland. The Bothrophyllum-Zaphrentites community was confined to the southern and western part of the region occupied by the Thysanophyllum community. These two communities merge into each other without a distinct boundary. The Humboldtia community is found only in the Baoshan area. The Hapsiphyllum-Rhopalolasma community is found in Xainza and Himalaya of Tibet. The distribution of the six Early Visean rugose coral communities was controlled by the palaeogeographical background. The Gangamophyllum community occurs along the southern margin of the Siberia Oldland, while the Siphonophyllia community is distributed along the northern margin of Tarim-Qaidam Oldland. The Hapsiphyllum-Rhopalolasma community is confined to the northern margin of the Gondwana Oldland. In the wide southern and western margin of Yangtze Oldland the distribution of the Thysanophyllum and the Bothrophyllum-Zaphrentites communities was controlled by the bathymetry. The Humboldtia community probably lived in island seas far from the Yangtze Oldland.</ABSTRACT>

39112 <TITLE>Early Carboniferous strata and corals of northwestern Szechuan. [in Chinese, with English summary]</TITLE>
39113 <SOURCE>Professional papers of Stratigraphy and Palaeontology 9: 1-47.</SOURCE>
39114 <ABSTRACT>The region of northwestern Szechuan is in the western of the line from Chengdu to Guangyuan which comprises the places of Longmenshan, Songpan and Nanping. It is characterized by Lower Carboniferous strata completely developed and by the distribution of corals and faunas of different varieties in those places. Based on more practical material, the writer studied the rules of coral distribution, suggested an opinion to divide the Lower Carboniferous strata, and to divide three coral zones from lower to upper according to these. Thus, the writer emended the original terms of the Zongchanggou series and subdivided these series into three different members as given below: * 3. Zongchanggou member - zone of Yuanophyllum and important member Melanophyllum (Upper Visean); * 2. Majiaoba member - zone of Pseudoouvalinia and important member Stelechophyllum (Upper Tournasian); * 1. Changtanzi member - zone of Cystophrentis, and important member Beichuanophyllum (Lower Tournasian). * In the paper presented, the writer describes 17 genera (4 of which are new and 2 new subgenera), 50 species (42 of which are new and 1 new subspecies, 2 species indet.) and establishes one new family. [original summary]

39125 <TITLE>Early Carboniferous corals in the ammonoid facies from Barkol, Xinjiang. [in Chinese, with English abstract]</TITLE>
39126 <SOURCE>Acta Palaeontologica Sinica 21, 2: 141-152.</SOURCE>
39127 <ABSTRACT>Our knowledge of the Carboniferous corals in the ammonoid facies in China is, on the whole, quite insufficient. However, new findings have been made in 1977 by the Regional Geological Surveying Team of Xinjiang Autonomous Region in Barkol, Xinjiang. The present paper describes the corals found from the Donggulubashitao formation of the Barkol area. They consist of 18 species belonging to 14 genera, i.e. Crassiphyllum irregulare (sp.nov.), Rhopalolasma? sp.,

- Lophophyllidium? sp., Neozaphrentis xinjiangensis (sp.nov.), N. xinjiangensis variabilis (subsp.nov.), Meniscophyllum irregulare (sp.nov.), M. xinjiangense (sp.nov.), Triplophyllum spinulosum (Milne-Edwards et Haime), Amplexus sp., Soschkieophyllum barkolense (sp.nov.), Fasciculophyllum sinense (sp.nov.), F. longiseptatum (sp.nov.), F. sp., Kinkaidia rhopaloides (sp.nov.), Cyathaxonia stereoseptata (sp.nov.), Hapsiphyllum crassum (sp.nov.), and Zaphrentites cf. pseudocrassus Wu. - 39153 <ABSTRACT>Most participants at the coral meeting [held in Oklahoma in 1974] concluded that the coral species illustrated by Yu could represent a rugose coral that is abnormal only in that the length of the major septa in the counter quadrants are variable in the middle and late growth stages, with some septa away from the counter being longer than the counter lateral septa. However, all agreed that a final conclusion could not be drawn without an examination of serial sections of actual specimens of Yu's species so that the insertion of new septa could be traced from one section to the next. [final fragment of a paper; reference is to Yu C.-C. 39203 <TITLE>Some Heterocorals from Late Carboniferous Taiyuan Formation in North China.</TITLE>
39204 <SOURCE>Acta Palaeontologica Sinica 29, 3: 371-375.</SOURCE>
39205 <ABSTRACT>The heterocorals described in this paper were collected from the Taiyuan Formation of the Upper Carboniferous in Shandong, Henan and Shanxi Provinces during the field work carried out in 1985-1986. They are assigned to two genera and three species, including 1 new genus and 2 new species. The associated rugose corals are identified as *Amandophyllum carnicum* Heritsch, *Amplexocarinia asturia* Rodriguez, *A. muralis* Soshkina, *Bothroclisia clisiophylloides* Fomitchev, *B. poriferoides* Fomitchev, *Bothrophyllum aequalum* Fomitchev, *Caninia mapingensis* Lee & Yu, *Cyathocarinia multituberculata* Soshkina, *Gshelia rouileri* Stuckenberga and ' *Lophotubularia*' *karpinskyi* (Fomitchev); the fusulinids include *Triticites* sp., *Quasifusulina* sp., *Pseudofusulina* cf. *fecunda* Shaver & Scherbovich, *Rugosfusulina* cf. *dastarensis* Bensch and *Sphaeroschwagerina* cf. *subrotunda* (Ciry). The heterocorals occur in a higher horizon in the North China Platform than in any other countries over the world. [original summary] The new taxa are: *Heterophyllia henanensis* sp.nov. and *Dichophyllia simplex* gen. et sp.nov.</ABSTRACT>

39216 <TITLE>New materials of Heterocorallia from Hunan with discussion on their structures.</TITLE>
39217 <SOURCE>Acta Palaeontologica Sinica 31, 4: 472-482.</SOURCE>
39218 <ABSTRACT>Recently a wealth of perfect specimens of Heterocorallia was collected from the dark grey limestone of the Upper Datang Stage of the Lower Carboniferous in Central Hunan, China. These specimens belong to four known genera: Hexaphyllia, Pentaphyllia, Haptaphyllia, Heterophyllia, and two new genera. A series of sections have been made. Based on detailed observation of these sections, some revisionary views about the structures of Heterocorallia can be proposed. Central tube: Yu C.-C. et al. (1978) first discovered and named Crepidopbyllia as a sub-genus of Hexaphyllia with their inner ends of six septa conjoined to form an aulos-like central tube. Among the specimens from Central Hunan, the central tubes were also found in some heterocorals with six or five septa, but they are very unstable, and they could appear or disappear in a distance of several millimeters. In the parts where they disappeared, the inner structures were the same as those in Hexaphyllia or Pentaphyllia. The unstable central tubes were formed by the splitting of the connected part of the septa. Tabula: It is a controversial issue whether the tabulae of Heterocorallia are convex upward or on the contrary, because it is very difficult to determine the growth direction of the specimen. In the collected specimens, an individual Hexaphyllia with a bud has been discovered, so that it is very easy to confirm the growth direction. In the longitudinal section of this specimen, tabulae ascend from the center to the wall. In many longitudinal sections deviating from the center, the tabulae between two septa are domical, but those between the septum and wall ascend to the wall. For this reason, it is inferred that the tabula of Heterocorallia is similar in form to an inclined saddle ascending to the wall. Septum: Nearly all septa are complete, and mostly even platelike. But in many of the specimens from Hunan the septa are wavy in longitudinal direction or in both longitudinal and transverse directions. Since the septa are usually thickened, mostly at outer ends, many septa are sphenoid. The septa and their stereoplasma stretch into the wall, forming clear limits with the peripheral stereozone. These limits have been mistaken as the supports of the septa. In a new species there are seven septa; one of them is incomplete with a free outer end. This fact is contrary to the inference that the septa were developed from the wall to the center. Wall: The epitheca is clearly observed in the specimens from Hunan, including all six genera. It is obvious that the wall consists of tabula wall, peripheral stereozone and epitheca. The peripheral stereozone is lamellar in both transverse and longitudinal sections.</ABSTRACT>

39307 <TITLE>Middle and Upper Carboniferous rugose corals from southern
Dahinganling (Great Khingan Mts).</TITLE>
39308 <SOURCE>Acta Palaeontologica Sinica 22, 2: 220-229.</SOURCE>
39309 <ABSTRACT>The rugose corals dealt with in this paper were collected
from Middle and Upper Carboniferous on the southern slope of
Dahinganling (Greater Khingan Mountains). They contain 44 species and
31 genera (including 17 new species and 1 new genus) as listed below:
Metriophyllum, Rotiphyllum, Empodesma, Duplophyllum, Barrandeophyllum,
Amplexocarinia, Calophyllum, Tachylasma, Cyathaxonia, Cyathocarinia,
Lophophyllidium, Stereostylus, Amplexizaphrentis, Lithostrotionella,
Hillia, Antheria, Koninckocarinia, Carinthiaphyllum, Dibunophyllum,
Amandophyllum, Bothroclisia, Neokoninckophyllum, Paracarruthersella,
Lomaphyllum (gen. nov.), Pavastephyllum (Thomasiphyllum), Caninia,
Timania, Caninophyllum, Cystolonsdaleia, Ivanovia, Akagophyllum.
Noticeably, among these corals 15 species are identical with or closely
related to those from the Middle and Upper Carboniferous or Lower
Permian in South China, Moscow and Donets Basin of USSR, Palencia of
Spain and North America. Moreover, in the Upper Carboniferous three
rugose coral assemblages may be recognized.</ABSTRACT>

39320 <TITLE>Late Carboniferous Tetracorals of Baicheng in Southern
Tian-shan, Xinjiang.</TITLE>
39321 <SOURCE>Acta Palaeontologica Sinica 25, 1: 55-62.</SOURCE>
39322 <ABSTRACT>A well-developed section consisting of Late Carboniferous
deposits in Bai-cheng region of Southern Tianshan, Xinjiang, is

characterized by distribution of fusulinids, tetracorals and brachiopods in extensive varieties in the region. The materials of the Late Carboniferous strata and the tetracorals studied in this paper were collected by the stratigraphical research Team in 1974. These strata yield abundant tetracorals, with 9 genera and 13 species (including 12 new species) and 2 indeterminate forms: *Kepingophyllum baichengense*, *Eokepingophyllum concavetabulatum*, *Ivanovia* sp., *Lophocarinophyllum lanceuse*, *Fomichevella elegantus*, *F. xinjiangensis*, *F. triseptatus*, *Pseudozaphrentoides elegantus*, *P. multitabulatus*, *P. brevisseptatus*, *Skotekophyllum regulare*, *S. brevisseptum*, *Caninophyllum convextabulatum*, and *Sochkineophyllum* sp. These fossils provide new evidences for the presence of the Upper Carboniferous in the Southern Tianshan region of Xinjiang. [original summary] </ABSTRACT>

39372 <TITLE>A strange form of the genus Axolithophyllum.</TITLE>
39373 <SOURCE>Acta Palaeontologica Sinica 24, 2: 181-185.</SOURCE>
39374 <ABSTRACT>The material described in this paper was collected by the author in 1981 from the Uppermost Carboniferous Maping Formation at Zhaojiashan, Weining County, Guizhou Province. So far as known, all the species referred to the genus Axolithophyllum are externally solitary in form except the present species A. squamatum sp.nov. It is of great interest that this species has a peculiar form with a small fasciculate corallum as compared with other forms of this genus. Following the change of geological times, this species developed and thus became the ancestor of the genera Stilbophyllum and Diversiphyllum in the Lowermost Permian Changmo Formation, both of which possess the peculiar colony appearance and naotic structure of the present species.</ABSTRACT>

39503 <SOURCE>Acta Palaeontologica Sinica 25, 5: 531-543.</SOURCE>
39504 <ABSTRACT>Based on their stratigraphic distribution, 19 genera and 26 species (including 1 new genus, 22 new species, and 2 new subspecies) are described in this paper. The corals are assigned to two assemblages in this area in ascending order: the Pseudocarniaphyllum-Chuanshanophyllum assemblage below and the Parawentzellophyllum-kepingophyllum assemblage above. Diagnosis of the new genus Pseudohillia (type-species P. hilloides): Compound coral, fasciculate-massive in shape, often somewhat cystose along marginarium. Septa of two orders: major ones thicker, extending nearly to the columella; minor ones shorter or absent. Columella plank-like, dissepimentarium narrower. Tabularium wider; tabulae complete, inclined toward the central area of corallite. Late Carboniferous from Guizhou, South-China. The other new forms are: Metriophyllum longlinense, Calophyllum paratypicum, Timania asiatica, Antheria irregularis, Protoivanovia sheshanensis, P. laticystata, Kionophyllum ellipticum,

Thomasiphyllum venustum, Qinglongshanophyllum simplex, Q. yishanense, Yokoyamaella robusta, Pseudocarniaphyllum orientale, Chuanshanophyllum dewuense, Akagophyllum regulare, Nephelophyllum simplex magnum, Kepingophyllum densum, K. weiningense, K. shuichengense, Peiraphyllum yishanense, Vesotabularia guangxiensis, Lonsdaleiastraea compacta.

39515 <TITLE>On the Early Carboniferous Corals from Xieertala District of Nei Mongol (Inner Mongolia).</TITLE>

39516 <SOURCE>Bulletin Shengyang Inst. Geol. Min. Res., Chin. Acad. Geol. Sci. 12: 68-73.</SOURCE>

39517 <ABSTRACT>The Xieertala Formation was established on the western slope of Da Hingan-ling (Great Khingan) by Hailar in 1976. Based mainly upon the determination of brachiopods, the age of the formation has been recognized as Late Carboniferous, but the coral fauna of the Xieertala Formation indicated that the age should be Early Carboniferous. This coral fauna consists merely of very few small solitary corals and its generic assemblage, such as Zaphrentites, Zaphrentoides, Trochophyllum, Cyathaxonia and Amplexus etc., clearly shows a Early Carboniferous feature, although its dominant species are endemic. Whereas in West Europe the characteristic forms of the Tournaisian corals are dominated by "Zaphrentis", the Xieertala coral fauna is comparable with the "Zaphrentis" konincki subzone (Z2) of England except for disappearance of caniniid corals. Our coral assemblage is also similar to some types of American Mississippian corals, therefore the Xieertala Formation seems to be able to compare with the Keokuk Limestone or the New Providence Shale of the Osagean Series of Mississippian in the United States.</ABSTRACT>

39528 <TITLE>Carboniferous corals from eastern and southern Liaoning, China.</TITLE>

39529 <SOURCE>Bulletin Shengyang Inst. Geol. Min. Res., Chin. Acad. Geol. Sci. 16: 99-120.</SOURCE>

39530 <ABSTRACT>The Liaoning province is situated in the northeastern corner of the Sino-Korean Platform. Lacking of lower part, the Carboniferous there has only the Middle and Upper Series, overlying disconformably on the Majiagou Fm. of Middle Ordovician and present in some small depressed fault basins. The Carboniferous corals in Liaoning have been seldom studied and described before. Recently, the writer systematically collected and studied the corals respectively from the Benxi Fm. of the Taizihe valley and from the Taiyuan Fm. of the Fuzhouwan-Luda area. They are as follows: Corals from the Benxi Fm. of Taizihe valley: Bradyphyllum? sp., Tachylasma sp., Lopholasma carbonaria Grabau, Gshelia nuanheziensis sp.nov., G.? sp., Arachnastraea manchurica Yabe & Hayasaka, Cystophorastraea

- benxiensis sp.nov., *Ivanovia manchurica* (Yabe & Hayasaka), *Boswellia obesa* sp.nov., *Multithecopora penchiensis* Yoh, *Cystilophophyllum* sp. indet.; Corals from the Taiyuan Fm. of Fuzhouwan-Luda area: *Cyathocarinia tuberculata* Soshkina, *Lopholasma carbonaria* Grabau, *Lophocarinophyllum acanthiseptum* Grabau, *Amploxocarinia* cf. *corrugata* (Mather), *Corwenia* sp., *Neokoninckophyllum* sp., *Multithecopora irregularis* sp.nov., i.e. 15 genera with 17 species (including 4 new species) in total [part of original summary].</ABSTRACT>

39541 <TITLE>Upper Carboniferous Rugose Corals from Central Hunan.</TITLE>
39542 <SOURCE>Acta Palaeontologica Sinica 26, 4: 471-485.</SOURCE>
39543 <ABSTRACT>The Upper Carboniferous rugose corals studied in the present paper were collected from Shaoyang, Lianyuan and Longhui counties of central Hunan. The collections cover 17 genera and 28 species, including 3 new genera and 13 new species belonging to 13 genera. They are in association with *Triticites* and *Pseudoschwagerina* and are characterized by the thickened septa in cardinal quadrant, striking cardinal fossula, simple axial structure and arched tabulae. According to their stratigraphic ranges, two assemblages may be suggested as follows: 1. Lower *Bothrophyllum*-*Koninckophyllum* assemblage, including *Bothrophyllum crassoseptatum* sp.nov., *B. tenuiseptatum* sp.nov., *Koninckophyllum caninophylloides* X. Yu, *K. longhuiense* sp.nov., *Arctophyllum copiosum* sp.nov., *Caninia lingwuensis* Jiang, *C. diphyllodes* X. Yu, *C. brockleyensis* minor X. Yu, *Caninophyllum gurovi* Fomichev, *Timania damiaoensis* X. Yu, *Pseudotimania hunanensis* Jiang, *P. subcylindricum* sp.nov., *Gshelia tianxinpingensis* sp.nov., *G. shaoyangensis* sp.nov., *Chuanshanophyllum* sp., etc. 2. Upper *Parawentzeloiphyllum*-*Longhuiiphyllum* assemblage, with such main elements as *Parawentzeloiphyllum irregularis* sp.nov., *P. hunanense* sp.nov., *Arctophyllum copiosum* sp.nov., *Cania obliquis tenuis* (Fomichev), *C. hunanensis* Jiang, *Caninophyllum domheri* Fomichev, *Koninckophyllum diphyllodes* X. Yu, *Neokoninckophyllum* sp., *Timania hunanensis* Jiang, *Orygmophyllum* sp., *Paraorygmophyllum sinense* gen. et sp.nov., *Gshelia hunanensis* Jiang, *G. shaoyangensis* sp.nov., *G. tianxinpingensis* sp.nov., *Longhuiiphyllum typicum* gen. et sp.nov., *L. simplex* gen. et sp.nov., *Tantouphyllum complex* gen. et sp.nov. These assemblages may be roughly related to those from southern Jiangsu (Yu 1980) and western Guizhou (Wu 1974). [part of original summary]</ABSTRACT>

39554 <TITLE>Tetracorals from Hebukehe Formation of Northern Xinjiang.</TITLE>
39555 <SOURCE>Acta Palaeontologica Sinica 27, 1: 39-47.</SOURCE>
39556 <ABSTRACT>The tetracorals described in the present paper were chiefly collected from the Hebukehe Formation in Northern Xinjiang, consisting of 9 genera and 15 species (including 12 new species), which are dominated by such endemic forms as *Kassinella*, *Parakassinella*, *Caninia*,

Amplexus, Amplexocarinia, Zaphrentites, Cyathocarinia, Nalivkinella, Hebukephyllum, etc. The Hebukehe Formation with Kassinnella and Parakassinnella might correspond to the Verchnekassinskaya Formation of Kazakhstan in USSR, and to the Chuanshangou Formation of Qinghai in China which is generally believed to be of the Early Carboniferous age. In USSR Caninia cornucopiae also is regarded as of the same age. According to the characters of the tetracorals, the author considers the Hebukehe Formation as possibly belonging to Early Carboniferous in age. The new species described are: Hebukephyllum equitabulatum, H. curvuse and H. elegantum. [part of summary] </ABSTRACT>

39607 <SOURCE>Xinjiang Geol. 6, 1: 10-20 [in Chinese, with English summary].</SOURCE>
39608 <ABSTRACT>The characteristics of Tetracoralla assemblage in Carboniferous and its distribution are discussed in the Xinjiang paper, and the conclusion is as follows: (1) the characteristic fossils Pseudouralina, Cystophrentis of the early Carboniferous in South China do not occur in Xinjiang, Hexaphyllia is distributed extensively in Tianshan Mountains and its southern adjacent district; (2) Siphonophyllia developed from late Tournaisian stage and thrived gradually in late Viséan stage; (3) Empodesma discovered in late Carboniferous series in Kunlun - Kalakunlun Mountains in Xinjiang has furnished fresh evidence for the definition of the northern boundary of the Gondwana mainland.</ABSTRACT>

39619 <TITLE>Early Carboniferous rugose corals from Longhuo area of Longlin, Guangxi.</TITLE>
39620 <SOURCE>Acta Palaeontologica Sinica 27, 5: 565-582.</SOURCE>
39621 <ABSTRACT>The Lower Carboniferous in the Longhuo area of the Multinational Autonomous County of Longlin is divided into two formations. The lower is the Sanjiazhai Formation (equivalent to Aikuanian), consisting of siliceous clastic rocks, unfossiliferous and 34 m in thickness. The upper is the Longhuo Formation (equivalent to Tatangian), mainly composed of carbonate deposits, yielding abundant marine fossils and attaining a thickness of 188 m. This paper describes 22 genera and 25 species, among which 1 genus, 1 subgenus, 21 species and 1 subspecies are new. All coral specimens were collected from the Longhuo Formation of the Tatang stage in the Longhuo area. In this area, the coral fauna is outstandingly characteristic of the South China zoogeographical province. There have been found some genera such as Yuanophyllum, Kueichouphyllum and Neoclisiophyllum, which appear all over the Guizhou, and Guangxi regions, with occurrence of certain genera such as Siphonophyllia, Cyathaxonia, Palaeosmia, Dibunophyllum, Carcinophyllum, Lithostrotion and Corwenia, which generally have a wide distribution in the west European - Tethyan coral [province], and a few coral elements either from the Ural - Arctic area such as Aulokoninckophyllum, Gangamophyllum, or from North America such as Vesikulophyllum. During the Early Carboniferous time the sea of the Longhuo area was connected with the European sea and possibly with the North American sea.</ABSTRACT>

39645 <TITLE>Late Early Carboniferous corals in ammonoid facies from Altay of Northern Xinjiang.</TITLE>
39646 <SOURCE>Acta Palaeontologica Sinica 28, 1: 89-108.</SOURCE>
39647 <ABSTRACT>The present article deals with the Early Carboniferous corals from the Nalingala Formation of the Altai area, northern Xinjiang. Here are described 9 genera, 11 new species and 2 indeterminate species, namely, Zaphrentoides crassiseptatus sp.nov., Amplexus regularis sp.nov., Paralleynia xinjiangensis sp.nov., Plerophyllum bilamellatum sp.nov., P. sp., Pleramplexus nalingalaensis sp.nov., P. multitabulatus sp.nov., P. raritabulatus sp.nov., Pentaphyllum elegantum sp.nov., P. sp., Cryptophyllum xinjiangense sp.nov., Cyathaxonia altaiensis sp.nov., and Endamplexus xinjiangensis sp.nov. They are especially rich in the middle and upper parts of the Nalingala Formation. This coral fauna is characterized by the corals which are all in simple forms, small, cornuted-conical and ceratoid with very thickened septa but no dissepiments. The occurrence of the ammonoids Goniatites, Epicanites, Prolecanites and Stenopronolites in the Nalingala Formation also lends support to such a conclusion. Therefore, the palaeoecological conditions of this coral fauna belong to offshore water rather than to warm water of low energy, and are prevailing in the transitional area from foreslope to organic (ecologic) reef. 39658 <TITLE>Carboniferous corals in Huize, Yunnan.</TITLE>
39659 <SOURCE>Acta Palaeontologica Sinica 28, 1: 79-97.</SOURCE>
39660 <ABSTRACT>The Carboniferous corals described were collected from two sections in the Huize County, Yunnan. At these sections are exposed the Upper Carboniferous Maping Formation with Axolithophyllum sp., the Upper Carboniferous Weining Formation with Amygdalophylloides kionophylloides sp.nov., A. aepitabulatus sp.nov. and A. stenotabulatus sp.nov., the Lower Carboniferous Shangssu Member with Corwenia magna Wu et Zhao, Arachnolasma leptaxia sp.nov., A. multitabulata sp.nov., Axophylloides huixensis gen. et sp.nov., A. varium (Fan), Durhamina yunnanensis sp.nov., Syringopora honanensis Lin, Kueichowpora distans sp.nov. and Chaetetes, accounting for 11,2 % of the total genera. * The corals from Huize, Yunnan, obviously belong to two groups. In the first group, since both Rugosa and Tabulata occur, and the rugose corals have tabulae or tabellae ascending towards the median plate, this group can be roughly correlated with the Yuanophyllum zone of the Zhimenqiao Formation of Hunan, the Zhongchangou Member of Sichuan, and the Shangssu Member of Guizhou. In the second group, there are only two

genera and four species of Rugosa, but it can be easily made out that this group had entered into the Late Carboniferous facies. According to the structural morphology of these corals, they are regarded as then living in a warm neritic environment, but of some mud and low turbulence. 39697 <TITLE>Some rugose corals from Late Carboniferous Taiyun Formation of Henan.</TITLE>
39698 <SOURCE>Acta Palaeontologica Sinica 28, 4: 488-494. VOL PP ???</SOURCE>
39699 <ABSTRACT>The fossil rugose corals described in this paper were collected from the limestones in some boreholes of the Upper Carboniferous Taiyun Formation in Gongxian, Hebi and Yongcheng districts, Henan. * There are totally 4 genera and 6 species (including five new species), namely: Lopholasma cratoseptatum sp.nov., Lophocarinophyllum karpinskyi sp.nov., L. misticarinum sp.nov., L. tenuiseptatum sp.nov., Tachylasma carinum sp.nov. and Yakovleviella raridissecta sp.nov. Among the four genera, Lopholasma and Tachylasma are first found in the coral-bearing strata of China; Lophocarinophyllum karpinskyi Fomichev is known to occur in the Upper Carboniferous of the Donetz Basin, while Yakovleviella occurs in the Upper Carboniferous of the Donetz Basin as well as in the Maping and Taiyun Formation of Guizhou and Shaanxi, China. 39711 <SOURCE>Acta Geoscientia Sinica 3, 1995: 310-327.</SOURCE>
39712 <ABSTRACT>The late Carboniferous rugose corals described in this paper were collected from the Shihuigou area on the north margin of the Qaidam basin. They contain 26 genera, and 49 species and subspecies (including 17 new species and 4 subspecies, and may be divided into five coral assemblage zones. They belong to the Keluke Formation of early late Carboniferous and the Zhabusagaxu Formation of late Late Carboniferous. In this area, the Late Carboniferous coral fauna is different from that in South China, but it is related to the East-Europe an coral fauna and especially similar to the Donets basin coral fauna.</ABSTRACT>

39775 <TITLE>Early Carboniferous Rugose Corals of Baoshan District, Western

Yunnan / China.</TITLE>

39776 <SOURCE>PhD Thesis [University? unpublished?]: 172 pp.</SOURCE>

39777 <ABSTRACT>[unpublished?] Based on materials from four sections of the Lower Carboniferous in Baoshan District, Yunnan, it is suggested that the Tournaisian-Visean boundary in the study area is drawn at the base of the Gnathodus taxanus Zone in the Shihudong Formation. The large solitary rugosans, i.e., Keyserlingophyllum, Siphonophyllum, in the formation, occur above the conodont Zone. In light of rugosan types and sedimentological features, three Visean rugosan biofacies are recognized as follows: I - the deeper water and soft substratum biofacies characterized by small cornute solitary rugosans, II - the shallow water and hard substrate biofacies characterized by solitary rugosans with dissepiments, and III - the shallow water and mobile substrate biofacies characterized by large solitary rugosans with lonsdaleoid dissepiments. Meanwhile, the Lower Carboniferous rugose corals in the area are grouped into 7 assemblages, they are: I. Zaphrentites parallelus-Saleelasma hadrotheca Assemblage, II. I to III interval Zone, III. Lophophyllum-Siphonophyllum sp.-Parazaphriphyllum cf. P. cylindricum Assemblage, IV. Cyathoclisia arachnolasmoidea-Siphonophyllia cylindrica-Kueichouphyllum sinense Assemblage, V. Palaeosmia murchisoni-Caninophyllum tomiense Assemblage, VI. Dibunophyllum-Diphyphyllum carinatum Assemblage, VII. Commutia exoletus-Sychnoelasma affossularis Assemblage. Among them, the first assemblage is attributed to Tournaisian and the latter six belong to Visean. Cladistical analysis is applied for discussing the relationships among all genera of Antiphyllinae and two genera (Neozaphrentis and Longiclava) of Hapsiphyllinae. Polarities of 7 character states are determined by ontogenetic criteria. The results show that the subfamily Antiphyllinae should be revised and might contain the following 10 genera: Actinophrentis Ivanovskiy, Longiclava Easton, Neozaphrentis Grove, Fasciculophyllum Thomson, Rotiphyllum Hudson, Falsiamplexus Fedorowski, Lytvolasma Soshkina, Monophyllum Fomichev, Bradyphyllum Grabau, Claviphyllum Hudson. A detailed taxonomical study on 72 species (13 new) of 38 genera is undertaken. Furthermore, intrapopulation variations of 4 new rugose species, (e.g. Commutia exoletus sp.nov., Pentaphyllum amoebum sp.nov., Ufimia baoshanica sp.nov., Neozaphrentis sphenoidale sp.nov.) are dealt with. It is suggested that the scarcity of small corallites in the four fossil populations is due to biases in sampling and in taphonomy, variations in some characters are caused by differently-oriented sections, and some discontinuous variation (e. g., diameters of Pentaphyllum amoebum sp.nov.) are due to paleoecological factors.

39789 <SOURCE>Boletin de la Real Sociedad Espanola de Historia Natural, Seccion Geologica 92, 1/4: 349-363.</SOURCE>

39790 <ABSTRACT>Studies of new coral faunas near the Tournaisian-Visean boundary, from the Malanbian and Zhouwangpu sections of Hunan, Huaqiao Farm and Longdianshan sections of Guangxi, define their stratigraphic distribution and permit the recognition of one coral zone between the Keyserlingophyllum and Thysanophyllum (Dorlodotia) Zones, i.e. the Keyserlingophyllum-Dorlodotia interval Zone. It is also shown that the

Tn-V boundary should be drawn within the interval zone. The lithostratigraphic sequences near the Tournaisian-Visean boundary are distinguished by an abrupt replacement of carbonate sediments with cherty nodules.

39801 <TITLE>Some Rugose corals from the Xiangshan Formation of the early Lower Carboniferous in Shidian County, Western Yunnan.</TITLE>
39802 <SOURCE>Bulletin Chinese Academy geological sciences 27-28: 155-173.</SOURCE>
39803 <ABSTRACT>The rugose corals dealt with in the present paper were collected from the Xiangshan Formation of the early Lower Carboniferous in Shidian County, western Yunnan. The early Lower Carboniferous strata, are called the Xiangshan Formation, it may be subdivided into two members: Upper and Lower. In this paper 12 genera, 15 species and 3 indetermined species (including 2 new genera and 12 new species) are described. They may be divided into two rugose coral assemblages as follows: Lower assemblage: Rotiphyllum yudongense - Commutia crassoseptata - Antikinkaidia typica assemblage, including Rotiphyllum yudongense (sp.nov.), R. dilatatum (sp.nov.), R. crassoseptatum (sp.nov.), Commutia crassoseptata (sp.nov.), Antikinkaidia typica (sp.nov.), A. sp., Parametriophyllum symmetricum (gen. et sp.nov.), Pentaphyllum crassoseptatum (sp.nov.), Shidianophyllum staurum (gen. et sp.nov.), Tachylasma sp. The fossil corals of this assemblage are simple, small in size and conical in shape, without dissepiments. They are not in intergrowth with compound rugose corals and genus Cystophrentis has not been found. The coral fauna possibly lived in the deep and calm sea water. It differs from that of South China, but closely resembles that of Europe. The coral fauna belongs to the Gattendorfia Zone and the lower part of the Cystophrentis Zone. Upper assemblage: Thuriantha sinensis - Tachylasma shidianense assemblage, containing Tachylasma shidianense (sp.nov.), Thuriantha sinensis (sp.nov.), Fasciculophyllum omaliusi (Edwards & Haime), Caninia cornucopiae Michelin, Sychnoelasma konincki (Edwards & Haime). The upper assemblage belongs to the upper part of the Cystophrentis Zone. The description of the new genera is given as follows: Genus Shidianophyllum Z.J. wang (gen. nov.) Type species: Shidianophyllum staurum Z.J. wang (gen. et sp.nov.) [fragment of extensive summary]

39827 <TITLE>Rugose corals from Early Carboniferous of Fanjiaping, Yunxi, Hubei.</TITLE>
39828 <SOURCE>Acta Palaeontologica Sinica 31, 1: 63-85.</SOURCE>
39829 <ABSTRACT>This paper makes a study of the lower Carboniferous rugose corals from Yunxi, Hubei, in the south of the East Qinling Mountains, with a systematical description of 24 genera, 39 species (including 21 new species and 2 new genera) separately belonging to 11 families. The lower Carboniferous corals of Fanjiaping can be divided into 4 assemblages: Fanjiaping Formation; upper part: Palaeosmia-Lithostrotion assemblage; lower part: Yuanophyllum assemblage; Yuanjiagou Formation; upper part: Shennongia majus assemblage; lower part: Zaphrentoides assemblage. After studying the coral fauna, the authors have modified division and correlation of the Carboniferous in this region, with the suggestion that the Fanjiaping Formation should be established.</ABSTRACT>

39840 <TITLE>A phaceloid colonial rugose coral from Late Carboniferous Taiyuan Formation of Henan.</TITLE>
39841 <SOURCE>Acta Palaeontologica Sinica 33, 5: 593-603.</SOURCE>
39842 <ABSTRACT>The genus Ccrocyathus [sic!] discovered in the Taiyuan Formation (Late Carboniferous) of Jiyuan, Henan, China, is a large phaceloid colonial corallum measuring 80cm in height and 40 x 25cm in diameter, in coexistence with the fusulinids Pseudofusulina, Quasifusulina and Rugosofusulina. In this genus, one phaceloid colonial species, C. proliferus (Hall) (in Sando 1983), is distributed in the Lower Carboniferous (Visean) of USA. The present specimen was cut in 22 transverse sections and 14 longitudinal sections. It is found that the corallites grew densely in the lower part (approximately in the early and middle stages), with their skeletons thickened on sides. Based on the development of septa and axis, 2 stages of the corallites may be recognized in descending order as follows: Stage I : Corallites measuring 1.0-4.0mm in diameter; major septa shortened; minor septa undeveloped; stereocolumella small, usually forming platform (text-fig. 4). Stage II: corallites measuring 4.1-9.0mm in diameter; major septa prolonged but not extending to the center; minor septa developed; stereocolumella enlarged with carina to form an irregular shape (text-fig. 5). Increase of Ccrocyathus jiyuanensis sp.nov. occurring frequently, usually with buds put forth from external walls or propagated from lonsdaleoid dissepimentarium. It must be pointed out that the axis of the present species is usually composed of a counter septum extending to the center to form a simple axial plate, but sometimes it is in coexistence with the upturned edges of tabulae to form a pseudosyncolumella. The phaceloid colonial coral lived in a beachy, slightly turbulent and shallow-water ecological environment with a slightly higher energy.</ABSTRACT>

39853 <TITLE>On Lophocarinophyllum of the Xiedao Limestone (Taiyun Formation, Upper Carboniferous, North China).</TITLE>
39854 <SOURCE>Neues Jahrbuch f. Geologie u. Palaeontologie, Abhandlungen 191, 1: 125-145.</SOURCE>
39855 <ABSTRACT>Several corals belonging to the species Lophocarinophyllum acanthiseptum and Lophocarinophyllum hippocrepiforme from the Taiyun Formation (Upper Carboniferous, North China) are described. The genus Lophocarinophyllum is common in the Upper Carboniferous and Permian of the Tethys Realm. More than 35 species and subspecies of this genus from North China, Donetz Basin, Carnic Alps and Cantabrian Mountains were described, but most of them were defined on the basis of features which show high variability in different sections of a single specimen. The validity of these features is discussed and some of the species are regarded as synonymous.</ABSTRACT>

- 39932 <SOURCE>Journal of Paleontology 78, 1: 77-83.</SOURCE>
- 39933 <ABSTRACT>Based on 137 specimens examined, the new species *Commutia exoleta* is characterized by a small, slightly scolecoïd shape with 21 septa at a mean maximum corallite diameter of 6mm (range 3 to 10.5mm); a persistent inner wall, which encloses an aulos with a mean maximum diameter of 1.2mm, formed during an early ontogenetic stage when the axial ends of the cardinal, alar and counter-lateral septa fused; short counter septa are lacking in the earliest stage of development. * Corallites are highly variable. Characters exhibiting a wide range of variation are: size and shape of corallites, number of septa, diameter of aulos and the timing of its appearance, number of septa connected to the inner wall, and the septal arrangement in each growth quadrant. Combinations of these variable characters result in corallites that are each uniquely different. Variations of those characters are partly due

to stressed environments, such as unstable, muddy substrates resulting in corallite rejuvenescence and redirection. [original abstract]

39945 <SOURCE>Palaeontographica A189, 4-5: 125-157.</SOURCE>

39946 <ABSTRACT>Lower Carboniferous solitary corals (Rugosa) are described from 9 localities in South China; they come from the Lower Tournaisian of Wangyou (prov. Guizhou), the Upper Tournaisian Liujiatang formation (Hunan province and the Autonom. region Guangxi) and from the Upper Visean Tzemenchiao formation (Hunan province). They belong to 15 species of the families Stereolasmatidae, Hapsiphyllidae, Zaphrentoididae, Lophophyllidae and Heterophylliidae. A new subgenus and a new genus are established: Drewerelasma (Fuchuanelasma) n.subgen., with the type species *D. (F.) fuchuanense* n.subgen., n.sp. from the Liujiatang formation in South China, and *Weyerelasma* n.gen., with the type species *W. seiberti* n.gen., n.sp. from the Lower Namurian Alba formation of the Cantabrian Mountains in North Spain. Seven species are new: *Drewerelasma (Fuchuanelasma) fuchuanense* n.subgen., n.sp., *Weyerelasma seiberti* n.gen., n.sp., *Zaphrentites omaloides* n.sp., *Z. hunanensis* n.sp., *Z. wuae* n.sp., *Z. weyeri* n.sp., *Stereostylus qiziensis* n.sp. Four more species are already known, four taxa are described in open nomenclature. The stratigraphic range of the described corals and their relationship to coeval coral faunas in other regions are discussed.

40010 <SOURCE>9th International Congress on Carboniferous Stratigraphy and Geology; Nanjing Institute of Geology and Paleontology, Academia Sinica, Nanjing, China</SOURCE>
40011 <ABSTRACT>The Carboniferous system in China was three-fold, corresponding to those in the Moscow basin of the USSR. This scheme of division is accepted by the pioneer geologist of China, but Sun (1943) suggested that the Lower Carboniferous of the old classification had become a separate system, restricted the Carboniferous system to include the Middle and the Upper Carboniferous (Weiningian and Mapingian) of the old classification. The writers, to some extent, agree with Sun's views, nevertheless, they hold that the Carboniferous in China is no more than a system in rank with two series included. * Broadly speaking, the logical and natural chronological classification should be based upon the cycle of sedimentation, the diastrophism and the faunal assemblages. The stratigraphical distribution of the Carboniferous fossils - illustrated in a table -

shows concerning the corals three evolutionary trends: in the Aikunian, Tatangian (Lower Carboniferous) and Weiningian-Mapingian (Middle and Upper Carboniferous). There is obvious dissimilarity between the Early and Late Carboniferous. [part of extensive summary] </ABSTRACT>

40165 <TITLE>On the geographic province of the lower Carboniferous coral of China.</TITLE>
40166 <SOURCE>J. Changchun Univ., Earth Sci. 27, 4: 361-368.</SOURCE>
40167 <ABSTRACT>Based on some factors, e.g. the distribution and evolution of sea, the obstruction of land, the paleolatitude variation and the characteristics of the coral fauna, the geographic province of the Lower Carboniferous coral of China is proposed in the paper. The Yanguanian coral geographic subprovince is subdivided into Northern coral region (N China coral region) and Tethys coral region (S China coral region). The N China coral region can be further classified into Xingan coral subregion and Zhungeer coral subregion, where the former

is represented by the coral *Ankhelasma*, *Homalophyllites* and the latter by the *Kassinella*, *Hebukephyllum*. The S China coral region can be subdivided into Huanan coral subregion characterized by the coral *Cystophrentis*, *Pseudouralinia* and the western coral subregion containing *Beichuanophyllum*, *Siphonophyllia* and *Humboldtia*. The Datangian geographic subprovince is subdivided into Tethys coral region (*Kueichouphyllum*-*Yuanophyllum* region). The *Kueichouphyllum*-*Yuanophyllum* region can be classified into N Tianshan-central Jilin coral region characterised by the coral *Yuanophyllum*, *Gangamophyllum*, *Siphonophyllia* and southern coral subregion yielding *Kueichouphyllum*, *Yuanophyllum*. The southern Tibet coral region is classified into *Gangdesi*-*Nianqingtangula* coral subregion containing the *Rhopalolasma*, *Mirusophyllum* and the Himalaya coral subregion with the coral *Longiclave*, *Cumminsia*. We think that the first appearance of the caninoid coral of China suggests the beginning of the Yanguanian stage.

40283 <SOURCE>Bulletin of the Tohoku University Museum 1 [Proceedings of the 8th International Symposium on Fossil Cnidaria and Porifera]: 265-278.</SOURCE>
40284 <ABSTRACT>West Yunnan, Southwest China, is composed of several allochthonous continental blocks. The Changning-Menglian Belt contains a continuous rugose coral succession ranging from Early Carboniferous to Middle Permian. The succession is dominated by such Eurasian and Cathaysian taxa as Siphonodendron, Fomichevella, Lublinophyllum, Sestrophyllum?, Caninella, and Nephelophyllum, thus, the Changning-Menglian Belt belongs to the Cathaysian province. However, the successions of coral faunas in the Baoshan and Tengchong blocks are similar of the Cimmerian blocks. The similarities, contrary to those observed in the Changning-Menglian Belt are: 1) an affinity with the Eurasian forms during the Early Carboniferous, 2) absence of Late Carboniferous faunas, 3) very low diversity of faunas during the Early Permian, and 4) presence of massive forms during the Middle Permian. Thus, it is clear, based on corals faunas, that the boundary between Gondwana and Cathaysia existed along the Lancangjiang suture and the Kejie-Nandinghe fault, the boundary between the Baoshan block and the Changning-Menglian Belt in West Yunnan.</ABSTRACT>

40347 <TITLE>Late Carboniferous-Early Permian coral faunas from Yishan, Guangxi.</TITLE>
40348 <SOURCE>Acta Palaeontologica Sinica 32, 6: 693-715.</SOURCE>
40349 <ABSTRACT>The Carboniferous-Permian boundary strata in Yishan County of Guangxi are composed of uniform carbonate facies rocks and contain greatly abundant fossil corals. From 1983 to 1984, the writers made a systematical study of the fossil corals between Upper Carboniferous Triticites zone and Lower Permian Misellina claudiae zone in Yishan, Guangxi. A total of 51 genera with 97 species (Table 1) are recorded in this area, among which 13 new species are described. The 5 coral assemblage-zones were established based on the Carboniferous-Permian boundary coral fauna in the Manaoshan-Wuguiling section. The present paper deals with these coral zones in order to make correlations with other regions both at home and abroad. The five coral assemblage-zones described are: 1. Paracarruthersella-Carinthiaphyllum carnicum (Pa-Ca)

- assemblage-zone, 2. Pseudocarniaphyllum-Pseudozaphrentoides mapingensis-Antheria polygonalis (Ps-Pm-A) assemblage-zone, 3. Chusenophyllum-Polythecalis nephelophylloides-Nephelophyllum yunnanense (Ch-Pn-N) assemblage zone, 4. Szechuanophyllum-Polythecalloidea pulchra (Sz-Pp) assemblage zone, 5. Yatsengia yishanensis-wentzelophyllum kueichowense (Y-wk) assemblage-zone. The new species described are: Gshelia yishanensis sp.nov., Petalaxis difformis sp.nov., P. guiensis sp.nov., P. wuguilingensis sp.nov., Polythecalis nephelophylloides sp.nov., P. variformis sp.nov., P. typica sp.nov., P. crassiseptata sp.nov., Parapolythecalis raredentata sp.nov., wentzelophyllum epicharis sp.nov., w. wuguilingense sp.nov., Yatsengia yishanensis sp.nov., Sinopora manaoshanensis sp.nov.

- 40388 <ABSTRACT>A dynamic pattern of coral faunal provincialism in the Carboniferous to Permian sequence is preserved in Tibet-west Yunnan. During the Early Carboniferous, an undifferentiated Eurasian province was present, containing the Kueichouphyllum, Keyserlingophyllum-Siphonophyllia, and Cyathaxonia faunas, that reflect major environmental differences relative to previous interpretations. During the Late Carboniferous-Early Permian, the Indoralian province

and the Cathaysian province can be distinguished. The former is recognised by an absence of Late Carboniferous-Asselian corals and by the presence of the Sakmarian-Artinskian Cyathaxonia fauna. The latter contains the Late Carboniferous and Early Permian compound corals *Nephelephyllum* and *Kepingophyllum*. As many blocks drifted northward beginning in the late Early Permian, the Indoralian province had evolved into two discrete provinces: the Himalayan and Cimmerian provinces. The Himalayan province as a relic of the Indoralian province was in the northern margin of Gondwanaland. The Cimmerian province between the Himalayan and the Cathaysian provinces consists of the present tectonic blocks: Lhasa, Qiangtang, Tengchong, and Baoshan in Tibet and west Yunnan. It is characterised by Roadian non-dissepimental solitary corals and wordian-Capitanian compound waagenophyllidae, as well as some endemic Cimmerian taxa such as *Thomasiphyllum* and *wentzellophyllum persicum*. The Cathaysian province is dominated by *Szechuanophyllum* and *Ipciphyllum*. During the Late Permian, the Himalayan province and the Cathaysian province can be recognised. The former contains only small solitary corals, referred to as the *Lytvolasma* fauna, and the latter is identified by *Liangshanophyllum*, a fasciculate waagenophyllid.  40412 <TITLE>Late Paleozoic Rugose corals from Batang and Yidun, western Szechuan.</TITLE>
 40413 <SOURCE>Acta Palaeontologica Sinica 18, 1: 25-38.</SOURCE>
 40414 <ABSTRACT>The present paper deals with the rugose corals found from the latest Lower Carboniferous Xuchika formation and the late Lower Permian Bingfeng formation in Batang and Yidun, western Szechuan. The Xuchika formation contains *Hiroshimaphyllum*, *Ozakiophyllum*, *Amygadalophyllidium* and *Ramiphyllum* with *Hiroshimaphyllum* as the leading form. It deserves to be mentioned that *Hiroshimaphyllum* was previously recorded only from the early Namurian in southwestern Japan, but unseen in this country. The Bingfeng formation yields a coral fauna of western Tethys called *Iranophyllum-Ipciphyllum* fauna, which, so far as known, includes *wentzelella*, *wentzelellites*, *wentzeelloides* (*wentzeelloides*), *w.* (*Multimurinus*), *waagenophyllum*, *Yokoyamaella* (*Yakoyamaella*), *Praewentzelella*, *Thomasiphyllum* and *Laophyllum*. Both the faunas are, however, quite different in assemblage from those in the contemporaneous deposits in southwest and southeast China. It seems that the distributional pattern of the two faunas must have something to do with the geotectonic condition. The range of the *Hiroshimaphyllum*

- fauna is more or less controlled by the eugeosynclinal factor, whereas the distribution of the Iranophyllum-Ipciphyllum seems to be restricted by the fold belts. * 9 genera and 11 species are described; two genera - Ramiphyllum and Batangophyllum - as well as six species are recognized as new ones. 40477 <TITLE>Diversity patterns of Carboniferous and Permian rugose corals in South China.</TITLE>
40478 <SOURCE>Geological Journal 41, 3-4: 329-343.</SOURCE>
40479 <ABSTRACT>The diversity and changing patterns of rugose corals in the Carboniferous and Permian of South China are analysed by statistical analyses of 45 families, 284 genera, and 1979 species from 14 consecutive time intervals. The ancestors of Carboniferous rugose corals originated early and underwent preliminary radiation in the late Famennian, but were eliminated by the Hangenberg global regressive event, which marks the Devonian-Carboniferous boundary. Radiation of typical Carboniferous rugose corals began in the late Tournaisian, when they were represented by an abundance of columellate taxa such as Kueichouphyllum and a significant diversification of Keyserlingophyllum. A decrease in the diversity of rugose genera occurred in the Serpukhovian, followed by a change in the composition of the rugose coral assemblages at the Mid-Carboniferous Serpukhovian-Bashkirian boundary, where large dissepimented taxa with complex axial structures disappeared. In the Bashkirian the Serpukhovian taxa were replaced by compound rugosan taxa of the Geyerophyllidae, Kepingophyllidae and Waagenophyllidae. This compositional change was associated with a global regressive event, recognized in South China by the absence of upper Serpukhovian strata in many places and by several erosional surfaces in carbonate sequences in the Lower Yangtze region. This regressive event was probably caused by an episode of glaciation in Gondwana. Subsequent transgression occurred in South China during the early Bashkirian, where a wide, uniform shallow-water platform developed in South China, on which were deposited tidal-flat dolostone and pure limestone containing compound rugose corals. Another change in the rugose coral assemblages, at the Sakmarian-Artinskian boundary, resulted in the absence from the Artinskian of representatives of typical Pennsylvanian and Early Permian families such as the Bothrophyllidae, Lithostrotionidae, Cyathopsidae, and Petalaxidae. Families uniquely typical of the Permian, characterized by Waagenophyllidae and Kepingophyllidae, dominate post-Sakmarian strata. This faunal change may be related to a major, worldwide regression, recognized at the end of the Sakmarian. Extinction of rugose corals at the end of the Permian occurred in two phases in South China. The first phase occurred at the end of the Capitanian and eliminated 47% of the families and 45% of the genera. Extrusion of the Omeishan Basalt, which is widely distributed in the western part of South China, and/or a global regression at the end of the Guadalupian could be the principal causes of this first phase of mass extinction. The second phase, which occurred at the end of the Changhsingian and is the largest extinction event in Earth's history, eliminated all remaining rugose corals.</ABSTRACT>

40490 <TITLE>Carboniferous and early Permian Rugosa from Western Guizhou and Eastern Yunnan, SW China.</TITLE>
40491 <SOURCE>Palaeontologia sinica 177, ser. B, 24: v + 1-230, 98 figs, 63 pls.; Beijing. [in Chinese, with comprehensive English summary]</SOURCE>
40492 <ABSTRACT>The fully developed marine Carboniferous and early Early Permian rocks in western Guizhou and Eastern Yunnan, SW China are represented by several hundred meters to more than 1000 m of limestones and argillaceous limestones, containing abundant faunas of rugose corals in association with brachiopods, fusulinids, and others. The Carboniferous and early Early Permian rugose corals here described and illustrated were collected at Weining, Shuicheng, Panxian and Pu#039; an Counties of Guizhou Province and Zhanyi County of Yunnan Province. These have been assigned to 215 species (including 106 new species and 13 new subspecies) in 96 genera (including 8 new genera and 1 new subgenus) and 24 families, providing the knowledge of their faunal succession, evolutionary stages and biological community of the Carboniferous and early Early Permian in the concerned area. [part of extensive summary] * The following new taxa are described: Parazaphrophyllum cylindricum gen. et sp.nov. (fam. Bothrophyllidae), Dizonophyllum eximium gen. et sp.nov., Empachyphyllum conicum gen. et sp.nov. (both fam. Aulophyllidae). Lithostrotion (Mictolithostrotion) sinensis subgen. et sp.nov. (subfam. Lithostrotioninae), Diphyphylloides regularis gen. et sp.nov. (subfam. Diphyphyllinae), Paralytvophyllum shuichengense gen. et sp.nov., Prolytvophyllum minus gen. et sp. nov (both fam. Petalaxidae), Paragangamophyllum weiningense gen. et sp.nov. (fam. Axophyllidae), Characophyllum carinatum gen. et sp.nov. (fam. Geyerophyllidae).</ABSTRACT>

40516 <TITLE>Rugose coral fauna of Huanglung Formation at Quanxia, Ninghua, Fujian.</TITLE>
40517 <SOURCE>Acta Palaeontologica Sinica 29, 6: 694-715.</SOURCE>
40518 <ABSTRACT>The Huanglung Formation exposed in Quanxia, Ninghua Country, SW Fujian is composed of continuously deposited marine carbonate rocks which contain abundant fossil corals with 27 genera and 59 species and subspecies, and can be grouped into two assemblages and two subassemblages in ascending order as follows: - 1. Yinophyllum crassum

Assemblage. [...] Besides, *Yinophyllum crassum* gen. et sp.nov. [it] is characterized by naotic septa and the thickened, curved columella, sometimes with a few axial tabellae, also some non-dissepimented solitary corals are also found in the assemblage, such as *Lophophyllidium* sp., *Bradyphyllum* sp., etc. The assemblage is associated with the fusulinid *Profusulinella*.- 2.

Protoivanovia-Arachnastraea Assemblage. (1) Protoivanovia *quanxiaensis*-*Koninckocarinia minor* Subassemblage. [...] It is dominated by the caninid corals and dreizoner corals developing lonsdaleoid dissepiments. Both of the index fossils are prosperous and characteristic, for example, *Protoivanovia quanxiaensis* sp.nov. is a kind of aphyroid compound corals with a simple columella. Besides, the dreizoner corals developing lonsdaleoid dissepiments include *Actinocyathus similis* (Dobr.), *A. sinensis* (Wu et Zhao), *Acrocyathus baijingensis* (H. D. Wang), *Dorlodotia subcaespitosa* (Meek), *Kionophyllum dibunum* Chi, *K. ovatum* Wu et Zhao, *K. sp.*, *Koninckocarinia* cf. *yishanensis* Wu, *K. minor* sp.nov., *K. sp.*, *Petalasis wyomingensis* Sando, etc. The caninid corals are characterized by the appearance of *Pseudozaphrentoides nosovi* (Fom.), *P. chuanshanensis* X. Yu, *Caninella* sp., *Caninia brockleyensis minor* X. Yu, *C. lipoensis* (Chi), *C. lipoensis chuanshanensis* X. Yu, *C. simpliseptata* Chi, *C. wangi* sp.nov., *C. sp.*, *Fomichevella holtedahli* (Herit.), *F. sinensis* X. Yu, *F. stuckenbergi* (Fom.), *Haplolasma lingwuensis* (Lee et Yu), *H. juddiformis regularis* (Gorskiy), *H. extensa* (Gorskiy), *Pseudotimania* cf. *mosquensis* (Dobr.), etc. The fusulinids in the subassemblage are *Fusulinella*, *Fusiella*. This fauna is obviously equivalent to the lower part of the *Fusulina-Fusulinella* Zone in age. (2) *Arachnastraea exquisita-Fomichevella* aff. *hoeli* Subassemblage. [...] It is characterized by the fasciculate and asteroid compound coralla, including such important components as *Arachnastraea manchurica* Yabe et Hayasaka, *A. exquisita* sp.nov., *Fomichevella campophylloides* Yan et Chen, *F. aff. hoeli* (Holt.), *F. holtedahli* (Herit.), *F. sinensis* X. Yu, *F. stuckenbergi* (Fom.), *F. sp.*, *Opiphyllum fomichevi* Kozyreva and *Crataniophyllum ninghuaense* sp.nov., among which the last one is a quasi-colonial coral, while the genus *Arachnastraea* is a kind of asteroid compound (or thamnasteroid in part) coral developing plate-columella and distributed widely in the Soviet Union, Spain and China as an index fossil for the late Moscovian. Taking into account the shared fusulinids *Fusulina*, *Beedeina*, etc., the subassemblage can be compared to the upper part of the *Fusulina-Fusulinella* Zone.

40529 <TITLE>Rugose coral fauna of late Carboniferous and early Early Permian in Fujian.</TITLE>

40530 <SOURCE>Acta Palaeontologica Sinica 29, 6: 668-693.</SOURCE>

40531 <ABSTRACT>The Chuanshan Formation widespread in western Fujian is composed of continuously deposited carbonate rocks and contains very abundant fossils. [8230;] The rugose corals comprise 83 species and subspecies in 38 genera, including 2 new genera, *Paraantheria* and *Pseudobothrophyllum*, 10 new species and 1 new subject [?]. Based on the obvious evolutionary phases, they can be grouped into three assemblages and two subassemblages in ascending order as follows: 1. *Nephelephyllum* Assemblage. [8230;] The common elements are *Nephelephyllum*, *Caninia*, *Haplolasma*, *Arctophyllum*, *Timania*, *Orygmophyllum*, *Pseudozaphrentoides*,

Caninophyllum, Fomichevella, Lytvophyllum, etc. Among them, the solitary corals with dissepiments, complete and domed or flat tabulae without axial structures are prominent, which are commonly called the **Carboniferous type**. But the occurrence of the massive rugose coral genus Nephelophyllum reveals an evolutionary trend from typical Carboniferous to Permian form. This assemblage is associated with the fusulinids Montiparus and Triticites. 2. Anfractophyllum-Kepingophyllum Assemblage. The first appearance of Kepingophyllum marks the beginning of this zone. It is sensibly different from the underlying Nephelophyllum Assemblage in the emergence of a great number of new types, such as the advanced Kepingophyllidae, which possess massive compound, tertiary septa, brambly [?] or septal thecae, more or less cystose dissepiments, clinotabulae, inclining tabulae towards the centre, and complex axial structure. The significant elements include Kepingophyllum simplex Wu et Chow, K. ninghuaense sp.nov., Monsteraphyllum yunnanense Wu et Kong, Anfractophyllum fujianense sp.nov., Ivanovia? elegans sp.nov., Paraantheria multiseptata gen. et sp.nov., Pseudobothrophyllum fujianense gen. et sp.nov., Pseudocarniaphyllum sp., Chuanshanophyllum sp., among which Anfractophyllum appeared in the upper part of this assemblage. Therefore, this assemblage can be subdivided into two parts, i.e. the Kepingophyllum Subassemblage below and the Anfractophyllum Subassemblage above. The fusulinids in the assemblage are Pseudoschwagerina, Sphaeroschwagerina, etc. 3. Wentzellophyllum volzi Assemblage. The first appearance of the zonal species is regarded as the beginning of this zone, which is coincident with the lower limit of the Gaodian Stage. The principal elements are wentzellophyllum volzi (Yabe et Hayasaka), Yatsengia asiatica Huang, Pseudohuangia tsengi (Zhao et Chen), etc. mainly the massive and fasciculate compound corals, in addition to some small non-dissepimented solitary corals and the tabulate Protomichelina. 40568 <TITLE>The Late Palaeozoic Rugose corals of Xizang (Tibet) and adjacent
regions and their Palaeobiogeography.</TITLE>
40569 <SOURCE>Earth, Series of Geoscience: 679 pp., 73 figs, 36 tabs, 73 pls;
Hunan Science & Technology Press.</SOURCE>
40570 <ABSTRACT>This monograph includes the following 8 parts (besides the
introduction): (1) stratigraphical regionalization and description of
section (2) the sequences and assemblage zones of the Rugose corals (3)
characteristics and distinction of Rugose Corals in the Palaeotethyan
Neritic facies, Slope facies and Gondwanan facies (4) composition of
carbon and oxygen isotopes of corals skeleton in Palaeotethyan neritic,
Slope, and Gondwanan facies (5) biogeographical Regions of the rugose
corals. * According to the characters of assemblage and distribution of
the much rugose corals in Late Palaeozoic, the authors have divided
into the China biogeographical Region of the Boreal Realm, the
Palaethethysan Realm and the Gondwanan Realm in China. (a) The China
Region of the Boreal biogeographical Realm; The rugose corals dominated
North America in type, most of them are solitary corals of no
dissepiments. (b) The China Region of the Palaeotethysan
biogeographical Realm; It occupied the richly solitary and compound
corals, with dissepiments, and some reef building corals appear usually
in this Realm. (c) The China Region of the Gondwanan biogeographical
Realm; The rugose corals are small solitary, their dissepiments absent.
But during the Late Middle Permian (Maokouan age), the Indian Plate
gradually shifted northwards into the Palaeotethysan Realm where
sediments were received, when the rugose coral fauna, adapted to the
warm water environment, is predominated by the Suborder wentelellina.
(6) The affinities of some rugose corals. The authors have made a
systematic research on the affinity of some rugose coral genera and
have solved the problems of their origin, the evolution and the
interrelationship of some rugose corals genera, revising their
taxonomic position. (7) Restatement on the classification of
wentelellina (8) Description of corals. The monograph describes totally
38 family (3 new family), 149 genera (12 new genera and 3 new
subgenera), 338 species [64 new species and 2 subspecies (1 new)] and 6
non-determinable species. Among of them, 12 [new?] genera, including 2
new genera are the small solitary without dissepiments being adapted to
the cold-water environment by the sea of the north margin of the
Gondwanaland, and 5 genera, including 1 new genus, belong to the slope
facies of the Palaeotethys. The 73 plates of fossils and 53
text-figures show the affinity and the characters of growth in various
stages of some genera and species. [part of original introduction]

40739 <ABSTRACT>The Baoshan block in west Yunnan, southwest China is one of the key areas for understanding Gondwana dispersion and Asian accretion. [8230;] The Late Paleozoic stratigraphic and paleontological characters of the Baoshan block contrast with similar characters in south China and Indochina but are close to those of the Sibumasu block of southeast Asia. These data indicate that the block is part of the Gondwana-derived Cimmerian fragment. [excerpts from extensive abstract]</ABSTRACT>

40815 <TITLE>Diversity and extinction patterns of Permian coral faunas of China.</TITLE>
40816 <SOURCE>Lethaia 33, 4: 285-294.</SOURCE>
40817 <ABSTRACT>Coral diversity and extinction patterns in the Permian of China are revealed through statistical analyses of 56 coral families, 263 genera and 2100 species from five consecutive time intervals. The highest coral diversity in the Chuanshanian, with 753 species, 167 genera and 39 families. In contrast, the lowest diversity is in the Changsibgian. with only 68 species, 20 genera and 10 families. Two decreases in diversity can be recognized during the Permian. The first occurred at the end of the Maokouan (end-Guadalupian) and is marked by the loss of 75,6% of coral families, 77,8% of coral genera and 82,2% of coral species. The second major diversity drop took place at the end of the Changsingian, when all rugose and tabulate corals became extinct. The extinction at the end of the Guadalupian in Pangea may be related to the middle Permian global regression of the Omeishan basalt. A triple-zoned palaeobiogeographical pattern is well preserved by coral diversity.</ABSTRACT>

40828 <TITLE>Permian coral faunas of the eastern Cimmerian Continent and their biogeographical implications.</TITLE>
40829 <SOURCE>Journal of Asian Earth Sciences 20: 589-597.</SOURCE>
40830 <ABSTRACT>Because of a depositional hiatus, Late Carboniferous corals are unknown from the eastern Cimmerian Continent. Early Permian (Asselian to Artinskian) corals are characterized by non-disseminated

solitary forms, and the absence of Kepingophyllidae and Waagenophyllidae, forms common in the Cathaysian biotic province. Roadian faunas in most areas of the eastern Cimmerian Continent are dominated by small solitary corals. These faunas are quite different from those of the Cathaysian area, where abundant large solitary and compound corals occur. By the Wordian, into the Capitanian, large solitary and massive Waagenophyllidae, with a Cathasian aspect, were well developed and widespread in the Cimmerian Continent. However, some endemic taxa, like Thomasiphyllum, also occur. Late Permian corals consist only of Cathaysian elements. Therefore, paleobiogeographically, the coral faunas in the eastern Cimmerian Continent reveal the following changes: 1) a Peri-Gondwana affinity during the Early Permian to early Middle Permian, (2) an endemic Cimmerian-Cathaysian affinity during the Late Middle Permian, and (3) a true Cathaysian fauna during the Late Permian. These changes may be related to the rifting of the Cimmerian Continent from Gondwana in the Late Early Permian and its subsequent northward drift.

 40842 <SOURCE>Acta Palaeontologica Sinica 21, 2: 249-265.</SOURCE>
 40843 <ABSTRACT>This paper deals with the Lower Permian corals from Southern China. 12 genera (four of which are new) are described, as well as a new sub-genus and 15 species (13 of which are also new). Regarding the Early Permian corals distributed in the Lower Yangtze Valley, the author also supposes that the Lower Permian should be divided into three zones and four subzones (in ascending order) as follows: Ipciphyllum zone (Zaphrentis permicus subzone; Ipciphyllum subtimoricum subzone); Polythecalis zone (Lophocarinophyllum-Chusenophyllum subzone; Polythecalis-Hayasakai subzone); Wentzellophyllum zone. The new genera are: Tachylasma (Praetachylasma) kwangchense n.subgen. et n.sp., Lophotabularia (type species: Lophocarinophyllum lophophyllidium Liao & Zhu, 1977), Naoticophyllum typicum n.gen. et n.sp., Prowebtzellites elegans n.gen. et n.sp., Parapolythecalis huangshiensis n.gen. et n.sp.</ABSTRACT>

40895 <ABSTRACT>The new genus *Lasmophyllum* (*L. beichuanense* n.gen., n.sp.) is described from the Lower Permian of Sichuan. Corallum fasciculate. Corallites cylindrical; these often in touch with another. Septa of two orders, major and minor in alternation. Major septa number never than 20. Minor septa rudimentary or absent. Counter septum often connected with cardinal septum forming an irregular median plate in the central area. Some of the major septa connected with median plate. Tabulae usually incomplete, convex upward, and inclined toward the periphery. 1-2 rows of dissepiments. This new genus resembles *Yatsengia* (Huang 1932), but differs from the latter in the counter septum connected with cardinal septum and forming an irregular median plate. The tabellae and radial plate are not developed.</ABSTRACT>

- 40921 <ABSTRACT>Abundant "hydrozoans" are important frame-building and accessory organisms in Middle and Upper Permian reefs of southern China, particularly in western Hubei, eastern Sichuan, eastern Yunnan, and northwestern Guangxi. The new genera Radiotrabeculopora, Lichuanopora, and Pseudopalaeoaplysina are described, as are the new species Disjectopora beipeiensis, D. irregulara, Radiotrabeculopora xiangoboensis, R. maokoui, R. elegans, R. astrorhiza, Balatonia robusta, Lichuanopora bancaoensis, L. (?) regulara, Pseudopalaeoaplysina sinensis, and P. major. The assemblage represents one of the most diverse upper Paleozoic "hydrozoans" assemblages known.</ABSTRACT>

- 40933 <SOURCE>Acta Palaeontologica Sinica 33, 1: 106-117.</SOURCE>
- 40934 <ABSTRACT>Since 1983, numerous Upper Permian reefs have been discovered in the Huaying Mountains, Central Sichuan, which are similar in textures, structures and developing process, with such main reef-building organisms as calcareous sponges, hydrozoans and bryozoans, and encrusting organisms such as Archaeolithoporella and Tubiphytes. Associated in great amounts with the reef building organisms are reef dwelling organisms, such as brachiopods, foraminifers, gastropods, crinoids, ostrocods and various calcareous algae. In sedimentological and palaeontological characteristics of these reefs, the Upper Permian reefs developed in central Sichuan represent the typical organic reefs in South China. All of these reefs occurred in the Upper Permian Changhsing Formation which is overlain by the Lower Triassic Feixianguan Formation. The tops of the reefs are covered with tidal flat deposits attaining about 1-7 m in thickness and made up of micritic dolomites accompanied by some evaporitic remnants in which specialized ostracods and stromatolites can be found. It is not very clear whether the tidal flat deposits belong to Triassic or to Permian. The decline of the Permian reefs corresponds to the mass extinction of various Permian organisms across the Permo-Triassic boundary, and therefore the reefs in this area can be regarded as the latest Palaeozoic reefs in the world. Here described are abundant "plate-shaped hydrozoans" found in these reefs over the past several years, with two new genera and three new species which are placed in

the family Palaeoplysilidae Chuvashov 1973 and included tentatively in the class Hydrozoa. [original summary] The following new taxa are described: Pseudopalaeoplysina huayingensis sp.nov., Phragmorpha asiatica gen. et sp.nov., Cnidopora tuberculosa gen. et sp.nov.

40946 <SOURCE>Acta Palaeontologica Sinica 21, 6: 709-714.</SOURCE>

40947 <ABSTRACT>Of late years, a number of fossil sponges have been obtained from different localities in the provinces of Sichuan, Guizhou and Jiangsu. Among them the Permian calcareous sponges preponderate in number over others. Some of them described in this paper include six genera and seven species. They are as follows: Sollasia aff. ostiolata Steinmann (Batang, Sichuan), Waagenella muliensis sp.nov., Cystauletes ribuzuoensis sp.nov., Coelociadia cf. spinosa (Muli, Sichuan), Cryptocolia sp. (Mianning, Sichuan), Heliospongia sp. (Wuxian, Jiangsu) and Heliospongia? houchangensis sp.nov. (Ziyun, Guizhou). * These forms belong to the classes Calcispongea and Demospongea respectively. They are collected from the Maokou Formation (P12) Southwest China except Sollasia aff. ostiolata Steinmann from the Bingfeng Formation (P12), and they may be compared with those from Carboniferous-Permian strata of the Tethysian area of Eurasia. * Here a fragment of hydroid collected from the Late Triassic Jieza Formation in Ylishu of Qunghai is also described. This form belongs to the order Sphaeactinoida and is designated under the name Ellipsactinia qinghaiensis sp.nov. [original summary]</ABSTRACT>

- 40985 <SOURCE>Acta Palaeontologica Sinica 22, 5: 510-516.</SOURCE>
- 40986 <ABSTRACT>The Lower Permian Chihsia Formation is well-developed in southern Anhui. In the upper part of the formation a considerable number of Chusenophyllum occurred which may be regarded as a guide fossil since it is confined to a certain horizon. Chusenophyllum is characterized morphologically by the entire vanishing of thecae, while Polythecalis is characterized by a partly vanishing of thecae and Wentzellophyllum by well-developed thecae. It seems that Polythecalis has evolved from Wentzellophyllum, and Chusenophyllum from Polythecalis through a gradual vanishing of the thecae. According to the lithological characters and the coral assemblage, the Chihsia Formation in southern Anhui may be divided into two zones and two subzones: 2. Polythecalis zone a. Chusenophyllum subzone b. Polythecalis yangzeensis subzone 1. Wentzellophyllum volzi zone. In addition eight new species of Chusenophyllum are described and illustrated: Ch. chaoxianense, multiseptatum, anhuiense, pingdingshanense, chaohuense, guichiense, intermedium and annulatum. 41049 <TITLE>Intraspecific variation in Kepingophyllum aksuense Wu et Zhou from the Lower Permian of Kelping, Xinjiang, Northwest China.</TITLE>
41050 <SOURCE>Acta Palaeontologica Sinica 43, 4: 579-585.</SOURCE>
41051 <ABSTRACT>After a detailed observation in a large number of thin sections of Kepingophyllum aksuense from Lower Permian of Kelping area, Xinjiang, we found that there are strong variations in corallites of colony. The characters exhibiting high variability include: shape of corallites, width ratio of tabularium to dissepimentarium, septal length, shape of tabulae, the number of septa, and the ratio of septal number to diameter. The shape of corallites is greatly different in transverse section. The [corallites] are commonly hexagon and some pentagon, and even triangle. The statistical analysis shows the ratio of tabularium to dissepimentarium has a random distribution. This abnormal distribution may be caused by unstable development of lonsdaleoid dissepimentariums. Major and minor septa are measured in the length and indicate a good linable relation between them. In longitudinal sections, shapes of tabulae can be differentiated into three kinds: the concave complete tabulae, incomplete tabulae, and clinotabulae. About 200 corallites are measured in number of septa to show a distribution pattern that the number 14-16 takes the majority.

Eighty corallites are measured for the ratio of septal number to diameter. The distribution pattern shows that data points are surprisingly scattered away from the curve and the R value is only 0.3923. In addition, in longitudinal section there exists a periodic increase that probably shows a kind of seasonal variation, represented by alternative arrangement of large and small vesicular dissepiments. The comparison between the present and type specimens indicates a less difference in variability.</ABSTRACT>

41062 <TITLE>Permian rugose coral faunas of Inner Mongolia-Northeast China and Japan: Paleobiogeographical implications.</TITLE>

41063 <SOURCE>Journal of Asian Earth Sciences 26: 369-379.</SOURCE>

41064 <ABSTRACT>The faunal characteristics, successions and geographical distribution of the Permian rugose corals in Inner Mongolia-Northeast China and Japan are reviewed using current coral taxonomy and the recently revised Permian global time scale. The co-occurrences of Cathaysian compound corals, abundant non-dissepimented solitary corals, and endemic corals indicate that Inner Mongolia and Northeast China present an independent biogeographical entity, quite separate from South China and the Japanese terranes. However, the common occurrence in South China of Permian taxa such as *Wentzellophyllum*, *Lonsdaleiastraea*, *Yatsengia*, *Ipciphyllum*, and *Waagenophyllum* indicates, in a broad sense, a Tethyan affinity for the Akiyoshi and Mino terranes in Japan. Rocks from the Asselian to the Artinskian in the South Kitakami Terrane of Japan contain eleven large dissepimented solitary and compound genera, including *Huangia*, *Iranophyllum*, *Laophyllum*, *Polythecalis*, *Sestrophyllum*, *Wentzelella*, *Wentzellophyllum* and *Yatsengia*. These genera are all typical of, and common in, South China, but are absent from coeval strata in Northeast China. Middle Permian rocks in the South Kitakami Terrane also contain rugose corals that are abundant in South China, in some cases the same species, such as *Parawentzelella regularis*, *Waagenophyllum indicum*, *Waagenophyllum virgalense* and *Yatsengia kiangsuensis*. Thus, the coral faunas from the South Kitakami Terrane indicate a close paleobiogeographical affinity with those from South China, which is consistent with the paleobiogeography based on ammonoids and bivalves.</ABSTRACT>

41075 <TITLE>Middle Permian rugose corals from Laibin, Guangxi, South China.</TITLE>

41076 <SOURCE>Journal of Paleontology 75, 4: 758-782.</SOURCE>

41077 <ABSTRACT>The Middle Permian Chihsia and Maokou formations in Laibin, central Guangxi, South China contain 19 rugose coral species; of these taxa, *Lophocarinophyllum sandoi*, *Asserculinia solida*, and *Innixiphyllum wuae* are new. *Innixiphyllum* represents a new genus characterized by contrasting minor septa. Ten species are reviewed and described in

detail, and the diagnoses of three of these species, *Allotropiophyllum heteroseptatum* (Grabau 1928), *Lophocarinophyllum taihuense* (Yan & Chen 1982), and *Ipciphyllum regulare* (Wu 1963), are emended. The morphological variation and ontogenetic changes of the solitary, nondissepimented species are particularly emphasized. Six additional taxa are described and illustrated but are left in open nomenclature. The corals from Labin are typically Tethyan. Four biostratigraphic assemblages are recognized: an assemblage of massive corals in the Upper Chihhsia Formation represented by *Polythecalis longliensis*; an assemblage of small solitary and nondissepimented corals in the lower Maokou Formation, dominated by species of *Allotropiophyllum*, *Innixiphyllum* and *Lophocarinophyllum*; an assemblage of mixed massive colonial and small solitary corals in the middle Maokou Formation, characterized by *Ipciphyllum regulare*; and an assemblage of solitary nondissepimented corals in the uppermost Maokou Formation, characterized by *Ufimia elongata*. These assemblages correspond well to those from other areas of South China. In Labin, only two rugose taxa, *Amphicarinia* sp. and *Paracania* minor, occur in the basal part of the Wuchiaping Formation of Lopingian age.

41142 <ABSTRACT>The Asselian corals described in this paper were collected in 1984 by Zhou Zuren and others during their investigation of the Carboniferous-Permian boundary in Nandan County, the Zhuang Autonomous Region of Guanxi. Those identified here as *Notophyllum liuzhaiense* gen. et sp.nov., *Liuzhaiphyllum intermedium* gen. et sp.nov., *Thomasiphyllum?* sp. and *Bayhaium nandanense* sp.nov. were found in association with the Asselian ammonoids and fusulinids. All of these fossils occur in the carbonate blocks of the debris flow, which derived probably from the foreslope of the Carbonate platform, 6 m in thickness at the quarry, 1.2 km southwest of the Liuzhai Town. In 1982, the author defined two paleogeographical regions of corals in the Sakmarian all over the world, the Durhaminidae region which is distributed in North America, Soviet Union and Spitsbergen and the Kepingophyllidae region which is limited within the Tethys only. Since no typical elements of the Kepingophyllidae have been found in the present coral fauna so far, it is difficult to define the exact age of the described corals. Of interest is the discovery of the specimens of the genus *Bayhaium* which was proposed in 1959 by Langenheim et McCutcheon. Since then, about five species of the genus have been described by different authors, including the American species found in the wolfcampanian of California (Langenheim et McCutcheon 1959; Wilson 1982), and two other species which also have been identified by Ding et Yu in 1983 from the lower part of the Permian in southern Shaanxi, China. These seem to indicate that the age of the present coral fauna could be recognized as the earliest Permian. However, the presence of the associated Asselian ammonoids is something noticeable which can be taken as an evidence to put them in the Asselian age [part of original summary].</ABSTRACT>

41193 <SOURCE>J. Graduate School, China Univ. Geosci. 6, 1: 23-29.</SOURCE>
41194 <ABSTRACT>The ecological-environment differentiation of the Early Permian rugose corals in Southern Guizhou and Central Hunan is very obvious. According to quantitative analysis of the rugose corals of different facies in some major stages of the Early Permian, the ecological-environment differentiation of these corals is discussed as the following: (1) In turbulent shallow marine on platform margin, massive compound rugose corals dominated. (2) In tranquil shallow marine on platform margin, solitary rugose corals of trizone type, aphyroid and thamnasterioid compound corals dominated, but massive compound corals decreased. In this environment, the diversity of rugose corals is the largest. The elements of these corals usually occurred in this environment. (3) In basin sedimentary area, only non-dissepimented rugose corals occurred. These studies will provide some important paleontological evidences for the sedimentology and paleogeography of future.</ABSTRACT>

41206 <SOURCE>Chinese science Bulletin 37, 13: 1108-1111.</SOURCE>
41207 <ABSTRACT>The process in which a colony is developed from protocorallite by asexual reproduction that made the majority of compound coral skeleton is called "increase pattern". Different taxa and even different colonies of the same taxon could exhibit different increase patterns. Conversely, it is possible that different taxa have the same increase pattern. Therefore, study on the increase pattern has significant implications not only for the taxonomy but for paleoenvironmentology. This study reports the unusual increase pattern of Kepingophyllum aksuense from Aksu area in Xinjiang.</ABSTRACT>

41220 <ABSTRACT>Microskeletal structures of the Late Permian rugose corals of Zhengan, Southern Shaanxi, investigated by SEM and optical microscope, are revealed as follows: 1. Their septal structures may be divided into two types: a trabeculate type and a non-trabeculate type; with two types of septal thickening, one formed by the clustered arrangement of minor trabeculae; the other by thick trabeculae with carinae on both sides of septa completely constituted by fascicles, not extending as part of the trabeculae. 2. The walls of both solitary and fasciculate compound corals are composed of parallel needles or brachycolumns. Two types of intercorallite walls exist in the massive corals, in one type, an obvious dark-line formed by irregular granules or needles present in the central part of the intercorallite wall. The other form is composed of densely interlocked trabeculae of septal outer ends from neighbouring corallites. 3. Lateral structures and columellar walls of the corals consist of parallel needles or brachycolumns.</ABSTRACT>

41245 <SOURCE>Boletin de la Real Sociedad Espanola de Historia Natural, Seccion Geologica 91, 1/4: 127-141.</SOURCE>
41246 <ABSTRACT>Two new genera (Timorocarinoiphyllum, Pseudoverbeekiella) and 10 new species are described from Lower and Upper Permian deposits of southeastern Pamir. Rugose assemblages characterizing the stages from the Bolorian (Lower Permian) to the Dorashamian (Upper Permian) are recognized. The following rugose zones are established: the Pseudoverbeekiella - Timorocarinoiphyllum - Ufimia (Kochusu assemblage), the Iranophyllum-Pavastephyllum (Gana assemblage) and the Waagenophyllum (w.) - (w.) (Huayunophyllum) (Takhtabulak assemblage). The family Verbeekiellidae is placed in synonymy with the Timorophyllidae, and the wannerophyllidae with the Lophophyllidae on the basis of the arrangement of trabeculae in their septa. The former pair is characterized by a fan-shaped arrangement, and the latter by a monoclinial arrangement of trabeculae.</ABSTRACT>

41257 <TITLE>Upper Permian coral reef and colonial rugose corals in Northwest Hunan, South China.</TITLE>
41258 <SOURCE>Facies 39, 1: 35-65.</SOURCE>
41259 <ABSTRACT>The roles of Permian colonial corals in forming organic reefs have not been adequately assessed, although they are common fossils in the Permian strata. It is now known that colonial corals were important contributors to reef framework during the middle and -late Permian such as those in South China, northeast Japan, Oman and Thailand. A coral reef occurs in Kanjia-ping, Cili County, Hunan, South China. It is formed by erect and unscathed colonies of Waagenophyllum growing on top of one another in situ to form a baffle and framework. Palaeontological data of the Cili coral reef indicates a middle to late Changhsing age (Late Permian), corresponding to the Palaeofusulina zone. The coral reef exposure extends along the inner platform margin striking in E-S direction for nearly 4 km laterally and generally 35 to 57 m thick. The Cili coral reef exhibits a lateral differentiation into three main reef facies; reef core facies, fore-reef facies, and marginal slope facies. The major reef-core facies is well exposed in Shenxian-wan and Guanyin-an sections where it rests on the marginal slope facies.

Colonial corals are dispersed and preserved in non-living position westward. Sponges become major stabilizing organisms in the eastern part of Changhsing limestone outcrop in Kanjia-ping, but no real sponge reefs were « formed. Coral reefs at Cili County in Hunan are different distinctly from calcisponge reefs in South China in their palaeogeography, lithofacies development, organic constituents, palaeoecology and diagenesis. The Cili coral reef also shows differences in age, depositional facies association, reef organisms and diagenesis from coral reefs in South Kitakami of Japan, Horat Plateau of Thailand, and Saih Hatat of Oman. Although some sponge reefs and mounds can reach up to the unconformable Permian/Triassic boundary, coral reef at Kanjia-ping, Cili County, is the latest Permian reef known. This reef appears to have been formed in a palaeoenvironment that is different from that of the sponge reefs and provides an example of new and unique Permian reef type in South China, and could help us to: 1) understand the significance of colonial corals in Permian carbonate buildups; 2) evaluate the importance of coral community evolution prior to the collapse of reef ecosystems at the Permian/Triassic boundary; 3) better understand the effects of the biotic extinction events in Palaeotethys realm; 4) look for environmental factors that may have controlled reefs through time and space, and 5) provide valuable data for the study of Permian palaeoclimate and global evolutionary changes of Permian reefs and reef community.

41270 <TITLE>Patterns and palaeoenvironmental implications of end-Permian extinction of Rugosa in South China.</TITLE>

41271 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 107: 165-177.</SOURCE>

41272 <ABSTRACT>Late Permian rugose corals are undoubtedly the last phylogenetic representatives of the Rugosa. These corals are widely, though sporadically, distributed, notably in South China. The Late Permian corals of South China decrease markedly in diversity and are represented by surviving genera from the Maokouan, showing common patterns of disappearance, morphologically and phylogenetically. Colonial wentzelellinae mostly disappeared by the end of the Maokouan, followed by solitary wentzelellinae and later waagenophyllinae having simple morphologies. Non-dissepimented solitary corals and fasciculate waagenophyllinae, though morphologically simple, are common during the Late Permian, ranging up to the latest Permian. Permian Rugosa apparently show two terminal patterns, suggesting environmental differences. One pattern is terminated with a progressive reduction, leaving only non-dissepimented solitary corals as survivors, and the other pattern is distinguished by the disappearance of the platform-dwelling colonial corals at the end of Permian. The general trend, characterized by later disappearance of the simpler corals, reflects progressively adverse changes in the marine environment. The persistence and disappearance of a latest Permian waagenophyllum fauna suggests that the regional continuation of favorable environments followed by the onset abrupt and severe, though temporary, environmental changes for coral growth. The causes of rugosan extinction are not necessarily attributed to factors characteristic of the latest Permian time, and the extinction was individually stepwise, each different disappearance event correlating with, and possibly caused by variable factors, such as sea-level fluctuations and volcanic activity. Multiple

- interactions of individual factors on a local and global scale affected each faunal component, resulting in selection of corals that culminates in the regional, and finally global, disappearance of Rugosa. </ABSTRACT>

- 41298 <ABSTRACT>Lower Permian (Guadalupian) outcrops in Luqu and Xiahe Counties and adjacent regions yield abundant fossils of rugose corals and other benthic organisms and have been selected as the standard exposures for marine Permian in West Qinling. Collected fossils in these areas are systematically described. Nine species and subspecies of massive and solitary rugose corals of Guadalupian age belonging to 9 genera and subgenera are described. Among them, one genus and 5 species and subspecies are new: Lophocarinophyllum triangulariseptum sp.nov., Carinowaagenophyllum xiaheense gen. et sp.nov., Parawentzelella (Parawentzelella) gansuense sp.nov., Ipciphyllum bijishanense rariseptum subsp.nov., and Iranophyllum (Laophyllum) gansuense sp.nov. This assemblage is characteristic of warm shallow water. The presence of the genera Parawentzelella (Parawentzelella), Ipciphyllum, wentzelelloides, Londaleiastraea and Iranophyllum indicates that this rugose coral assemblage belongs to the Tethyan zoogeographical Province (Fedorowski 1981). </ABSTRACT>

41362 <SOURCE>Journal of Jilin University (Earth Science Edition) 33, 4: 399-405.</SOURCE>
41363 <ABSTRACT>Based on biostratigraphical discussion, the paper gives a detailed description to the rugose fauna of the early-Permian, including 7 new species. Two coral assemblages are distinguished: Lytvolasma-Cyathocarinia and

Lytvolasma-Caninophyllum-Pseudopolythecalis. The first assemblage is mainly made up of minitype, monocase. Septa and their ectecines are all thickened; the second assemblages exhibits mixed fauna including colony and monocase corals. The paper also puts forward the overlapped type and mixed type of the mixed fauna in the area, and points out that the appearance of the mixed fauna in this area is consistent with the general decreased temperature from late Carboniferous to early Permian, and also reflects climate changes from warm to cold, then to warm again. The study also reveals that the nature of the Paleo-Asian oceanic crust had essentially changed a little before the early Permian; it was shallow sea in an arch-island environment, not an open sea. 41374 <TITLE>Discovery of Lytvolasma Fauna from Western Section of Eastern Kunlun Mountains.</TITLE>
41375 <SOURCE>Acta Palaeontologica Sinica 28, 4: 486-491. VOL PP ???</SOURCE>
41376 <ABSTRACT>Our knowledge of the Lytvolasma fauna from Qinghai is, on the whole, quite insufficient, especially of those from the Kunlun-Qinling geosyncline province. However, new findings have been made in recent years at some localities from the western section of the Eastern Kunlun mountains in western Qinghai. Here described are seven species in six genera from this area, namely: Pleramphlexus similis Schindewolf, Wannerophyllum sp., Lytvolasma asymetricum Soshkina, Lophophyllidium wichmanni (Gerth), L. nucleum sp.nov., Timorphyllum variabilis Gerth and Stereostylus sp. In palaeoecological conditions, this coral fauna, which is characterized by all simple forms with no dissepiments, belongs to the cold-water type. Besides, the Lytvolasma fauna-bearing beds are regarded as belonging to late Early Permian, and may be compared with the Langcuo Formation in the Saga, Zhongba, Namfo Areas of Xizang and the Basleo beds in Timor. 41426 <TITLE>Palaeoecological and phylogenetic implications of a new scleractiniamorph genus from Permian sponge reefs, south China.</TITLE>
41427 <SOURCE>Palaeontology 43, 2: 199-217.</SOURCE>
41428 <ABSTRACT>Scleractinian corals are the most important constituents of modern coralgal reefs. For many years, it as thought that they first appeared in the Middle Triassic and subsequently underwent explosive radiation. However, abundant scleractinian-like corals within ancestral morphological traits have recently been recovered from the Middle Permian sponge reefs in China, which not only confirms a role in Permian reef ecology but also suggests a possible Palaeozoic origin for the group. Two species of a new Permian scleractiniamorph genus from China are described herein as Houchangocyathus wangi gen. et sp.nov. and Houchangocyathus yaoi gen. et sp.nov. Putative Palaeozoic Scleractinia may have evolved over a substantial time interval and diverged into stem lineages by the end of the Permian. These forms evolved within both the rigid framework of their basic body plan and the morphological constraints characteristic of each lineage. The Middle Permian development of calcisponges reefs was closely related to habitat expansion, which would have provided an ideal dwelling for scleractinian-like corals and enhanced their chances of fossilization. Such scleractiniamorphs disappeared at the end-Permian extinction, but may have survived as progenitors of Triassic Scleractinia.</ABSTRACT>

41492 <SOURCE>Senckenbergiana lethaea 73, 1: 31-35.</SOURCE>
41493 <ABSTRACT>Two new coral genera are described from lower Permian strata

of the Darvaz Mountains, Tadzhikistan. The skeleton of the small rugose coral *Liauria multiplex* n.g. et n.sp. consists almost entirely of a pleonophoran (bizonal) basal apparatus. The species occurs in association with an auloporid tabulate coral *Gundarina nana* n.g. et n.sp. The unusual skeletal morphology of the two new species provides the basis for description of the two new genera, for which they are the type species.

41531 <SOURCE>Acta Geologica Sinica 1977, 2: 174-189.</SOURCE>
41532 <ABSTRACT>The present article deals with the following contents: (1) For the Lower Permian Tabulata two distinct zoogeographical provinces in China - the South China and North China provinces are recognized. In the South China province, the tabulate coral fauna comprises *Tetraporinus*, *Thamnopora*, *Sinopora*, *Protomichelina* *Michelina*, *Cystomichelina* and abundant *Hayasakaia*. This tabulate coral fauna marks an independent zoogeographical province. In the North China province, Tabulata are few, lacking the typical South China genera *Hayasakaia* and *Cystomichelina*. (2) In the Lower Permian two major

tabulate zones and three tabulate subzones are established in descending order as follows: Maokou Limestone 2. Zone of Protomichelinia multitabulata Yabe et Hayasaka. Chihsia Limestone 1. Zone of Hayasakaia (3) Subzone of Protomichelinia microstoma (Yabe et Hayasaka)-Protomichelinia siyangensis (Reed) (2) Subzone of Hayasakaia elegantula (Yabe et Hayasaka)-Tetraporinus nankingensis (Yoh) (1) Subzone of Hayasakaia syringoporoides (Yoh).</ABSTRACT>

41596 <SOURCE>Acta Palaeontologica Sinica 29, 3: 315-320.</SOURCE>
41597 <ABSTRACT>Two species of calcareous sponges are described in this paper. One is the type species of a new genus, Corynospongia tubuliforma gen. et sp.nov. found from the upper Lower Permian Maokou Formation, Hongqiao, Xingwen County, south Sichuan; the new genus, Corynospongia, is characterized by the body wall with two types of canals. The other is a fragment of sponge body collected from the Lower Permian strata in Laibin of Guangxi; this form belongs to the order Heteractinida and is referred to Talpaspongia clavata King 1943.

41608 <TITLE>Upper Permian silicified sponges from central Guangxi and western Hubei, South China.</TITLE>
41609 <SOURCE>Journal of Paleontology 69, 2: 232-250.</SOURCE>
41610 <ABSTRACT>well-preserved silicified sponges have been recovered from the Upper Permian Changxing Formation at Huangnitang in western Hubei province. The new species Cystauletes grossa and Cystothalamia irregulara are associated with Cystothalamia sp., Colospongia salinaria irregularis Zhang 1983, Sollasia ostiolata Steinmann 1882, Virgola? osiensis (de Gregorio 1930), a questionable inozoan species, and a form questionably referred to the genus Hikorodium? sp. These sponges were detrital fragments that accumulated at the toe of the forereef, at the margin of slope facies and basin facies, at Huangnitang. Amblysiphonella vesiculosa minima Zhang 1983, is represented in the collections from the Upper Permian Heshan Formation at the village of Guwu, near Heshan City in central Guangxi. Heshan beds that produced the silicified sponges are of Wujiapingiang age and accumulated on a normal-marine, shallow-water carbonate platform, or in skeletal shoals within the carbonate platform, and represent a level-bottom community.

41621 <TITLE>Inozoan calcareous Porifera from the Permian reefs in South

- China.</TITLE>
41622 <SOURCE>Journal of Paleontology 63, 6: 778-800.</SOURCE>
41623 <ABSTRACT>Inozoans are described from patch reefs on the carbonate platform of eastern Sichuan, from the uppermost Permian Laolongdong reefs in the Changxing Formation (Kazanian-Tatarian) at Beipei, northwest of Chongqing, and from the Middle to Upper Permian reefs from the Maokou (Kungurian), Wujiaping (Ufimian), and Changxing Formation at Xiangbo, Longlin County, in northwestern Guangxi. Classification of inozoans, particularly late Paleozoic ones, is still in a state of flux, but genera recognized to date can be keyed using the general nature of the spongocoel, canals, and growth form. New genera described are Intratubospongia, Grossotubenella, Cavusonella, and Radicanaloespongia. The new species described are Stellispongia radiata, S. minor, Peronidella beipeiensis, P. regulara, P. parva, Intratubospongia typica, I. tenuiperforata, I. multisiphonata, I. minima, Grossotubenella parallela, Cavusonella cavema, and Radicanaloespongia normala. A Corynella that is not identifiable to species and a sphinctozoan-like inozoan (?) sp. A that has a fibrous-appearing internal skeleton but is poorly preserved are also described. Inozoans and other sponges are major frame-builders in the Permian reefs of South China and our fauna is one of the most diverse late Paleozoic assemblages described to date.</ABSTRACT>

41634 <TITLE>Inozoan, Major Reef frame-building organisms in Late Permian, Hunan. [in Chinese, with English abstract]</TITLE>
41635 <SOURCE>Oil & Gas Geology 24, 1: 70-74.</SOURCE>
41636 <ABSTRACT>The late Permian reefs are distributed in Chengxian, Guiyang and Chenxi Counties in southern Hunan province. Reefs in Bangxian and Guiyang are patch reefs developed along Chengru shallow sea. Reefs in Chenxi are bioherms, undeveloped patch reefs. The reefs in both sites occur in the late Permian Changxing Formation. A lot of samples of fossils and rocks have been collected while surveying 8 reef composite sections in southern Hunan. We find that the most important frame-building organisms are calcisponges, just as other Permian reefs in southern China. By systematically researching Inozoans, one of the important frame-building calcisponges, it is thought that the water system and fibres might be important evidence in classification. Twelve species and 8 genera of Inozoans including one new species, one comparative species and one undefined species are found, and some species are newly classified. [original abstract]</ABSTRACT>

41675 <ABSTRACT>An overview on the Permian lithological characters and faunas
of three Gondwana-related regions, namely the Baoshan area of West
Yunnan, western and southern Thailand, and southern Sydney Basin, is
here introduced. During Asselian and Sakmarian time, these three
regions are very similar not only in lithology that is characterized
by marine glacio-origin diamictites but also in faunas that are mainly
composed of cold water brachiopods and small nondissepimental corals.
Started from Artinskian, differences on lithology and faunal characters
occur among these three regions. Warmwater faunas such as fusulinid
Pseudofusulina and conodont Sweetognathus, and carbonatedeposition are
present in the Baoshan area during the Artinskian. A warm water
fusulinid Monodiexodina fauna occurs in western Thailand during the
Kungurian. These two regions possibly located in relatively northern
area comparing to the Sydney Basin due to rifting from Gondwanaland and
drafting northward closing to the Tethyan continent. And more later
time, during the Roadian to Capitanian or even Wuchiapingian, particular
Cimmerian mixed fauna and complete carbonate sequence dominated in the
Baoshan block and western and southern Thailand. In the contrast,
southern Sydney Basin continued to be characterized by siliciclastics
and cold-water brachiopods, bivalves, and small nondissepimental corals
during the Middle Permian.</ABSTRACT>

41686 <TITLE>Permian reef types and controlling factors of reef formation in
South China.</TITLE>
41687 <SOURCE>Acta Palaeontologica Sinica 34, 1: 67-75.</SOURCE>

- 41688 <ABSTRACT>In South China, the Permian is a period of maximal marine transgression in Late Paleozoic and the best reef-formation since Middle Devonian. There are two major Permian reef-formation cycles, the Maokouan and the Changhsingian. In the Changhsingian, reefs are better developed and common in occurrence, mainly occurring in Guizhou, Guangxi, eastern Sichuan, Hunan, western Hubei and the Lower Yangtze Region. Based on the reef-forming origin, composition and texture, abundance of reef-forming organisms and reef rock types, with reference to the classification of Dunham (1962), the Permian reef in South China are of the premagmatic origin and may be divided into 4 types: (1) Organic reefs; (2) Bioherms; (3) Lime-mud mounds; and (4) Stratigraphic reefs. The Changhsingian reefs in Cili of Hunan are the largest Permian organic reefs in China, which are entirely built of corals (Waagenophyllum) and preserved with original growing conditions in situ (ecological reef), with clumpy branching corals closely woven together. There are many types of Permian reefs developed in South China. Their growth, development and disappearance were controlled not only by internal biological factors, but also by external factors such as tectogenesis (especially fault-block movement), paleogeography, paleoenvironments, transgression-regression and eustatic changes. The bioherms and stratigraphic reefs formed on platforms are especially sensitive to sea-level changes. Since the reef growing rate is sometimes in accordance and sometimes in discordance with the rise of sea-level, the vertical distribution of reefs shows multicyclic and rhythmic characteristics in stratigraphic sequence.</ABSTRACT>

41765 <SOURCE>Journal of Asian Earth Sciences 20, 6: 647-656.</SOURCE>
41766 <ABSTRACT>Recent progress in the study of Permian stratigraphy in western Yunnan, southwest China, is reviewed with particular references to the Tengchong and Baoshan blocks and the Changning-Menglian Belt. Where confusion or controversy exists in stratigraphical nomenclature and/or dating, we attempt to clarify the situation based on our recent field observations and newly obtained research results. The Permian within the Changning-Menglian Belt embraces different stratigraphic successions, suggesting different tectonic settings, ranging from passive margin and active margin, to oceanic basin and seamounts. Permo-Carboniferous faunas in the carbonate sequences of the Changning-Menglian Belt are of typical Cathaysian affinity, as demonstrated by abundant fusulinaceans and compound rugose corals. The Permian stratigraphy and faunas of the Tengchong and Baoshan blocks are markedly different from those of the Changning-Menglian Belt. The Baoshan Block lacks upper Carboniferous deposits, and its subsequent

Lower Permian sequence consists predominantly of siliciclastic strata yielding cool-water faunas and possibly glaciogenic diamictites, overlain by thick basaltic lava and volcanoclastics of probably rift origin. The upper part of the Permian in the Baoshan Block is characterized by carbonates containing mixed Cathaysian and Gondwana faunas. The Tengchong Block has a similar evolutionary history to the Baoshan Block, but completely lacks volcanic rocks. [original abstract]

</TITLE>

41778 <SOURCE>Earth Science-Journal of China University of Geosciences 28, 6: 601-605.</SOURCE>

41779 <ABSTRACT>The paper discusses the nature and evolution of reef based on the study of the Early-Middle Permian reef section in Maerzheng, eastern Kunlun and the sequence stratigraphy of the reef. The reef can be divided into 12 reef-building cycles, including 5 third class sequences, on the basis of rock features, biocommunities and sea level changes. Moreover, it puts forward the basic rule of reef development on the continental margin in comparison with those reefs of Early-Middle Permian in eastern Kunlun and in the Yangtze platform. 41790 <TITLE>Communities, palaeogeography and reefs of Middle Permian Qixia period in Hunan. [in Chinese, with English abstract]

</TITLE>

41791 <SOURCE>Chinese Journal of Geology 38, 2: 190-199.</SOURCE>

41792 <ABSTRACT>Various fossil communities on different places indicated a shallow marine with various depositional environments developed in Hunan during the Qixia Period of Middle Permian. The Stigmara and Skolithos communities indicated the environments of seamarsh (or littoral depression) and supratidal respectively. The Pycnostroma community meant a very shallow turbulent environment, including the intertidal zone and very shallow subtidal zone. The Orthotetina community was characteristic of the nearshore subtidal environment with soft-mud substratum. The Lophophyllidium community occupied the underturbulent subtidal environment, suffered occasionally by storm turbulence; and the Wentzellophyllum community showed the clear subturbulent subtidal environment, where compound rugose corals were broken and overthrown frequently by storms. The trace-fossil Zoophycos community developed in a clear and relatively turbulent subtidal environment, which was very suitable for flourishing of benthic organisms. * In the Sangzhi-Shimen, Chenxi-Huaihua and Dongkou-Xinhua areas, the Stigmara community developed well at the beginning of Qixia Period, indicating environments of seamarsh or littoral depression. Then the Orthotetina

and Zoophycos communities dominated, meaning a relatively restricted sea near the old land. In Liangyuan-Liuyang, the Skolithos and Pycnostroma communities at the beginning of Qixia Period proved a wide tidal flat zone or very shallow subtidal zone. In Shaoyang-Leiyang, the Skolithos and Pycnostroma communities were never found, the Lophophyllidium and Zoophycos communities supported an evidence of the area far away from the old land and the environments being more restricted. * Based on distributions of the various communities, five paleogeographic units could be divided in Qixia Period; the Sangzhi-Shimen littoral-shallow sea, Chenxi-Huaihua littoral-shallow sea, Dongkou-Xinhua littoral-shallow sea, Lianyuan-Liuyang open shallow sea and Shaoyang-Leiyang restricted shallow sea. The reefs of Qixia Period, composed of the sponges of Pronidella community and firstly discovered from Shuangshouting to Xiandong of Lianyuan, Central Hunan, was located on the margin of the Lianyuan-Liuyang open shallow sea.

41803 <TITLE>Emergence of the Late Permian Changhsingian reefs at the end of the Permian. [in Chinese, with English abstract] </TITLE>

41804 <SOURCE>Acta Geologica Sinica 77, 3: 289-296.</SOURCE>

41805 <ABSTRACT>Dolostones occur on the top of the reef core, reef front and back reef sequences of the Upper Permian. The Changhsingian reef in Ziyun County, Guizhou Province, southwestern China. Comprehensive study on them reveals that these dolostones are of the supratidal sabkha genesis: (1) all have $\delta^{18}O$ values higher than those of their precursor limestones, (2) all have Sr and Fe contents similar to those of know typical supratidal sabkha evaporative finely crystalline dolostones from a well in the Ordos Basin, Shaanxi-Gansu-Ningxia provinces, China, (3) all are composed of finely crystalline euhedral-subhedral dolomite, (4) all occur on the top of reef core, reef front and back reef, (5) algal laminated structure, bird-eyes, mudcracks and crustose limonite occur in the reef front and back reef. These features indicate that this reef was once emerged at the terminal Permian. The emergence of the Changhsingian reefs at the terminal Permian might be caused by sea-level drop. This inference is in agreement with the sedimentary environmental changes in China and North Italy. The Cadore Basin in North Italy changed from a mid-shelf environment to a meteoric phreatic diagenetic environment at the end of the Permian. During the Permian-Triassic transition, the water depth of the Lower Yangtze Basin changed from more than 1000m (below the carbonate compensation depth) to less than 1000m (near the carbonate compensation depth). The sea-level drop indicated by evidence from not only reefs but also non-reef deposits might be one aspect of the mechanism that caused the mass extinction of biota at the end of Permian. - 41817 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 146, 1-4: 1-18.</SOURCE>
- 41818 <ABSTRACT>A 1m thick carbonate crust, layered and commonly domal, caps crinoidal limestones on reef complexes of the top Permian Changxing Formation in the Huaying Mountains, eastern Sichuan, China. The crust's stratigraphic level lies at a sharp change in facies, and is overlain by poorly fossiliferous laminated micrites and shales of the Lower Triassic Feixianguan Formation. The crust therefore appears to coincide with the end-Permian extinction event, although the dating of the strata is currently imprecise. The crust is composed mostly of digitate carbonate, locally thrombolitic, with remnant lobate fabric, and resembles microbialites, but is mostly recrystallised and a microbial origin is unconfirmed. It is enclosed in micrite with pyrite crystals, ostracode and other shell debris. The crust is absent from interreef areas. Previous interpretations of karstification and calcrete formation are not upheld, and the facies were deposited under water. Overlying sediments are low energy, with abundant ferroan calcite and pyrite, reflecting anoxia associated with rising sea level. Various interpretations of the crust are possible: (1) it was organic, and microbes grew preferentially on topographic highs of reef tops; (2) microbes were a disaster biota in the absence of grazers; (3) microbes took advantage of favourable conditions for calcification, associated with a rapidly rising environmental-CO₂ content during the Late Permian; (4) the crust was an inorganic precipitate associated with CO₂-rich water. Microbial crusts are rare after the Cambrian, but whether this crust is organic or not, its presence in these strata reinforces the view that oceanic-atmospheric conditions in the Permian-Triassic boundary interval were unusual. 41842 <TITLE>Deep-water hexactinellid sponge mounds from the Upper Triassic of northern Sichuan (China).</TITLE>
41843 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 76: 17-29.</SOURCE>
41844 <ABSTRACT>A belt of upper Triassic (Carnian) sponge mounds was discovered in northern Sichuan in the transition zone between a shallow shelf sea in the SE (Chuan-Dian Shelf) and a deeper marine trough (Ganzi-Aba Trough) in the NW. Individual sponge mounds are up to 60 m high and 150 m wide and interfinger laterally with dark shales. Main framebuilders of the mounds are Lychniscosa and Lyssacinosa, accompanied by (much rare) Hexactinosa, Lithistida, annelid worms, occasional crinoids and Bryozoa. The reef-dwelling fauna consists of brachiopods, ostracods, foraminifera, pelecypods, gastropods and ammonites. Typical shallow water reef builders (scleractinian corals) and calcareous algae are lacking or extremely rare (coralline sponges). This supports the interpretation of the mounds as buildups in deeper water of several tens up to one hundred meters. The sponge mounds of northern Sichuan are thus an equivalent of similar buildups of late Jurassic age in central and western Europe. They provide the first well-established record of Lychniscosa in the Triassic and their first reported pre-Tertiary occurrence outside of Europe.</ABSTRACT>

41935 <ABSTRACT>The data on the distribution, the Late Norian-Rhaetian age and the stratigraphic subdivisions of the Lokzun Group in the South-East Pamirs are given. The Lokzun Group includes four Formations: Igrimuz - with an assemblage of Late Norian (Sevastian) bivalves and cephalopods, as well as Bostanak, Jilgakochui and Gudar Formations with the diverse Rhaetian faunas. The coral assemblage assigned to the Jilgakochui Formation includes the following genera: Stylophylloopsis (1 species), Retiophyllia (2 species), Parastraeomorpha (2 species), Pamirosaris (1 species), Crassistella (2 species).</ABSTRACT>

41998 <TITLE>The Middle Triassic scleractinia-like coral Furcophyllia from the Pamir Mountains.</TITLE>
41999 <SOURCE>Acta Palaeontologica Polonica 52, 2: 401-406. <http://www.pp.pan.pl/article/item/app52-401.html></SOURCE>
42000 <ABSTRACT>Furcophyllia is an unusual coral with septa regularly splitting into branching sets called septal brooms. This pattern of septal apparatus is so alien to scleractinians, that, despite a trabecular microstructure of septa resembling that of the Scleractinia, the genus was originally ascribed to a rare group of corals informally referred to as scleractiniamorphs, previously known from the Ordovician and Permian. Genus Furcophyllia emerged together with corals of several groups, after the post-Permian crisis diversification of skeletonized anthozoans, some of them markedly differing in their skeletal features from typical Scleractinia. So far, the genus was represented by middle Carnian Furcophyllia septafindens from the Dolomites, in the Southern Alps. Here, we report Furcophyllia shaitanica sp.nov. from limestone boulders found in the volcano-clastic deposits of the upper Ladinian Shajtan suite of the South Eastern Pamirs. A new species of Furcophyllia signifies that the genus was a faunal element widely distributed in the Tethys.</ABSTRACT>

42076 <TITLE>Sponges from the lower Upper Anisian (Middle Triassic) of Bangtoupou near Qingyan, SW-China.</TITLE>
42077 <SOURCE>Muenster. Forsch. Geol. Palaont. 85: 251-271.</SOURCE>
42078 <ABSTRACT>From the lower Upper Anisian (Middle Triassic) of Bangtoupou in the vicinity of Qingyan, Guizhou Province, SW-China, three sponge taxa are described. Two taxa of large lyssacinosa sponges, Hexactinoderma? cf. roemeri (Rauff 1937) and Lyssacinosa gen. et sp. indet. A, lived on soft substrate. These fossil sponges are calcified, but in parts relics of their spicules and their spicular skeleton are preserved. One specimen of Hexactinoderma? cf. roemeri is an usual twinned sponge. Hartmanina? bangtoupouensis n.sp., a new sclerosponge species (Demospongia), on the other hand, was attached to (secondary) hard substrates. Its variable growth form largely depends on the size of the substrate. In spite of their rarity in the fossil associations preserved at Bangtoupou, sponges had some ecological importance as substrates for the attachment of other invertebrates. [original abstract]</ABSTRACT>

42104 <ABSTRACT>Additional data on the stratigraphy and the correlation of the SE Pamirian Triassic sediments have been gathered since the publication by Dronov et al. (1982). The age of the Karatash, Sarytash (Dronov & Polubotko 1988; Dagys & Dronov 1989), Aktash, Lokzun and Buryukurmes Groups and their formations (Dronov 1982; Dronov et al. 1982; Dronov & Melnikova 1985) was specified, based on the new findings of different faunas in many zones and subzones of this region. A fourth subzone of the Axial Zone (Sarygorum Subzone) has been established in addition to three previously distinguished subzones. Additional palaeontological data were contributed by many palaeontologists: foraminifers by O.A. Korchagin; sphinctozoans, hydroids and sponges by E.V. Boiko; corals by G.K. Melnikova; brachiopods by A.S. Dagys; bivalves by E.B. Payevskaya, I. V. Polubotko, Yu. S. Repin; ammonoids by A. A. Shevyrev; conodonts by A. A. Dagys.</ABSTRACT>

- 42182 <ABSTRACT>The distribution and some paleoecological peculiarities of Early Mesozoic colonial and simple Scleractinian coral development in the near-shore marginal volcanic belts and archipelago basins are observed. Changes of coral communities from the Middle Triassic (Ladinian) to the Early Jurassic (Hettangian) are discussed together with analysis of their reflections to tectonic events, sedimentation differences and temperature fluctuations on the basis of several previous studies in Primorye regions of the Russian Far East. The Coral community is compared with that of conodonts, megalodonts, sponges and some planctonic groups. Paleotemperatures calculated by Ca/Mg ratios are also given.</ABSTRACT>

- 42194 <SOURCE>Paleontologicheskii Zhurnal 1972, 2: 53-63.</SOURCE>
- 42195 <ABSTRACT>A revision of some Late Triassic and Early Jurassic representative forms of the family Stylophyllidae is based on large collections from Southeastern Pamir, Northwestern Afghanistan and Central Iran and on published literature. The independence of the genus Stylophyllopsis Frech 1890 is proved as a consequence of a study of skeletal morphology, septal microstructure and forms of habitus. The diagnosis of the ancient genera Stylophyllum and Stylophyllopsis is rendered more precise and a new genus, Phacelostylophyllum is proposed. Six species are described: Stylophyllopsis polyactis (Frech), S. bortepensis sp.nov., Stylophyllum pamiricum sp.nov., S. iranicum sp.nov., Phacelostylophyllum zitteli (Frech), Ph. karaulclyndalaensis sp.nov.</ABSTRACT>

- 42207 <SOURCE>Bulletin Nanjing Inst. Geol. Palaeont., Acad. Sinica 1989, 9: 285-307. [in Chinese, with English summary] </SOURCE>
- 42208 <ABSTRACT>Here are the supplemental notes on the Mesozoic corals from the Mts. Hengduan in Southwest China. Altogether, twenty-five species and fifteen genera of scleractinian corals (including eleven new species and one new genus) as listed below: Pinacophyllum cf. parallelum Frech, Sichuanophyllia sichuanensis (gen. et sp.nov.), S. sp., Pachysolenia ? sp., Volzeia aff. badiotica Cuif, Astraeomorpha minima sp.nov., Distichophyllia decora sp.nov., D. cf. norica Cuif, Paradistichophyllum delicatum sp.nov., P. cf. dichotomum Melnikova, Craspedophyllia spinifera sp.nov., Procyclolites elongatus sp.nov., Margarophyllia persticta sp.nov., M. aff. capitata (Muenster), M. sp., Omphalophyllia cf. gracilia (Muenster), Thamnotropis megaxis sp.nov.,

Beneckastraea medialis sp.nov., *B. ruida* sp.nov., *B. multigranulata* sp.nov., *Montlivaltia* aff. *degenensis* Deng & Zhang, M. sp. 1, M. sp. 2, *Plesiocunolites* aff. *ellipticus subcircularis* (Oppenheim), P. sp. Except the two forms of *Plesiocunolites* collected from the possible Upper Cretaceous in the Markam of eastern Xizang, all the above-stated corals were found from the Upper Triassic deposits in western Sichuan and northern Yunnan. In general respects they are similar to those of the Alps and Turkey. [part of extensive summary]

42233 <SOURCE>Courier Forschungsinstitut Senckenberg 164: 205-210. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 1]</SOURCE>

42234 <ABSTRACT>The Mesozoic and Early Cenozoic marine strata of Tibet are very rich in scleractinian corals. The fossil Scleractinia on which the present study is based include 108 genera comprising 221 species, some of which are new. The occurrences indicate strong palaeogeographical relations between the Tibetan and the other Tethyan scleractinian corals. The Triassic strata are widespread in Tibet, especially in the Hengduanshan Mts. and in the Himalayas. The marine Jurassic strata of Tibet have been well known, except for those east of the Lancang Jiang River area. The Early Cretaceous corals have been found in the area south of the Nagqu-Ngari highway and the area west of the Qinghai-Tibet highway. The marine Upper Cretaceous beds are only distributed in the Himalayan Mts. of S Tibet. The Early Tertiary (Palaeocene and Eocene) marine strata are also restricted to the Himalayas of S Tibet. The highest marine strata in Tibet are known to be of Middle Eocene age. It seems that in Tibet the history of marine sedimentation came to an end during post-Eocene time. After the Middle Eocene, the sea withdrew completely from the Himalayas, although the tremendous uplift forming

the Tibetan Plateau did not occur until the Pliocene epoch. Based on the scleractinian corals occurring in the stratigraphic sequence, 11 scleractinian assemblages of Mesozoic and Early Cenozoic from Tibet are recognized.

42245 <TITLE>Stromatoporoids and Hydrozoans from the Mt. Everest Area.</TITLE>
42246 <SOURCE>Nanking Inst. Geol. Paleont., Chinese Acad. Science.</SOURCE>
42247 <ABSTRACT>Four species of stromatoporoids belonging to three genera are recognized: Actinostromina cf. grossa (Germovsek), Actinostromaria taenia Yang and Wang, sp.nov., A. tibetensis Yang and Wang sp.nov., Stromatopora? stromatoporiforma Yang and Wang sp.nov. Five species of hydrozoans belonging to three genera are also present: Ptychochaetes cf. globosus Koechlin, Spongiomorpha robusta Yang and Wang sp.nov., Spongiomorpha (Heptastylopsis) cf. ramosa Frech, Bauneia irregularia Yang and Wu, sp.nov., B. gangbaensis Yang and Wu sp.nov. Among these the geological age of S. cf ramosa collected from Chue-Tsung-Pei Shan, Ting-Jih Hsein is Late Triassic, B. gangbaensis from Ho Shan, Gang-Ba Hsien, Eocene; the remainder of the fauna all from Hsi-Mu-Tihsien Shan, Ting Jih Hsien - although mostly new species are considered by us to be Late Jurassic because A. grossa was first described from the Upper Jurassic of Yugoslavia and P. globosus from the Upper Jurassic of Germany. Other areas of Late Jurassic strata along the Mediterranean coast, in the Middle and Far East also have stromatoporoids similar to those of the Mt Everest Area. Occurrences of the genus Spongiomorpha from several localities show its geological range to be Late Triassic to Late Jurassic. S. ramosa reported from the Alps and Alaska occurs in Late Noric rocks and the specimens reported here should come from Late Triassic or late Noric rocks. The genus Bauneia occurs commonly in Mesozoic strata. However, B. gangbaensis from Ho Shan occurs with the Eocene forams Orbitolites, Nummulites and Fasciolites indicating an age range of Mesozoic to Eocene. The geographic distribution of these fossils indicates that during Jurassic and Triassic time the Mt Everest Sea was closely related to basins in the areas mentioned above. Depositional environments and conditions support the presence of a Tethys Sea. [abstract translated and abridged by C. Fong]</ABSTRACT>

42414 <TITLE>Organogenic structures in the Upper Jurassic Carbonate rocks of southwestern Gissar. [in Russian; English translation in Lithol. miner. Resources (USA), 1974, 9, 1: 43-52] </TITLE>
42415 <SOURCE>Litol. polezn. Iskopaem. SSSR, 1974, 9, 1: 54-66.</SOURCE>
42416 <ABSTRACT>5 types of organogenic structures are distinguished: biostromes, bioherms and reefs. Biostromes (coral and sponge) are tabular bodies 15-17m thick, 5-10km long in outcrop. Bioherms are lenticular or mound-like bodies composed of massive limestones and dolomites containing numerous entire fossil shells. Reef complexes are made up of a combination of bioherms and their erosion products, differing in age, visible dimensions, nature of their relations to the enclosing rocks, assemblage of reef-building organisms, and so forth. In Middle Callovian time, shallow water conditions of marine sedimentation were dominant, with weakly differentiated submarine relief. In Late Callovian time the basin became differentiated and the Karasan reef formed, the position of which marks the facies change of the Late Callovian. Change in facies of Lower Callovian rocks takes place to the south. In Late Callovian time, the zone of reef formation shifted still farther to the south.</ABSTRACT>

42427 <TITLE>Upper Jurassic and Lower Cretaceous Scleractinia from Bangoin district of Northern Xizang (Tibet).</TITLE>
42428 <SOURCE>Mém. Nanjing Institute Geology 21: 119-174.</SOURCE>
42429 <ABSTRACT>Late Jurassic was a period of extensive reef-building, especially in the Tethys. In Xizang, there are a lot of such species as *Actinastrea ramulifera* (Etallon), *Cryptocoenia tabulata* Koby, *C. octoseptata* (Etallon), *Epistreptophyllum giganteum* Roniewicz, *E. cf. densum* Roniewicz, *Heliocoenia bandukdzeae* Babaev, *Kobyastrea tenuis* Roniewicz, *Latiastrea foulassensis* Beauvais, *Pseudocoenia decipiens* (Etallon), *P. hexaphyllia* (d'Orbigny), *Stylina parvicosta* Koby and *Stylosmilia michelini* Edwards et Haime. The fauna, as a whole, shows close affinities to those of the Late Jurassic in Portugal, France, W.Germany, Switzerland, Poland, Romania, Yugoslavia as well as the Caucasus of USSR. Thus the fossil-bearing bed may be Late Oxfordian-Early Kimmeridgian in age. * The Lower Cretaceous may be subdivided in ascending order into the Xarqung Group (Berriasian to Hauterivian) and the Bangoin Group (Barremian to Cenomanian). The corals described in this paper were collected from the lower part of Xarqung Group and the upper part of Bangoin Group respectively. Those from the Xarqung Group appear to bear, to some extent, a Jurassic aspect. Among them *Montlivaltia* continued to develop slowly, and some old forms still survived, such as *Montlivaltia* cf. *gigas* Fromentel and *M. caryophyllata* Lamouroux. Besides, a few new elements such as *Leptoria* (*Dictyophylia*) *collignoni* Alloiteau, *Placotrochus* cf. *texanus* (Vaughan), *Stylina* cf. *regularia* Fromentel, *S. parvistella* Volz, etc., are also present in this group. The latter group contains *Eohydrophora tosaensis* Yabe et Eguchi, *Blothrocycathus harrisi* Wells, *Pleurcora*

- crassa (Reuss), *Agathelia asperella* Reuss, *Preverastraea iseli* (Prever) and some new species, bearing a close relationship with those from France, Poland, Yugoslavia, Japan as well as Texas of USA. [extracted from original summary]

42506 <SOURCE>Journal of Asian Earth Sciences 19, 5: 661-667.</SOURCE>
42507 <ABSTRACT>The spatial and temporal distribution of Cretaceous coral faunas from the Tibet range is reviewed in detail. The relationship of the Tibetan faunas to other Tethyan or Caribbean faunas is discussed. Obviously the faunas had closer relationships with Tethyan faunas in Asia and Europe than with Caribbean faunas. The rather large number of new species results from a general abundance of corals in certain time spans. The paper is complemented by an appendix, which lists all formations with their localities and coral occurrences. [original abstract]</ABSTRACT>

42558 <SOURCE>Sedimentary Geology and Tethyan Geology 23, 4: 68-70. </SOURCE>
42559 <ABSTRACT>The Coqen Basin is located in the hinterland of the Qing-Xizang Plateau. Eight organic reef sections have been identified in the basin along the Qiekang-Guchang-Luobo-Dangqiongco fault zone. It is inferred, from the radiolarian siliceous rocks and volcanic rocks, that the fault zone should be a facies-controlling fault zone, where the deep-water deposits including platform-margin slope and basin deposits were once accumulated. Afterwards these deep-water deposits disappeared within the fault zone due to subsequent reactivation of faulting. The organic reefs along the both sides of the fault zone should be assigned to the platform-margin reefs. [original abstract] </ABSTRACT>

42596 <TITLE>Recent corals of Taiwan. Part I. Description of Reefs and Coral Environment. </TITLE>
42597 <SOURCE>Acta Geologica Taiwanica 19: 79-102. </SOURCE>
42598 <ABSTRACT>About 2240 distinct coralla specimens were collected from fifty-two field stations in northern and southern Taiwan coasts. A general physiographic description of the reef zone; note on current, sedimentation, and turbidity; and records of the dominant associated corals, flora, and other fauna at each collecting station were given. In general, two principal types of coral growth and development occurring in Taiwan were recognized: (a) the "fringing reefs"

- mostly developed in the southern coasts, and (b) **"**coral community **"** chiefly distributed in the northern and eastern coasts. **</ABSTRACT>**

- 42637 **<ABSTRACT>**This is the third part of a study of the Recent corals of Taiwan. In Parts I and II the reefs and other coral environments are described at 89 field stations located along the northern, eastern and southern coasts of Taiwan and at Liu-Chiu Island situated a short distance off the southwest coast. In Part III, taxonomic descriptions and keys to the genera and species and the field ecology, community structure, and distribution patterns of the shallow water hydrozoan corals in the orders Milleporina and Stylasterina are given. Eight species in the genus Millepora and one species each in the genera Stylaster, Allopora, and Distichopora are described. Special attention

- is given to describing the range of variation observed in the hydrozoan coral species, especially in respect to their ecological setting.

- 42688 <SOURCE>Earth and Planetary Science Letters 237, 3-4: 370-386.</SOURCE>
- 42689 <ABSTRACT>Coupled records of δ180 and Sr/Ca in Porites coral have

been used to derive hydrological conditions by removing the Sr/Ca-inferred temperature component from the $\delta^{18}O$ signal. Nanwan, a semi-enclosed bay in southern Taiwan, provides an opportunity to demonstrate the feasibility of quantitatively reconstruction past precipitation history. Recurrence of seawater $\delta^{18}O$ offsets between wet and dry seasons in the early 1990s is well correlated with the precipitation record. Even though the hydrological signal only accounts for 20% of the total annual coral $\delta^{18}O$ variation of ca. 1‰, offsets can be found in the residual $\delta^{18}O$ of modern corals after removing the thermal effect, which contributes to the other 80%. The observation timing and amplitude of the seasonal seawater $\delta^{18}O$ offsets in Nanwan and their correlation with precipitation are reproduced by hydrological models. In the mid-Holocene, the seasonal anomaly of residual $\delta^{18}O$ was twice of the modern value based on the 9-yr Sr/Ca- $\delta^{18}O$ data recorded in a 6.73-ka Porites coral. Hydrological models suggest an annual rainfall of 1800–3000 mm/yr at the window during mid-Holocene, 20% higher than that of the average of 30yr modern instrumental records of 1500–2500mm, consistent with the qualitative pollen record from lake sediments. The seasonal decrease of residual $\delta^{18}O$ in 5 of 9 yr was earlier than the increase of the coral Sr/Ca-inferred temperature, which implies that these rainy seasons probably occurred from the early-mid spring to midsummer, earlier than that from late spring to late summer today. The driving force may be related to the changes of solar insolation and the East Asian monsoon. It [is] cautioned that the variation of hydrographic conditions impose restrictions on a precise calculation of the amount of paleo-precipitation. The dynamic nature of local tectonics, monsoons and water circulation should be further addressed to precisely quantify precipitation over the past 10,000yr from coral geochemical records.

42700 <TITLE>Scleractinia of Taiwan (IV): Review of the Coral Genus Acropora from Taiwan.</TITLE>

42701 <SOURCE>Zoological Studies 36, 4: 288–324.</SOURCE>

42702 <ABSTRACT>The coral genus Acropora is reviewed from Taiwan for the first time. Forty species belonging to the coral genus Acropora occurring in waters of Taiwan are briefly described and illustrated. The Acropora fauna of Taiwan is seen to come from an essentially Pacific Ocean or broad Indo-Pacific fauna: all 40 species found also occur on the Pacific coast of Australia; 2 species (Acropora verweyi and A. azurea) are not found in the central Indo-Pacific (Indonesian) region, although A. verweyi is also found in the western Indian Ocean. The dominant species in the Taiwan Straits, Acropora formosa, occurs in extensive polymorphic populations, which invite further exploration of species boundaries within this species in this locality. The 40 species of Acropora herein recorded from Taiwan show an 89% similarity in species composition compared with 49 species recorded from islands in the Capricorn group of SE Australia, which is at a similar latitude south. The Acropora fauna of Taiwan is seen to be less diverse compared with 74 species recorded from Japan to the north, 67 species recorded from the Philippines to the south; 83 species recorded from Indonesia, and 51 species recorded from the South China Sea. This variation is possibly due to differences in sampling effort and species interpretation; however, differences in the areas of reef available for

- colonization, and fewer types of reef habitat within Taiwanese waters, would also imply that many species recorded from those other localities will not be found in Taiwan.</ABSTRACT>

42804 <TITLE>Heterocoral of China.</TITLE>
42805 <SOURCE>Journal Changchun Univ. Earth Sci. 25, 3: 251-300.</SOURCE>
42806 <ABSTRACT>Since 1960's, 13 genera and over 160 species have been
found and published by Chinese authors, the number of which is more

than that found by alien authors. Chinese scientists have gotten outstanding achievement in the classification, microstructure and septal evolution of the heterocoral. After we found a kind of heterocoral with 3 septa, the septal variety of the different genera and the developmental model of the septa have been clearly revealed. The heterocoral can be divided into two series, one with fossula and another without fossula. The geologic age of the heterocoral should be from the Early Devonian to the Late Carboniferous in mainland China. In our country most of the heterocoral are found at the Datang stage of Early Carboniferous and they frequently associate with the elements of the rugose coral in the Yuanophyllum zone, so the heterocoral is an important fossil group in classifying the lower Carboniferous of China.

43091 <SOURCE>Acta Palaeontologica Sinica 30, 5: 582-591.</SOURCE>
43092 <ABSTRACT>Four species (with three new ones) of Cystomichelina and three species (with one new species) and one subspecies of Protomichelina are dealt with. * In the outline of the corallum, Cystomichelina is very similar to Protomichelina, but differs in having peripheral vesicles. However, some members of the former have very rare peripheral vesicles and are almost similar to the latter, such as C. equitabulata Ting, C. multispinosa King, C. vesicata Chen & Qi, C. simplex Deng & Zhang and C. michelinoides n.sp. In the structure of peripheral vesicles and tabulae, Cystimichelina is more complex than Protomichelina. In the growth time, the former is shorter than the latter.</ABSTRACT>

43285 <TITLE>Sequence stratigraphy of the Frasnian-Famennian transitional strata: a comparison between South China and southern Belgium.</TITLE>
43286 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 123, 1-4: 289-296.</SOURCE>
43287 <ABSTRACT>The sedimentological evolution of the Frasnian-Famennian transitional strata in South China and southern Belgium has been investigated. A similar trend in the deepening and shallowing of the sedimentation environment occurs in the two palaeogeographically distinct areas. The stratigraphic succession has been subdivided into depositional sequences. A general deepening occurs in the *Palmatolepis rhenana* conodont zone. During the most rapid rise in sea level, a transgressive systems tract formed. This transgressive systems tract is followed by a highstand systems tract in the late P. rhenana zone. A major sequence boundary within the latter zone is indicated by an unconformity in intraplatform and platform areas and by a conformity in the basinal area. The uppermost sediments within the late rhenana zone correspond to a lowstand systems tract. A rapid flooding took place near the base of the *Palmatolepis linguiformis* zone and dark shales and limestones formed. A second sequence boundary coincides with or is very close to the Frasnian-Famennian boundary (base P. *triangularis* zone). The global extinction event at the Frasnian-Famennian boundary coincides with an important eustatic fall in sea level. The proposed stratigraphic subdivision should allow worldwide correlations of shallow and deep water deposits.</ABSTRACT>

43298 <TITLE>Comparative faunal content between Strunian of Etaoucun (Guanxi, South China) and the stratotype area (Etroeungt, North of France).</TITLE>
43299 <SOURCE>30th Internat. Geol. Congress, Abstract vol. 2, p. 109, Beijing.</SOURCE>
43300 <ABSTRACT>In the Etaoucun area (Guanxi, South China), a well developed and continuous section is exposed at the Devonian-Carboniferous boundary, in a platform environment context. The following formations have been sampled.- The Dongchium Formation (upper Famennian) consists of thick, bird-eyes limestone, they are azoic except in the uppermost part in which several Leperditidae Ostracod bearing beds have been observed and one reefal level recognised for the first time.- The Etaoucun Formation (uppermost Famennian = Strunian) consists of grey and dark thick bedded limestone; many reefal levels are present (with a lot of Stromatoporoids and Tabulate corals but few Rugose corals). The other groups are usually very poorly represented and slightly diversified (Brachiopods, Ostracods, …); however, Gastropods are abundant, but often very badly preserved in dolomitized beds; Foraminifera are also very common and allow some good biostratigraphical zonation.The

D/C boundary is located about two meters below the top of this formation. The lower part of the overlying Zaoyunling Formation (Lower Carboniferous), beginning with the Shanyeshan Member, mainly consists of thin bedded, dark limestones; they contain a more open marine fauna with very diversified Ostracods, few Brachiopods and also Foraminifera. This Chinese fauna is compared with the fauna of the Strunian stratotype in Etroeungt (Avesnois, North of France), where precise bed to bed sampling has been done; Except Foraminifera, which allow some correlations, the other benthic groups present very few taxa in common; this support the endemism of the Strunian faunas, already underlined by some authors. </ABSTRACT>

43324 <TITLE>Comparative Faunal Content of Strunian (Devonian) between Etaoucun (Guilin, Guangxi, South China) and the Stratotype Area (Etroeungt, Avesnois, North of France).</TITLE>
43325 <SOURCE>Proc. 30th International Geol. Congr. 12: 79-94.</SOURCE>
43326 <ABSTRACT>In the Etaoucun area, near Guilin in Guangxi (South China), a continuous section is exposed through the Devonian-Carboniferous boundary, in a platform environment. The following formations have been sampled in detail: the upper part of the Dongcun Formation (Upper Famennian), the Etaoucun Formation (Uppermost Famennian = Strunian) and the lower part of the Yaoyunling Formation, Shangyueshan Member (Lower Carboniferous). Foraminifera, stromatoporoids, tabulate and rugose corals, brachiopods, ostracods, conodonts and vertebrates micro-remains have been investigated and compared with Strunian faunas of the stratotype area (Avesnois, North of France) near Avesnes (Godin), Avesnelles and Etroeungt, where precise bed-to-bed sampling has been done. Excepting foraminifera, which allow some correlations, the benthic fossil groups present very few taxa in common; this supports the endemism of the South-China Strunian faunas already emphasized by some authors.</ABSTRACT>

43390 <SOURCE>Geol. Palaeont. Mitt. Innsbruck 17: 101-117. [in German, with English summary]</SOURCE>
43391 <ABSTRACT>From the Upper Artinskian and / or lower Kungurian of the Hunza-region (Pakistan) and the Shaksgam valley (China) coral faunas with the genera Ufimia, Paracania, Duplocarina, Yatsengia, Verbeekiella, Euryphyllum, Lophophyllidium (Lophophyllidium), Allotropiochisma (? A.) and Amandophyllum (?) are described. In addition two species of the new genus Petraphyllum are named P. hunzaianum and P. columnum. Petraphyllum is characterized by a fanlike arrangement of their septa of naos type and a septobasal columella. The genus belongs to the new family Petraphyllidae. The coral fauna shows very close similarities to the coldwater "Lytvolasma"-fauna of the Lower Permian of the Lhasa- and the Kunlun Terrane and the Permian coral faunas of the Himalaya-Timor zone, but no affinity to the Waagenophyllum-fauna of the Maokou of the Qiangtang and Lhasa Terrane of Tibet.</ABSTRACT>

43415 <TITLE>The biogeographic affinities of East Asian corals.</TITLE>
43416 <SOURCE>Mem. Geol. Soc. 12 [McKerrow W.S. & Scotese C.R. (eds): Palaeozoic Palaeogeography and Biogeography]: 175-179.</SOURCE>
43417 <ABSTRACT>In East Asia the oldest tabulate and rugose corals appeared in the Early and Middle Ordovician. All rugose corals and most tabulate corals appear to have become extinct at the end of the Permian. The Ordovician corals of North China were most closely related to the Americo-Siberian region, but those of South China occupied an independent province. The Silurian corals of Junggar, Hinggan, Mongolia, Altai and Tuva are genera characteristic of the Uralian-Cordilleran region. The South China fauna had a close affinity to that of the East Australia in the Early Silurian, but was more akin to that of the Urals and Central Asia in the Middle and Late Silurian. During the Early and Middle Devonian, there were 5 biogeographic provinces in East Asia, all belonging to the Old world Realm: (1) Arctic province; (2) Junggar-Hinggan province; (3) Uralo-Tian Shan province; (4) Palaeotethyan province and (5) South Chin province. In East Asia, two distinctive zoogeographic provinces are fairly clearly defined: a southern province, with occurrence of Kueichouphyllum and a northern province with occurrences of Gangamophyllum during the Early

- Carboniferous. In addition, during the Early Permian, an Uralo-Arctic province was dominated by Durhaminidae and a Tethyan province by Waagenophyllidae. </ABSTRACT>

- 43443 <ABSTRACT>The Devonian is widespread in East Asia and is represented by all three series. The Devonian of East Asia may be mainly differentiated into two categories: stable continental domain deposits and mobile intercontinental domain deposits. On the basis of different composition and thickness, the Devonian of East Asia may be separated into regions: Siberia; Mongolo-Sayan; Verkhoyansk-Chukotka; Taimyr; Junggar-Hinggan; Southern Tianshan; North China-Tarim; Kunlun-Qinling; Xizang (Tibet); South China; Western Yunnan-Indochina; Himalaya; and West Pacific Island Arcs. Study of the fauna permits discrimination of five paleobiogeographical provinces, all belonging to the Old World Realm. They are: Palaeotethyan; Uralo-Tianshan; Arctic; Junggar-Hinggan; and South China.</ABSTRACT>

43467 <TITLE>Early Carboniferous Chinese and Australian *Siphonodendron* (Anthozoa, Rugosa): ecological and geographical influence on taxonomy.</TITLE>
43468 <SOURCE>Geologos 14, 1: 3-17.</SOURCE>
43469 <ABSTRACT>Normal marine salinity is the main limiting factor for the subclass Rugosa. Water depth and temperature are less critical. Individual characteristics of specimens and some characteristics of species are, however, excellent environmental indicators. Being distributed exclusively by larvae, Rugosa required free distribution by means of marine currents, as well as midway areas suitable for settlement and metamorphosis of the larvae. Not distance but rather geography and midway environments are therefore the limiting factors for their distribution, relationships and stratigraphic value. *Siphonodendron* and *Siphonodendron*-like (*Siphonodendron*;) corals are discussed as examples of morphological similarity, but not necessarily representing a phylogenetic relationship. The known homeomorphy of European and western North American *Siphonodendron* taxa (Fedorowski & Bamber 2007) may be extended on the European, some southern Chinese and all south-eastern Australian *Siphonodendron*-like corals, but only the Chinese and SE Australian forms may be truly related. The latter relationship would extend the boundaries of the Early Carboniferous Australian rugose coral province. The Late Tournaisian age of the earliest Australian *Siphonodendron* indicates an ancestry of the coral fauna within the province (SE Australia and S China). A mechanism for north-westward migration of this fauna, from SE Australia to S China, is not clear.</ABSTRACT>

43480 <TITLE>Stromatoporoid-grade and other sponge fossils from the upper Krol Formation of the Lesser Himalaya (India): implications for the biotic evolution around the Precambrian-Cambrian boundary interval.</TITLE>
43481 <SOURCE>Facies 49, 1: 351-372.</SOURCE>
43482 <ABSTRACT>A study of fossils in thin sections of a sample from the uppermost Krol E Member in the Mussoorie Hills of the Lesser Himalaya, India, proves the existence of morphologically differentiated calcified sponges within the Precambrian-Cambrian boundary time interval. The sponges described as *Mussooriella kroli* n.gen. n.sp. and *Maldeotainia composita* n.gen. n.sp. indicate the presence of different organization grades at the Precambrian-Cambrian interval. *Mussooriella* had a calcareous skeleton consisting of skeletal elements composed of an inner laminated part and a distinct peripheral layer with knobs. *Maldeotainia* is characterized by a stromatoporoid-grade growth pattern following a thalamid-grade pattern. The stromatoporoid grade part of the skeleton is very similar to skeletal elements common in labechiid Ordovician and younger stromatoporoids. *Maldeotainia* also shows criteria of Early Cambrian fossils originally described as stromatoporoids and later excluded from this group and transferred to archaeocyathids. These similarities point to an Early Cambrian age of

- the fossil - bearing horizon in the topmost Krol E member. Growth cavities within crypts indicate that the sponges might have contributed to the formation of small metazoan reef-like structures. Although the study is based on limited material, and many interpretations are still tentative, a thorough documentation of the preliminary results seems reliable considering the high potential of fossils of the upper Krol Formation as an important source in the understanding of early metazoan differentiation. 43506 <TITLE>Glimpses into fossil assemblages of Thailand: Coral perspectives.</TITLE>
43507 <SOURCE>Bulletin of Siam Society of Natural History 51, 1: 37-67.</SOURCE>
43508 <ABSTRACT>Fossil corals are widespread in Thailand. They belong to many geological intervals, from Ordovician to Quarternary. They have been studied actively during the last 20 years. They are better known, even though some research still needs to be carried out; for instances, Triassic corals, which occur in abundance at many localities of Thailand, remain inadequately known. Carboniferous, Permian and Triassic corals are widespread in Thailand. Devonian and Jurassic corals are in abundance in restricted areas. Ordovician and Silurian corals are rare and remain poorly known. Cretaceous corals are completely absent. In Thailand, the study of corals is the study of long history. One can observe living corals as well as many groups of fossil corals. Corals provide important information on past environments and help to reconstruct paleogeography; they also provide information on the ages of the rocks in which they are included. In this paper, two Devonian localities are mentioned for the first time; they were discovered in January 2002. [original abstract] </ABSTRACT>

- 43519 <TITLE>Fossil diversity in limestones of Thailand: a cornucopia of information about the history of life.</TITLE>
43520 <SOURCE>Siam Society Natural History, Bulletin 53, 1: 33-70.</SOURCE>
43521 <ABSTRACT>In Thailand, fossils are common and diverse. They come from both terrestrial and marine environments. They belong to many time periods beginning with the Cambrian, thus spanning more than 500 million years (the Phanerozoic eon). This rich past emerges from extensive published data and is still very interesting to explore. This publication concerns only fossils included in limestones deposited in the seas of the past. Limestone is widespread in Thailand and of various ages. Marine floras (algae) and faunas are in abundance at many limestone exposures and their skeletons are an important component of the limestone. They give deep-time perspective on the evolution of the life in the seas of the past. The limestones of Thailand are not restricted to the widespread visible on the land. They have been found by hydrocarbon exploration at varied depths and in different areas. Permian limestone has been reached by wells under the Khorat Plateau and its extent has been determined by seismic interpretation; it is widespread (for instance, see Mouret, 1994). This publication is concerned only with limestones exposed at ground surface. Limestone is a general term for diverse types of rocks, deposited in different environments. Before describing their biodiversity, we discuss the origin of the limestones of Thailand.</ABSTRACT>

43532 <TITLE>Siliceous sponge spicules in the Early Cambrian chert-phosphorite member of the Lower Tal Formation, Krol belt, Lesser Himalaya.</TITLE>
43533 <SOURCE>Geology 26, 10: 899-902.</SOURCE>
43534 <ABSTRACT>we present the first record of siliceous hexactinellid and demosponge (?) spicules from lower Tommotian chert and phosphorite of the Lower Tal Formation of the Mussoorie and Garhwal synclines in the Lesser Himalaya. Spicules include cross-shaped as well as single-rayed forms, and occur sporadically in a chert or phosphatic groundmass. Scanty records of siliceous sponge spicules in the Proterozoic sedimentary rocks and their abundance and rapid proliferation during the Early Cambrian are interpreted as a result of major change in seawater chemistry due to enhanced availability of nutrients, leading to progressive evolution of siliceous biological forms and phosphatic shelly faunas.</ABSTRACT>

43558 <TITLE>Palaeontology of Malaysia: Palaeozoic corals.</TITLE>
43559 <SOURCE>FC&P 27, 2: 37-40.</SOURCE>
43560 <ABSTRACT>Very rare solitary corals have been noticed in the Terbat Limestone of Sarawak (Carboniferous and Permian). They have never been studied. They are the only Palaeozoic corals seen in East Malaysia (Sarawak and Sabah). On the contrary, corals younger than the Palaeozoic are known in East Malaysia and Jurassic corals are in abundance in the Bau Limestone of Sarawak. * All the published results mentioning Palaeozoic corals concern West Malaysia (=Peninsular Malaysia). They range from Permian down to Ordovician. However, Devonian, Silurian and Ordovician corals commonly have been collected in small quantity or have been found in a poor state of preservation; they have been the subject of few studies. </TITLE>
- 43637 <SOURCE>x + 375 pp., Bangkok.</SOURCE>
- 43638 <ABSTRACT>Contrary to the idea that oil and gas could be found only in Tertiary basins throughout most of East Asia, CCOP [Coordinating Committee for Geoscience Programmes in East and Southeast Asia] decided in 1973 to investigate the pre-Tertiary series which had already generated some interest in China and which were rather incompletely known in large areas of the CCOP region. Accordingly, it included in its programme of work a critical review of the current knowledge on the pre-Tertiary oil and gas potential of East Asia. In 1974, A. Bonnet started the CCOP pre-Tertiary Programme; his work is continued by H. Fontaine. Very rapidly, interesting results on stratigraphy were obtained in areas easily accessible and previously investigated by geologists. The sedimentary rocks of these areas contained few macrofossils, and for example, Carboniferous microfossils, were poorly known and difficult to study in the past. Hence, the first fieldwork led to many new palaeontological and stratigraphical discoveries, especially in remote areas. Ten years of geological research with CCOP is indeed an adventure. Many fossils have been discovered and provided new data to stratigraphy and paleogeography. Results of the studies have been published regularly, giving the impression of plainly logical development of knowledge. [review by Kl. Oekentorp] Almost every article in this book refers to fossil corals and related groups. In the following - however - only the most important articles are mentioned here, this means only those dealing with systematic aspects.</ABSTRACT>

43742 <ABSTRACT>A form of pentamerid brachiopod denoting the Late Silurian age and some corals are recorded from the upper part of the "Muth Quartzite" in Kiogad valley of Garhwal Himalaya. This finding implies that, in spite of previous assignment of the Muth Quartzite as of exclusively Devonian, it is a lithostratigraphic unit of largely Silurian age.</ABSTRACT>

43754 <SOURCE>Facies 15: 35-52.</SOURCE>
43755 <ABSTRACT>The silurian sequence in Spiti and Kinnaur was studied at Takche, Gechang, Muth-Shian, Leo and Manchap. At all these localities the sequence commences with an intertidal - near-shore argillo-arenaceous succession. The overlying part at Takche comprises arenaceous dolomite, calcareous sandstone and dolomite. It sporadically contains rugose and tabulate corals deposited in a shallow undathem near the shore. The succession at Gechang is more calcareous and in some parts rich in corals; stromatoporoids occur locally. Here bioclastic wacke/packstones and framestones formed a buildup which was possibly formed in a lagoon. The Muth-Shian area is characterized by bioclastic mudstones, bioclastic wacke/packstones and framestones. Reef builders are corals, stromatoporoids and solenoporoids. These sediments seen to be lateral equivalent of the coastal arenaceous sequence exposed at Baldar and may represent a fringe reef.</ABSTRACT>

43766 <TITLE>Middle Palaeozoic corals from the southern slope of the Central Ranges of Irian Jaya, Indonesia.</TITLE>
43767 <SOURCE>Alcheringa 19: 1-15.</SOURCE>
43768 <ABSTRACT>Rugose and tabulate corals of Frasnian (early Late Devonian) and pre-Frasnian Devonian and Silurian(?) ages from Irian Jaya (western New Guinea), Indonesia, are described and illustrated for the the first time. The Frasnian corals are the most important; they occur in the uppermost part of the Modio Formation (redefined), are well-preserved and suggest a biogeographic linkage to Western Australia. The source carbonates may represent a reef environment. The pre-Frasnian corals are from stream cobbles at two localities. They indicate the presence or former presence of a more complete Middle Palaeozoic sequence than was previously known in Irian Jaya.</ABSTRACT>

43779 <TITLE>Late Devonian (Frasnian) corals from central Dolpo, Nepal.</TITLE>
43780 <SOURCE>Rivista Italiana di Paleontologia e Stratigrafia 99, 1: 3-26.</SOURCE>
43781 <ABSTRACT>Rugosa and Tabulata from the Late Devonian of central Dolpo (Nepal) belong to the genera Kuangxiastraea, Scruttonia, Sinodisphyllum, Tabulophyllum (?), Fruehwirthia gen. n., Thamnopora, Cladopora, Alveolites and Alveolitella. The calcarenitic beds yielding the fossils are overlain by a prominent oolitic ironstone with thick ferruginous nodules and crusts. The age of the corals is probably Early Frasnian, thus younger than the Givetian fauna previously reported from eastern Dolpo. Biogeographic relations of the new fauna are with Western Europe and South China.</ABSTRACT>

43792 <TITLE>Devonian rugose corals from the Karakorum Mountains (Northern Pakistan).</TITLE>
43793 <SOURCE>Rivista Italiana di Paleontologia e Stratigrafia 110, 3: 605-641.</SOURCE>
43794 <ABSTRACT>The Karakorum Block is regarded as a microplate of " Gondwanan" origin and was part of the Cimmerian continent (" Mega Lhasa";) which rifted away from the northern margin of Gondwana during the Late Palaeozoic/Early Mesozoic. From the Northern Karakorum Range (Yarkhun and Karambar River Valleys: structurally belonging to the Northern Sedimentary Belt) an Upper Givetian to Lower Frasnian rugose coral fauna of the Shogram Formation is described. The fauna is dominated by cosmopolitan genera such as Hexagonaria, Disphyllum,

Macgeea and the Temnophyllum/Spinophyllum group, generally showing a geographically wide distribution, although being absent from the Eastern Americas Realm in the Upper Givetian/Lower Frasnian. Therefore its components are of little use for biogeographical deductions at sub-realm level, and in explaining the relation between the Karakorum Range and other Cimmerian crustal blocks. A remarkable exception is the first record of the genus Pseudopexiphyllum outside of Turkey, indicating a connection to the western part of the Cimmerides. On species level, the coral fauna of the Shogram Formation is characterized by the development of a diverse and rather unique fauna including about 35 taxa, that differs from the faunas known from neighbouring crustal blocks. So far, faunistic links to the Central Iranian Microcontinent (Yazd-, and Tabas-Block), the northwest Iranian Plate (Elburz), Central Pamir, the Lhasa Block and western Qiangtang are not clear, and although each of these fragments are believed to be closely connected they were apparently not in direct contact during the Devonian. However, the Karakorum fauna is remarkably close to one known from the Helmand Block in Afghanistan, showing a very similar generic composition that includes numerous morphologically closely related, although not identical species. Accordingly, the restricted faunal exchange led to the development of new taxa. Distribution of the new species of Spinophyllum, Pseudopexiphyllum and Pseudozaphrentis is limited to the Karakorum Mountains. Reasons for this individual faunistic development and the missing faunal exchange are unexplained, but suggest that some kind of active faunal barrier must have existed during the Devonian, which led to the development of the specific Karakorum fauna. With the exception of Phillipsastrea orientalis Smith, 1930, which is elsewhere only known from the Burmese Devonian, the occurrence of some other species suggest a connection to regions which are regarded as biogeographically unrelated. A weak relation to central European faunas is indicated by the occurrence of characteristic species of Macgeea and Hexagonaria known from the Ardennes and the Holy Cross Mountains. More unusual are the faunistic affinities to the Altai-Sayan region shown by the surprising occurrences of species of Spinophyllum and siphonophrentid corals morphologically very close to those known from the Altai Mtns. and Kazakhstan. </ABSTRACT>

 43819 <SOURCE>Journal of Geology [Viet Nam], Series B, 22: 19-30.</SOURCE>
 43820 <ABSTRACT>The stratigraphy of Givetian, Frasnian and Famennian beds in

Vietnam is reviewed and the macrofossils in each of the stages are listed. Of stromatoporoids, 22 genera are reported from Givetian beds, 12 from Lower and Middle Frasnian beds and 6 genera from uppermost Famennian beds. The F/F boundary is drawn in 3 typical sections on the disappearance of several groups of macrofossils, including the stromatoporoids, and the appearance of Famennian conodonts and forams.

- 43871 <SOURCE>Geologos 1: 19-67.</SOURCE>
- 43872 <ABSTRACT>Upper Fammenian and Tournaisian deposits are present in the eastern, northern and western parts of North Viet Nam and in the northern part of Central Viet Nam. Argillaceous and siliceous limestones are predominant lithologies. Transitional deposits of Devonian / Carboniferous age represented by the Halong, Toctat, Bancai, Phongnha and Sebanghieng Formations. The Rugosa from Halong, Phongnha and Sebanghieng Formations have not previously been described. This is an endemic fauna, similar in some ways to the deep-water fauna from the Shaodong Formation of southern China. The Rugosa from the Chernyshinella Zone (Upper Tournaisian) are also described here. Two new genera: Fedorowskia and Cobaiphyllum, both from the Quasiendothyra Zone have been recognized. Cystophrentis, which is very common in Viet Nam, is present in the Halong and Sebanghieng Formations. Dematophyllum is typical of the Chernyshinella-Dainella Zones. Two Rugosa Assemblage Zones: Cystophrentis-Cobaiphyllum Ass. Zone (Middle Fammenian to Early Tournaisian) and the Pseudouralina-Fedorowskia Ass. Zone (Middle and Late Tournaisian) have also been determined.</ABSTRACT>

- 43885 <ABSTRACT>Diverse fossils of Devonian and Lower Carboniferous age have been found in the Ba Na Klang area in Loei Province, Northeast Thailand, in limestones previously mapped as Permian. The undescribed Devonian fauna consists of reefal corals and stromatoporoids. The Upper Visean - Serpuhkovian coral fauna consists of Syringopora, Chaetetipora, Rotiphyllum, Kueichowphyllum, Arachnolasma, Lithostrotion, Solenodendron, Aulokoninckophyllum, Lansdaleia, Heterophyllia and Hexaphyllia. It is associated with foraminifera, fenestellids, brachiopods and crinoids.</ABSTRACT>

</SOURCE>
- 43950 <ABSTRACT>In the Ban Na Duang area of Loei Province, Northeast Thailand, new Middle-Upper Carboniferous localities have been discovered. They have yielded coral assemblages consisting of Rugosa (Lublinophyllum, Caninia, Caninophyllum, Ivanovia) and Tabulata (Multithecopora, Chaetetes). These corals belong mainly to Moscovian. Higher up, only few corals are Kasimovian and Gshelian in age. Genus Ivanovia, rarely found in Thailand in the past and unknown in other countries of South East Asia, is reported at a locality near Ban Na Duang. Middle-Upper Carboniferous and Permian strata were deposited continuously, apparently without stratigraphic gap at the boundary between Carboniferous and Permian.</ABSTRACT>

- 43963 <ABSTRACT>Carboniferous fossils have been collected from limestone lenses which intercalated with basic to intermediate volcanoclastic sediments in an area of central Thailand east of Lam Narai. They consist of calcispherids, algae, foraminifers and corals; they mainly indicate a Late Moscovian (Miatchkovian) age, locally extending to early Kasimovian. They bring interesting new information showing that the stratigraphic range of the sedimentary rocks of that area extends in continuity from Middle Carboniferous to the top of Middle Permian. [original summary; the taxa are: an undetermined Micheliniiid genus, Multithecopora sp., Caninia sp., Bothrophyllum aff. conicum Trautschold 1879, Bothrophyllum sp., Amygdalophyllum sp., and Petalaxis siamensis Fontaine, 1994]</ABSTRACT>

- 43976 <ABSTRACT>Since 1980, many Carboniferous localities have been found in Northeast Thailand (Northeast of Loei and southwest of Phetchabun); some of them have yielded corals. In 1988 and 1989, new Carboniferous sections have been discovered as well as new scattered outcrops, especially in the new area west of Phetchabun (Noen Maprang area). A summary of our knowledge on the Carboniferous corals of Thailand will show that several different coral assemblages have been indentified. This result is important because Carboniferous corals, which were almost unknown in Thailand ten years ago, indicate the presence of a

- shelf with shallow and warm sea water around the Khorat Plateau during the whole Carboniferous. Elsewhere in Thailand, no Carboniferous coral has been found yet. </ABSTRACT>

- 44015 <ABSTRACT>A new research is currently carried out on the poorly known Carboniferous of East Thailand. A diverse coral assemblage has been found for the first time; it is described in this paper and consists of Tabulata, solitary (Kueichouphyllum ?) and compound (Siphonodendron and

Solenodendron) Rugosa as well as abundant Heterocorallia (Hexaphyllia). It belongs to the Upper Viséan and may extend to the Serpukhovian. It is associated with a rich fauna. A warm climate is suggested. The presence of these corals and the large development of limestone do not fit with the former attribution of the Carboniferous of East Thailand to the Kaeng Krachan Formation.</ABSTRACT>

44065 <TITLE>The Bashkirian "Fenestella Shales" and the Moscovian
"Chaetetid shales" of the Tethys Himalaya (S Tibet, Nepal,
India).</TITLE>
44066 <SOURCE>Journal of Asian Earth Sciences 16, 2-3: 119-141.</SOURCE>
44067 <ABSTRACT>The "Fenestella shales" are a mid-Carboniferous
marker unit which has long been described from classic localities of
the NW Himalaya (Kashmir, Spiti). Correlative shaly units have recently
been traced in central Nepal and as far as South Tibet, where they
yielded varied brachiopod assemblages indicative of Bashkirian age. * A
second distinct interval of black shales, characterized by the
abundance of chaetetids and directly underlying the widespread
Gondwanan diamictites, has been dated as Moscovian in Spiti and
represents the youngest fossiliferous horizon hitherto identified in
the Upper Carboniferous of the Tethys Himalaya. The "Chaetetid
shales" are recognized also in Manang, whereas in South Tibet the
stratigraphic framework still needs improved definition. These major
fossiliferous black shale units, marking repeated transgressive events
in the middle part of the Himalayan rift sequence, have not only major
stratigraphic significance but also represent a fundamental landmark in
palaeogeographic and palaeoclimatic reconstructions of Northern
Gondwana. With the onset of continental rifting, arid tropical climates
at the close of the Tournaisian were replaced by temperate humid
conditions in the Visean-Serpukhovian, when diamictites were deposited
in South Tibet. After this first cooling stage, the "Fenestella
shales" mark a widespread transgression at the very beginning of
the Late Carboniferous, coupled with reduced tectonic activity and
temperate to temperate-warm climates. After renewed tectonic activity
during a second cooling episode, marked by local deposition of
diamictites in central Nepal, the "Chaetetid shales" represent
another major transgression in the Moscovian, shortly preceding the
final and most intense cooling event marked by deposition of
glacio-marine diamictites in the whole Tethys Himalaya from Kashmir to
South Tibet during the latest Carboniferous / earliest Permian. Two
fossiliferous horizons containing very similar brachiopod faunas of
early Late Carboniferous age have recently been found also in North
Karakorum, at lower southern latitudes, where climatic conditions
always remained temperate and there is no trace of Upper Palaeozoic
glacial deposits or ice-rafted debris. [original abstract]</ABSTRACT>

44104 <TITLE>Carboniferous corals from the Kuantan area, Peninsula Malaysia, and associated microfauna: peculiar faunas for Southeast Asia and puzzling faunas for stratigraphy.</TITLE>
44105 <SOURCE>Minerals and Geoscience Department Malaysia, Technical Papers 2: 69-99.</SOURCE>
44106 <ABSTRACT>In Malaysia, Carboniferous corals are few in number; usually scattered in the sediments and commonly represented by assemblages, which are not rich and diverse. The corals are commonly reworked; broken specimens and small fragments prevail. They do not build reefs at all. In contrary to other areas, the Kuantan area is relatively rich in corals. A peculiar Carboniferous coral fauna collected from four limestone hills i.e. Bukit Tenggek, Bukit Sagu, Bukit Charas and Bukit Panching in the Kuantan area has been studied. Systematic descriptions are given for the selected corals. In order to give better information on stratigraphy, associated algae and foraminifera have also been identified. The Kuantan fauna is not very diverse, but it is very interesting, even from an international point of view, because it belongs to the boundary between Lower and Middle Carboniferous, to a horizon of contention. Hexaphyllia is common, at least locally. Other corals belong to Fomichevella, Amygdalophyllum, Dibunophyllum and Axophyllum; such a fauna has not been found so far in other parts of Southeast Asia. Among the foraminifera, the important taxa are Howchinia, Monotaxinoides, Bradyina cribrostomata, Eastaffella mosquensis, Janichewskina and Archaediscus karreri.</ABSTRACT>

44182 <TITLE>The Carboniferous of Northeast Thailand. A review with new data.</TITLE>
44183 <SOURCE>J. Southeast Asian Earth Sci. 12, 1/2: 1-7.</SOURCE>
44184 <ABSTRACT>A synthesis is provided of the many papers published on the Carboniferous of northeast Thailand since 1960, which have been restricted to localities north of latitude 17°10'039"N. In addition, new data are provided on Carboniferous localities recently discovered south of latitude 17°10'039"N. All stages of the Carboniferous are represented in northeast Thailand and their exposures are delimited in this paper. In northeast Thailand Carboniferous rocks are widely exposed in an area where Loei and Wang Saphung are the main towns, an area 20-40km wide and 140km long. In parts of this area, they are overlain by Permian strata (mainly limestone) in the core of a syncline. Middle-Upper Devonian limestone, shale and chert occur occasionally in the central and northern parts of the area. They are less widely distributed than the Carboniferous rocks but are obvious features because the limestone forms karstic hills and the chert outcrops are prominent. An important development of shale during the Middle-Upper Carboniferous has favoured differential erosion so that today these rocks are distributed commonly in flat areas with paddy fields; the shale concealed under a few meters of earth. Their discovery has been due to farmers digging ponds at several places.

- 44210 <ABSTRACT>In 1996 for the first time, Carboniferous microfossils were discovered in east Thailand, at a single limestone locality. In 1997, another locality of the same area yielded Early Carboniferous corals. Because of these two discoveries, a systematic search for microfossils has been carried out in all the limestone exposures at that area. Microfossils have been found almost everywhere; they are rare to common. The fossils and the facies focus on an age ranging from Late Viséan to Bashkirian. - 44223 <ABSTRACT>Permian corals, representing 3 typical Tethyan genera (Protomichelinia, Iranophyllum and Ipciphyllum) are described from the Shyok Melange, near Shigar, Baltistan. The Carboniferous corals Pseudazaphrentoides, Pseudotimania, Arachnolasma and Bothrophyllum (?), and a Devonian Ceratophyllum are also described from a Devonian-Carboniferous sequence developed near Tanze, Zanskar Region. These fossils form the first records of Late Palaeozoic corals from the above-mentioned regions of the Himalayas. The Permian corals are of Chihshian to Maokouan age. The Carboniferous are of late Viséan or early Namurian age, and the Devonian representative is of Famennian age.</ABSTRACT>

44261 <SOURCE>Bulletin geological Society of Malaysia 19: 183-191.</SOURCE>
44262 <ABSTRACT>Lower Permian corals (Protomichelina, Kepingophyllum, Chusenophyllum? and Polythecalis) are for the first time recorded from Sumatra. These corals are associated with fusulinids indicative of the Middle-Late Asselian, Pseudoschwagerina Zone. Lower Permian sediments appear to be widely developed in the upper Mesumai River area and appear to represent a forested volcanic arc surrounded by a shallow muddy sea. (Original summary)</ABSTRACT>

44286 <TITLE>Permian corals of peninsular Thailand and other associated fossils.</TITLE>
44287 <SOURCE>CCOP Newsletter 26, 3 & 4: 14-19.</SOURCE>
44288 <ABSTRACT>[The Permian limestones of Peninsular Thailand range in age from the upper Lower Permian to Dzhulfian (wuchiapingian). They are poor in many kinds of fossils at their base. Diverse fossils with corals become quite widespread at their top, especially in Murgabian-Midian horizons. In this conclusion, the corals are taken into account as well as the associated fossils for the sake of certainty and clarity. All the fossils focus on the same facts, which are important for paleogeography.1. Tabulata are widespread, but belong only to Sinopora at many localities. Rugosa are more interesting, but they are not actually diverse, even in younger Permian beds where they may be in abundance to a certain extent. They do not build reefs but are scattered. They do not include the well known genera of Central and Northeastern Thailand such as Ipciphyllum or Pseudohunagia. On the other hand, Paraipcyphyllum is a common genus of Peninsular Thailand whereas it is rare elsewhere in Thailand. This genus had been described for the first time in China (Wu, 1963).]</ABSTRACT>

44390 <TITLE>Permian corals from Chom Bung area west of Bangkok: Their paleogeographic significance.</TITLE>
44391 <SOURCE>CCOP Newsletter 20, 3-4: 23-26.</SOURCE>
44392 <ABSTRACT>The Permian corals found in Chom Bung area belong to an aberrant fauna when compared to those of central and eastern Thailand. They are similar to other faunas known to the south in Peninsular Thailand. Chom Bung is 115 km westsouthwest of Bangkok as the crow flies and this town belongs to the extreme north of Peninsular Thailand. It is surrounded by a flat land where limestone hills are scattered. Limestone is bedded and massive, commonly dolomitised. It belongs to the "Ratburi Limestone" as shown by the following study of the corals. In the past, it yielded a few Murghabian foraminifers at Khao Chom Phon, a hill within the town of Chom Bung (Fontaine and Suteethorn 1988, p. 34-35). Recently, much more abundant fossils (foraminifers, Tabulata, solitary and massive Rugosa, bryozoans, brachiopods, gastropods and crinoids) have been found at other hills 5 to 10 km from Chom Bung: Khao Lan 5.5 km to the south, Khao Pak Kwang 10 km to the northeast, and Khao Kwak 9 km to north-northeast. The fauna is very interesting because of strong affinities with the fossils found to the south in Peninsular Thailand which is part of a distinctive biogeographic unit (Fontaine et al. 1994). It is different from the faunas known in central, eastern and northeastern Thailand.</ABSTRACT>

44403 <TITLE>Permian corals of Southeast Asia and the bearing of a recent discovery of Lower Permian corals in northeast Thailand.</TITLE>
44404 <SOURCE>National Conference on Geologic Resources of Thailand: Potential for Future Development: 346-354.</SOURCE>
44405 <ABSTRACT>Permian corals have been mentioned in many papers concerning the geology of Southeast Asia; they are much more diverse and prolific than what is known in Australia during Permian. Even Timor or

- Peninsular Thailand where coral faunas are somewhat restricted are richer than Australia. Accordingly, the impression may be that coral reefs are common and geographically widespread in Southeast Asia from bottom to top of Permian sections. This is not actually correct although not entirely wrong. The aim of this paper is to access what we currently know. Lower Permian corals have been poorly known in Southeast Asia up to now. Therefore, the recent discovery of these corals in northeast Thailand is an important result which cannot be ignored by this paper.</ABSTRACT>

- 44417 <SOURCE>[journal?] The International Conference on Stratigraphy and Tectonic Evolution of Southeast Asia and the South Pacific Bangkok, 19-24 August, Thailand.</SOURCE>
- 44418 <ABSTRACT>Permian limestones are common in a large area of East Thailand near the Cambodian border; they are studied in this paper. They are clearly divided into two areas where they show different ages: Roadian with *Cancellina* and *Neoschwagerina simplex* (= Kubergandian-Early Murgabian) to the west and Capitanian with *Yabeina* and *Lepidolina* (= Midian) to the east. Corals are in abundance in the Capitanian limestones; they consist of rare *Tabulata* (*Sinopora*), solitary *Rugosa* (*Tachylasma*, *Khmerophyllum* *Lophocarinophyllum*, *Paracaninia*), fasciculate and massive *Rugosa* (*Waagenophyllum* and *Multimurinus*). They are described in this paper and a new species is established: *Multimurinus makkaensis*. These corals from east Thailand as well as those previously found in west Cambodia are clearly different from the corals collected from the Murgabian (sensu Leven 1981) of central Thailand and of other areas of Southeast Asia. They raise the problem of the Murgabian-Midian boundary and more generally of the Permian division.</ABSTRACT>

44443 <SOURCE>CCOP Technical Bulletin 24: i-vi + 1-171, 19 figs., 3 tabs., 31 pls.</SOURCE>
44444 <ABSTRACT>Permian corals are present at many localities distributed all over Thailand. They are locally prolific and diverse. Accordingly, they are very important fossils of this country. Even though their number has fluctuated with time, they are found in beds ranging from Early to Late Permian. Their assemblages change with depositional environment. In quiet and confined environments, assemblages are poor and restricted to solitary Rugosa without dissepiments. In more favourable environments, assemblages are luxuriant with high diversity. Moreover, Permian corals clearly show two biogeographic provinces. In Peninsular Thailand, they are different from those of central Thailand; they share this characteristic with fusulinids. A halt to the dispersal of many corals and fusulinids into Peninsular Thailand is obvious. In Thailand, Permian corals went on the wane a long time before the closure of Permian; their decline was rapid during Late Permian. They are no more diverse in Dzhulfian limestones and are poorly known in Dorashamian limestones. In the past, Permian limestones of Thailand were called "Ratburi Limestone" (Brown et al. 1951) or were included in "Ratburi Group" (Javanaphet 1969 in the Geological Map of Thailand of scale 1:1,000,000). No type section was designated. Bunopas (1981) limited the "Ratburi Group" to limestone and interbedded shale exposed in Peninsular Thailand; he proposed several names for other Permian limestones, with an important name: "Saraburi Limestone" for the limestone exposures of central Thailand and Loei-Wang Saphung-Pha Nok Khao region. Local names for different limestone outcrops will be discussed in the next chapter. Recent studies show that the Ratburi Limestone of Peninsular Thailand is actually Permian and Triassic in age (Fontaine et al. 1993). Saraburi Limestone is restricted to Permian. Accordingly, Ratburi Limestone and Saraburi Limestone belong to two different paleogeographic units as indicated by their coral and fusulinid assemblages as well as by their stratigraphic ranges (Fontaine et al. 1992 and 1993). [part of introduction].</ABSTRACT>

44494 <TITLE>The Permian of Khao Tham Yai area in Northeast Thailand.</TITLE>
44495 <SOURCE>The Symposium on Geology of Thailand, 26-31 August 2002,
Bangkok: 58-76.</SOURCE>
44496 <ABSTRACT>A very fossiliferous limestone is exposed at Khao Tham Yai;
it is thick and ranges from Murghabian to the top of the Midian.
Fossils are diverse and in abundance. The fusulinacean genus *Lepidolina*
occurs at the top of the limestones; it has a palaeogeographic meaning.
Photographs of the main fossils are provided in this paper [including
Ipciphyllum subelegans Minato & Kato, *I. phadaengense* Fontaine,
1992, *Multimurinus fontainei* Kato & Ezaki, 1986, *M. cf. frechi*
Volz, *M. sp.*]. In the valley east of Khao Tham Yai, a clastic sequence
with predominant scale has yielded recently some fusulinaceans. Farther
to the east, Khao Pa Khi limestone is very poor in fossils; its age was
doubtful because of an apparent absence of fusulinaceans. Other samples
have been collected recently; they bring new information suggesting a
Permian age, but still with a slight doubt. The occurrence of a fault
appears probable between Khao Tham Yai and Khao Pa Khi. South of the
Khao Tham Yai - Khao Pa Khi area along the Lomsak - Chumphae Highway,
other limestone outcrops contain characteristic fossils, in particular
common *Codonfusiella*. [original abstract, but included coral taxa]

44560 <SOURCE>C. R. Acad. Sci. Paris 287, D: 13-16.</SOURCE>
44561 <ABSTRACT>L'examen de lames ultra-minces d'une forme permienne attribuable à Cladochonus crassus (McCoy) a révélé l'existence dans la partie médiane de la muraille d'une couche de lamelles en zig-zag, entourée de deux couches de nature fibreuse. Ces lamelles onduleuses, à limites cupuliformes, sont identiques à celles reconnues chez le Tétracoralliaire Plerophyllum, également du Permien. La microstructure des Cladochonides du Carbonifère a été décrite comme finalement feuilletée, sans doute constituée de lamelles rectilignes, parallèles aux bords des structures. De ce fait, le matériel permien devra être rapporté à une unité générique différente de Cladochonus sensu stricto.</ABSTRACT>

44598 <TITLE>Permian of Southeast Asia: an overview.</TITLE>
44599 <SOURCE>Journal of Asian Earth Sciences 20, 6: 567-588.</SOURCE>
44600 <ABSTRACT>Permian rocks are widely distributed throughout Southeast

Asia. Because of the tropic-equatorial climate the rocks are commonly deeply weathered and covered by dense vegetation over much of the region. Elsewhere, Permian rocks are well exposed and easy to access, particularly where limestone outcrops have weathered to form spectacular, castellated, tower karst. Many limestone outcrops, containing abundant fusulinaceans, were early recognized to be of Permian age, but many outcrops without fusulinaceans, erroneously assigned to the Permian, were found subsequently to be of Triassic age, and more careful studies have established the Permian age of rocks of other lithologies. It is now recognized that different depositional environments are represented by the Permian deposits in various parts of the region. Massive limestones, widespread throughout the region, represent extensive carbonate platforms; local occurrences of thick bedded cherts indicate deposition in deep marine environment, coal, bauxite and clastic sediments with vertebrate remains in the North Vietnam and Laos indicate deposition in a continental environment, and pebbly mudstones in Myanmar, Peninsular Thailand, northwest Malaysia and Sumatra, are considered to have been formed in a glacial environment. Volcanic rocks are absent in northwest Peninsular Malaysia and Peninsular Thailand, but are extensively developed in North Vietnam, Sumatra, the eastern Malay Peninsula and Timor. Fossils, representing many fossil groups, are often prolific in Permian sediments, with fusulinaceans, for example, occurring in astronomical numbers in many limestone outcrops. Age-diagnostic fossils demonstrate that the whole of Permian is represented in different areas of Southeast Asia. Fossil faunal and floral assemblages have been used to establish climatic and environments of deposition, to define distinct crustal blocks and to provide the basis for reconstructing the palaeogeography during Permian times. 44611 <TITLE>Permian fossils recently collected from limestones of Nan area, North Thailand.</TITLE>

44612 <SOURCE>The Symposium on Geology of Thailand, 26-31 August 2002, Bangkok: 46-57.</SOURCE>

44613 <ABSTRACT>Permian limestones are exposed in Nan area at several localities: they are less widespread than what was thought in the past. They belong mainly to Middle Permian; at an important hill, the occurrence of the Midian has been strongly evidenced and an unexpected fauna including *Lepidolina* has been found. The lower part of Lower Permian (Asselian - Sakmarian) is entirely unknown in Nan area. The upper part of Lower Permian (Artinskian - Kungurian) has been evidenced at a single locality. Late Permian shale (Wuchiapingian) is exposed locally north of Nan. The presence of Upper Permian limestone is possible. Fossils are locally in abundance, they show mainly Cathaysian affinities. * Nan region is a remote and mountainous area of northern Thailand where an impressive number of new roads has been built during the last few years. These new constructions have allowed an actually new geological research because of many road-cuts reaching the bedrock. Permian exposures consist of shale and limestone. * The studied localities are limestone hills north of Nan as well as south of Nan. At a locality, limestone is restricted to a small lens in shale. 44625 <SOURCE>Bulletin of the Geological Society Malaysia 45 [Proceedings of Geosea '98]: 453-446.</SOURCE>
44626 <ABSTRACT>A limestone which has been uncovered during the extension of an oil palm plantation appears to be an important deposit. It is rich in relatively well preserved fossils although it out crops only 500m from a granite. The fossils are diverse and consist of common Tubiphytes, a few algae, calcispherids, smaller foraminifers, abundant fusulinaceans (including Levenella, Pamirina, Brevaxina, Chalaroschwagerina, Leeina, Toriyamaia, Laosella), calcareous sponges, a few bryozoans, brachiopods, bivalves, rare gastropods, ostracods and crinoids. They indicate a Late Cisuralian age (Yahtashian-Bolorian) and appear to belong to three biozones. The rocks of the area were previously considered to be Early Carboniferous in age. 44650 <TITLE>Triassic coral buildups observed in the Chaiburi Formation, near Phatthalung, Peninsular Thailand.</TITLE>
44651 <SOURCE>Ann. Rep., Inst. Geosci., Univ. Tsukuba 19: 27-31.</SOURCE>
44652 <ABSTRACT>Light colored carbonate rocks extensively crop out in the southern part of Peninsular Thailand. Their distribution further extends to the south and crosses the national border of Thailand and Malaysia. These rocks are mostly limestones intercalated with dolomite beds in the lower part and constitute many isolated hills surrounded by steep cliffs with spectacular pinnacles at their tops or with flat tops of which elevation is 50 to 300m above sea level. Thailand geologists assigned these limestones to the Permian Ratburi Limestone, but Igo et al. (1988) reported the occurrence of lower Middle Triassic conodonts in one of the limestone hills, Khao Chiak, about 5km west of the

Phatthalung city area. More recently, Sashida & Igo (1992) added new data of geochronology based on radiolarian biostratigraphy. Recently, one of the authors, Ampornmaha (1993, MS) has studied extensively the geology of the Phatthalung area and newly designated the Chaiburi Formation for these limestones. She further subdivided this carbonate formation into the Phukhaothong Dolomite Member, Chiak Limestone Member, and Phanomwang Limestone Member in ascending order. This formation attains a total thickness of more than 400m. According to her biostratigraphic reconnaissance, this formation ranges from Dienerian to early Carnian in age, but the lower part of this formation probably grades into the Upper Permian. She also studied microfacies of these carbonate rocks and clarified their depositional environments. The microfacies of the Chaiburi corresponds with Facies 3 and 4 of Standard Facies Belts proposed by Wilson (1975). During our field survey in 1990 and 1991, we found coral buildups in the basal part of the Phanomwang Limestone Member exposed in a quarry of Phanom Wang about 9km north of Phatthalung. Triassic coral buildups have not been fully known in calcareous facies of southeastern Asia. Fontaine & Gafoer (1989) reported the presence of reefal limestone in the Sibaganding Limestone exposed near Lake Toba, northern Sumatra, but they did not document any details of this limestone. We describe the coral buildups observed in the Phanomwang and discuss their geologic significance in this paper.

 44663 <TITLE>Upper Triassic Knoll Reefs: Middle Norian, Spiti-Kinnaur, Himachal Himalaya, India.</TITLE>
 44664 <SOURCE>Facies 12: 219-242.</SOURCE>
 44665 <ABSTRACT>Coral reefs of Middle Norian age are reported from Rangring, the Pin-Spiti confluence, Kiomo, Latarse (all Spiti), and Pamachen, Hangrang Pass and Tapuk (Kinnaur). All these reefs are rather small (up to 30 m thick) and form a low-angle contact with the underlying beds. The Rangring and Pin-Spiti Reefs were studied with regard to microfacies, biocommunities and facies interpretation. The Rangring Reef is characterized by wacke/Floatstones with whole fossils, Pack/wackestones, and Boundstones. Main reef builders are calcisponges (Colospongia catenulata OTT), corals (Montlivaltia, Stylophyllopsis, Thamnasteria rectilamellosa} tabulozoans and hydrozoans (Spongioaorpha ramosa) and Pycnoporidium ? eomesozoicum. This reef structure probably represents a reef formed on the lower part of a slope.</ABSTRACT>

- 44691 <ABSTRACT>An Upper Triassic (Upper Norian-Rhaetian) carbonate complex, composed of open marine to reefal deposits, has been investigated for the first time in Eastern Sulawesi. The age is based on the occurrence of benthic foraminifera, and also of the Upper Sevatian to Rhaetian conodont Misikella posthernsteini Kozur and Mock. Palynological assemblages contain Upper Triassic-Lower Jurassic palynomorphs. The scleractinian coral Retiophyllia seranica and the chaetetid sponge Blastochaetetes intabulata, together with Solenoporacean algae, are the main framebuilders of the reefal facies. * The entire carbonate series, composed of conodont bearing limestones, reefal deposits, and intertidal/supratidal cryptalgal laminites, shows a general regressive trend from a marginal to an inner platform environment. The relationship between microfaunal distribution and sequence analysis is discussed. * The Upper Triassic foraminifers and palynomorphs of Eastern Sulawesi show affinities to microfaunas of the Australian-Indonesian southern Tethyan domain, and the general organisation of the platform should be investigated through further studies from Banda Sea dredgings. 44756 <ABSTRACT>The Jurassic of Thailand has provided corals belonging to the three main parts of the Jurassic; Lower, Middle and Upper Jurassic. Nevertheless, these species which have been found in Thailand display generally a long stratigraphic range and cannot give any accurate stage indication without the help of associated fauna and flora. As in Sumatra, the Scleractinia do not form true reefal buildups in Thailand; they may be considered as an adapted fauna, dependent of the very specific food offered by the abundance of microorganisms occurring in the muddy environments in which they lived scattered (Beauvais et al. 1985). The true reef builders are, in fact, microorganisms (bacteria and microalgae) producing a biobuilt micrite. Even in Ban Phu Kloe Khi (Burma) where metric colonies of Scleractinia in life position have been found, we cannot speak of "reef limestone" in the classic sense of the term, the limestone being there undisputably of microbial origin also. [original introduction] 22 genera and 5 new species are described.</ABSTRACT>

44845 <TITLE>Sedimentology of Upper Jurassic deposits in the Tembesi River
area, Central Sumatra.</TITLE>
44846 <SOURCE>Geol. Soc. Malaysia Bull. 22 (GEOSEA V proceedings, vol. 2):
45-64.</SOURCE>
44847 <ABSTRACT>In the Tembesi River area, the Upper Jurassic crops out along
two parallel NW-SE oriented lines. It consists of black, massive or
bedded limestones intrrbedded with either black, more or less laminated
shales or with more or less shaley sandstones. * The limestones include
numerous Madreporaria which indicate an Upper Jurassic age. *
Examination of the limestone microfacies leads to them being
interpreted as mud-mounds of microbial origin (bioclasts encrusted with
micrite and various algal structures, occurrence of filaments in the
sparite, rhombohedrons of dolomite, bituminous stylolites, fenestrae
etc.). * The study of the clay minerals contained both in the marls,
the shales, the sandstones and in the mud-mounds themselves, indicates
a close shore deposit with sporadic influx of terrigenous sediment
coming periodically from the continent. [original abstract]</ABSTRACT>

44884 <TITLE>Implications of paucity of corals in the Paleogene of SE Asia: plate tectonics or Centre of Origin? </TITLE>
44885 <SOURCE>In: Hall R. & Holloway J.D. (eds.). Biogeography and Geological Evolution of SE Asia., pp. 165-195, Backhuys Publishers, Leiden.</SOURCE>
44886 <ABSTRACT>Two contrasting major patterns can be discerned: a Paleogene one in which diversity, endemism and origination rates of corals in SE Asia were low, and a post-Paleogene one which is effectively the opposite. The change coincides with tectonic events, especially the collision of Australia with SE Asia. During the paleogene, the marine region between the continental margins of SE Asia and Australia was about 3000 km wide and, compared with the post-Neogene, there were few shallow water areas suitable for z-corals. A much more extensive, but now largely inaccessible area of shallow water carbonates existed in the mid-Pacific (on the Darwin Rise/Superswell) especially during the Eocene. However, the z-coral faunas of both regions appear to have been low diversity outposts of the very much richer faunas of Europe, eastern Tethys and the western Indian Ocean margins. The modern high diversity pattern in SE Asia and the Indo-west Pacific center began to emerge around the earliest Neogene with an apparent regional radiation of corals. However, detailed studies are revealing that relicts, and migrations of taxa into the region were both as qualitatively important as originations within the region. Local originations derived, at least in part, from these antecedent elements. The geographical complexity of the region since the neogene favoured all three processes. Although

increased habitat heterogeneity and potential allopatric speciation amongst fragmented shallow water areas, would have been enhanced in the last 10 Ma by the effects of glacio-eustasy and increased climatic fluctuation. Our fossil patterns show that a Centre of Origin model (Table 1) is completely inapplicable to Paleogene corals of the SE Asian region, since there was only a small non-endemic fauna here. In fact, it is misleading to think of it as a 'centre' of any kind during this time. This contrasts with the neogene onwards, which superficially accords with a Centre of Origin model, though the combined patterns from a range of different studies show that a more appropriate model requires a combination of all three of the possibilities in Table 1. A longer-term perspective suggests that the above contrast in Paleogene and post-Paleogene patterns represents a cyclical sequence which has occurred at least twice before with strong coral developments in the late Triassic and late Jurassic in SE Asia, coincident with times when rifted Gondwanan blocks docked against the Asian continent in the tropics. Thus plate tectonic processes rather than intrinsic evolutionary processes (like Centres of Origin, competitive displacement, etc.) have been a major control on regional diversity patterns of z-corals, and presumably also numerous other shallow marine organisms.

44911 <SOURCE>Mitteilungen des Geologisch-Palaeontologischen Institutes der Universitaet Hamburg 71: 243-251. [in German, with English abstract] </SOURCE>
44912 <ABSTRACT>Tectonical movements during the Pleistocene formed the morphology of numerous islands of the central Philippine Visayan archipelago. Tectonically uplifted coral reefs were believed to be a striking feature of the coastal area of Cebu, an island located in the Central Visayans. Previous work on the coastal area of Cebu mostly dealt with uplifted coral reef terraces and their geological age. Radiometric age data obtained during these investigations show that the age generally increases with increasing elevation of an uplifted coral reef. Sea-level oscillations during the Pleistocene could have caused the formation of a flight of coral terraces whilst Cebu was

- tectonically uplifted. Coastal morphology of Eastern Cebu and tectonic data also allow an interpretation of terrace-like structures as a system of tectonic horsts and grabens.</ABSTRACT>

- 44951 <ABSTRACT>The monograph (5th volume) is a description of reef-building scleractinian corals that form both living reef communities and organogenic framework of reefs in Indo-Pacific tropic zone. The history of their systematics, problems and peculiarities of taxonomy are considered. A morphology of skeleton and terminology are examined. Special investigations on taxonomy features of some genera and species were made. The description of corals consist of diagnosis, list of synonymic names, data on location in Vietnam and world distribution.

- Figures and photos of corals and details of their structure are given.

44964 <SOURCE>Nauka, Moskva; 144 pp.</SOURCE>
44965 <ABSTRACT>The third part of the monograph describes the corals of the
suborders Faviida and Fungiida. Ninetysix species of the genera
Caulastrea, Barabattoia, Favia, Favites, Goniastrea, Australogyra,
Platygyra, Leptoria, Oulophyllia, Montastrea, Diploastrea, Plesiastrea,
Leptastrea, Cyphastrea, Echinopora, Moseleya, Oulastrea, Trachyphyllia,
Cycloseris, Diaseris, Fungia, Heliofungia, Polyphyllia, sandalitha,
Herpolitha, Halomitra, Lithophyllon and Podobacia are described, among
them one new species.</ABSTRACT>

44978 <ABSTRACT>In the fourth part of monography are described the very
wide-spread reef-building Scleractinians, belonging to family
Poritidae, which form both living reef community and organogenic
framework of reefs of the tropic zone of the world Ocean.
Dendrophylliidae are with very large corallities and no less wide-spread
between colonial scleractinian are described too. A morphology of the
described corals, difficulties and principles of their systematics and
role in reef-building of Vietnam are in detail examined. In the first
time specific signs of the morphology and structure of septal apparatus
are revealed. On the basis of these data of specific diagnosis are
provided. Figures and photos of appears and details inner structure
this corals are resulted.</ABSTRACT>

45003 <ABSTRACT>The vertical distribution of Ostracoda from two digs from the beach of the Satonda Crater Lake reflects the Holocene history of its water chemistry. In the lowermost parts, monospecific associations dominate in fresh to brackish waters, whereas there is a higher species diversity and evenness of several marine species, typical for warm and shallow waters, in the middle parts of the sections. In the upper parts of the digs and in the alkaline waters of today's crater lake, the same cypridid species as in the lowermost horizons dominates, indicating the reestablishment of a more stressful environment compared to the marine layers in between.</ABSTRACT>

- 45029 </SOURCE>
<ABSTRACT>The small crater lake of the Island Satonda is characterized by highly alkaline conditions as a whole probably due to an intense sulfate reduction in the deep anoxic water body. Some portions of the highly alkaline water is penetrating through the uppermost pycnocline and increases the alkalinity in the upper oxic water body (alkalinity pump). The upper water body is beside its slightly increased alkalinity (4-5 meq/l) characterized by a decreased salinity (32 ‰). This special hydrochemical situation led to a very specific and endemic development of the biota. Cyanobacteria and heterotrophic microbes exhibit large diversities in contrast to just one sponge taxon (Suberites/Polmastia n.sp.). Common are cyanobacteria of the taxa Pleurocapsa, Phormidium, Calothrix, spirulina, Microcoleus and Microcystacea.</ABSTRACT>

- 45042 <ABSTRACT>The Satonda crater lake is up to now the only known " marine" lake with an increased alkalinity compared to seawater. Therefore, the lake contains a decreased amount of Ca²⁺. Its pH values about 8.5-8.6. The lake was originally filled with freshwater, which is evident from peat deposits (3,150 14C-yrs BP). Shortly after the lake was rapidly filled with seawater and a marine fauna had established. Large input of organic matter has caused an intense oxygen consumption and, as a result, the bottom water of the lake became anaerobic. Thus, an intense sulfate reduction occurred producing high amounts of bicarbonate ions. The lake became stratified into three water bodies with various salinities separated by two pycnoclines. The surface water body is oxygenated and exhibits brackish conditions. The algae/microbialite reefs exhibit a vertical development which started with a serpulid framework, followed by loose crusts of the calcified red alga Peyssonnelia and thalli of the green alga Cladophoropsis calcified by cyanobacteria (microstromatolites). The top calcified layer is formed by a network of Lithoporella, Peyssonnelia and microbialites. On the top layer the living reef community is located.</ABSTRACT>

- 45054 <SOURCE>J. sediment. Res. A 64, 4: 752-764.</SOURCE>
- 45055 <ABSTRACT>Most fringing reefs of the SE coast of Phuket, Thailand, have

wide (up to 300m) intertidal reef flats and narrow (2-5m) reef fronts that abut the muddy forereef only a few meters deep. These reefs prograde by splitting, toppling, and regeneration of reef-front massive corals, notably *Porites lutea*. Splitting of massive corals is greatly aided by the boring action of *Upogebia* sp. shrimps and by planes of weakness developed within the colony skeleton by nestling bivalves. The large size of toppled blocks ensures that some of the uppermost polyps are viable above the soupy forereef sediment surface. Cores indicate that the reefs are essentially tabular features consisting of mainly massive reef-front corals grown on muddy foundations that have shallowing-upwards sediment characteristics. ¹⁴C ages and leveling data of fossil former reef-front corals exposed on the reef flat suggest that reef growth started in the mid-Holocene when sea level was at least 0.8m higher than now. Since then, the rate of lateral reef progradation has averaged 40 mm/yr. The preservation potential of these reefs is low because of the combination of a lack of organic or inorganic binding of the corals into a rigid frame, and the unconsolidated nature of the underlying sediments.

45066 <TITLE>Philippine artificial reefs: anatomy of a failure.</TITLE>
45067 <SOURCE>Mitt. Geol.-Palaeont. Inst. Univ. Hamburg 71: 31-43.</SOURCE>
45068 <ABSTRACT>The use of artificial reefs or artificial habitats is gaining ground in Southeast Asia. They are considered to be a tool to improve living aquatic resources in coastal areas where coral reefs are unsuitable for attracting fish or other commercially important marine organisms. More than ten artificial reef systems have already been developed in the Philippines and other coastal areas. Module of scrap rubber tire, different concrete units and pyramid bamboo constructions are common. Our studies on Cebu Island on encrusting organisms, e.g. bryozoans on the above mentioned artificial reef types, have shown that most of these noncryptic designs are not favourable for reef organisms. Instead, the so-called Geo-Artificial-Reefs are proposed. This natural material consists of blocks of the very common Plio-Pleistocene " Carcar Limestone" in the Central Visayas Region. These rocks can be easily quarried and dumped as clusters in areas where reefs have been destroyed.</ABSTRACT>

45131 <TITLE>Sedimentary rocks of the Loei Region, Northeast Thailand.</TITLE>
45132 <SOURCE>Sedimentary rocks of the Loei Region, Northeast Thailand: 165 pp., 15 figs, 1 tab, 30 pls; Bangkok. ISBN 9789749674512</SOURCE>
45133 <ABSTRACT>In the 1950s, the Department of Mineral Resources was very active in the geologic reconnaissance of the diverse mineral deposits of Thailand (Brown et al., 1951), but it was also interested to extend the investigation to other geologic problems. For instance, it was

eager to find good sections of sedimentary rocks, to study their fossils, and then, to distinguish biozones easy to correlate with the rocks of other countries (Sethaput, 1956). An important programme started in Loei Province and was carried out by M. Veeraburus, D. Bunnak and A. Hongnusoithi, with the cooperation of Japanese paleontologists (T. Kobayashi, H. Igo, T. Hamada, J. Iwai, J. Yanagida). K. Pitakpaivan (1966) studied fusulines from calcareous shale of Wang Saphung area as well as from other localities of Thailand; he became the first Thai paleontologist. Near Wang Saphung, Middle-Upper Carboniferous and Permian fossils were collected in fair quantity. They were diverse and consisted of trilobites, foraminifera, conodonts, brachiopods, and ammonoids. They were described in many publications; see the references of this publication. Permian plant imprints were discovered in Loei area. In 1980 in Loei region, information on rocks older than Middle Carboniferous was very poor. Fossils, supposed to be Devonian in age, had been mentioned as early as 1925, but at a single locality, without good identification and description. New research was needed; it was undertaken under an agreement between the Department of Mineral Resources and CCOP. New results were obtained during the first fieldwork carried out with the cooperation of Mr. N. Nakornsri and Mrs. B. Sektheera; they were published in CCOP Newsletter in 1981. Devonian and Lower Carboniferous fossils had been discovered at a few localities. Outside of the Wang Saphung area, other parts of the Loei region appeared as also very rich in fossils and very interesting, but they remained poorly known. Some geologists became enthusiastic for new investigations, especially Dr. V. Suteethorn and Mr. W. Tantiweanit. New field work led to many new discoveries of fossiliferous localities. Later on, Mr. S. Salyapongse was happy to be involved in this research and was eager to extend it. Dr. D. Vachard of the University of Lille (France) has been very helpful in the identification of the Carboniferous and Permian microfossils. Dr. B. Mistiaen and Dr. D. Brice of the University of the University Federation of Lille are presently studying Devonian samples collected from the Loei region and consisting of stromatoporoids, Tabulata and some brachiopods. The study of this publication corresponds to the programme proposed in 1956 by Mr. V. Sethaput.

45171 <SOURCE>Journal geol. Soc. India 34: 575-586.</SOURCE>
45172 <ABSTRACT>Additional examples are given of assorted disinformation injected into the Devonian, Carboniferous, Triassic and Cainozoic literature on palaeontology of the Himalayas. These include biogeographically and temporally incredible conodont-brachiopod associations, phantom localities, and re-use ('recycling') of specimens. The 'recycling' includes assemblages of Carboniferous corals and Triassic and Carboniferous conodonts used as documentation for reports from specific regions of the Himalayas being used subsequently as 'documentation' of reports from other regions, an illustration of a Welsh Carboniferous coral specimen being used as basis for a 'report' from Kashmir, and a Silurian coral specimen reported from two regions with different names. Attention is also drawn to curious practices regarding coauthorship.</ABSTRACT>

45197 <SOURCE>[journal?] The International Conference on Stratigraphy and Tectonic Evolution of Southeast Asia and the South Pacific Bangkok, 19-24 August, Thailand.</SOURCE>
45198 <ABSTRACT>Prior to 1980, a single palaeontological paper concerned eastern Thailand and only one locality (Pitakpaivan et al. 1969). On the contrary, several palaeontological studies were carried out during

the 1980s and 22 fossiliferous localities were discovered (Pitakpaivan & Lagavat 1980; Sugiyama & Toriyama 1981; Fontaine & Vachard 1981; Fontaine 1982; Bunopas et al. 1983; Buffetaut & Ingavat 1983; Vachard & Fontaine 1988). Then, palaeontological research was brought again to a standstill for a few years. It has resumed very recently (Chaimanee et al. 1993; Sashida et al. 1993 and 1997; Fontaine et al. 1996 and 1997). During 1996 and the beginning of 1997, intensive research has been carried out in the field by S. Salyapongse and H. Fontaine, more than forty new fossiliferous localities have been discovered; they are currently studied. A list of all the localities known so far is given in the following with short remarks on the fossil assemblages. Then, our present knowledge will be summarized in a conclusion.</ABSTRACT>

 45236 <SOURCE>Geobios 30, 2: 193-204.</SOURCE>
 45237 <ABSTRACT>A new genus of dendroid stromatoporoid, Vacuostroma, is proposed. The genus is present in the Devonian of Vietnam, with two species, V. thanhlangense and V. sp. A. It is also present in the Devonian of Boulonnais (North of France) with another species, V. michelini. The genus Vacuostroma is typically characterized by coenosteal elements with vacuolate microstructure. The characteristics

of other dendroid stromatoporoid genera are compared with those of the new genus.</ABSTRACT>

45326 <TITLE>Silurian rugose corals from the Gionyama Formation, Gokasecho, Miyazaki Prefecture, Southwest Japan.</TITLE>
45327 <SOURCE>Fukuoka University Science Reports 35, 1: 11-29.</SOURCE>
45328 <ABSTRACT>The Gionyama Formation, a unit of Silurian and Devonian rocks, is exposed in the Gokase-cho, Miyazaki Prefecture, and assigned to the Kurosegawa Terrane in Southwest Japan. Two localities from the G2 Member of the Gionyama Formation contain an abundant rugose corals fauna consisting of 17 species in 12 genera. These are: Tryplasma sp. A, T. sp. B, T. sp. C, Cystiphyllum sp., Holmophyllum sp. A, H. sp. B, Labechiellata regularis, Rhizophyllum sp. A, R. sp. B, Neobrachyelasma sp. aff. N. balchascicum, Pseudamplexus sp., Amsdenoides sp., Amplexoides sp., Strombodes sp., Nanshanophyllum sp. aff., N. typicum, N. sp. aff. N. mirandum and Ptychophyllum sp. The following genera are reported for the first time from this member: Cystiphyllum, Holmophyllum, Rhizophyllum, Neobrachyelasma, Pseudamplexus, Amsdenoides, Amplexoides, Strombodes, Nanshanophyllum and Ptychophyllum. In addition, Neobrachyelasma, Strombodes and Ptychophyllum are previously unknown from the Silurian of Japan. Of these genera in the G2 Member of the Gionyama Formation, eight commonly occur in the Upper Llandovery sequence in the Ningqiang - Guangyuan depression in the northern part of South China. In China, Nanshanophyllum indicates a middle to late Telychian age. Therefore the coral fauna from the G2 Member can be inferred to indicate a Late Llandovery age. Also, this is the second report of the co-occurrence of Neobrachyelasma and Nanshanophyllum, which previously was known only from the Ningqiang - Guangyuan depression. Neobrachyelasma is also known from Kazakhstan and the Altay area, and Nanshanophyllum has been

reported from the Hunan Province in South China, Gansu Province in Qidam, Australia and Canada. Thus, the similarities of the coral faunas between the Gionyama Formation and these areas should be considered in any paleobiogeographic reconstruction of the Kurosegawa Terrane.

45365 <TITLE>Silurian Holmophyllidae (Rugosa) from the Gionyama Formation of the Kurosegawa Terrane, Southwest Japan.</TITLE>

45366 <SOURCE>Palaeontological Research 13, 3: 293-306.</SOURCE>

45367 <ABSTRACT>Three rugose species of the family Holmophyllidae wang, 1947 are described for the first time from the Gionyama Formation of the Kurosegawa Terrane, Southwest Japan. They are Holmophyllum sp., Holmophyllum? sp., and Labechiellata regularis (Sugiyama, 1939). These species are found in the Middle Member of the Gionyama Formation, which is Late Llandovery to Early Ludlow (Silurian) in age. Holmophyllum and Labechiellata are typical cosmopolitan genera. The compound holmophyllids such as Labechiellata may indicate tropical environments and suggest that 'Proto-Japan' was, like other areas that yield these corals, located in subtropical to tropical latitudes during the Silurian. 45379 <SOURCE>Journal of Paleontology 83, 2: 280-292.</SOURCE>
45380 <ABSTRACT>Three rugose species in two genera - Nanshanophyllum hamadai n.sp., N. gokasense n.sp., and Shensiphyllum sp.- are described for the first time from the Kurosegawa Terrane, Southwest Japan. These species occur in the Middle Member of the Gionyama Formation, which is Late Llandovery to Early Ludlow (Silurian) in age. The two genera, Nanshanophyllum and Shensiphyllum, formerly were known only from South China and Qaidam. The occurrence of these two genera in Japan may indicate a paleogeographic connection between Proto-Japan and the South China Block during the Silurian. [original abstract]

45392 <SOURCE>Journal of Paleontology 84, 3: 466-476.</SOURCE>
45393 <ABSTRACT>Four species of rugose corals (one new) are described from the Silurian of the Kurosegawa Terrane, Southwest Japan. They are Neobrachyelasma japonica n.sp., Pseudamplexus sp., Amsdenoides sp., and Amplexoides sp. aff. A. chaoi (Grabau, 1925). These species occur in the Middle Member of the Gionyama Formation, which is Late Llandovery to Early Ludlow in age. Neobrachyelasma is reported for the first time from Japan. This genus occurs in the Lower Llandovery to Upper Silurian of Japan, South China, Kazakhstan, and the Altai and might be distributed only in South China and Japan during the Late Llandovery. Its occurrence in Japan may support a paleogeographic proximity of Proto-Japan and the South China Block during the Silurian. [original abstract]

45418 <SOURCE>Hokkaido University, Faculty of Science Journal ser. 4, 19, 3: 273-303.</SOURCE>
45419 <ABSTRACT>Seven halysitids, newly found and described from the silurian Okuhinotsuchi Formation, developed in the Shimoarisu district, Setamai region of Iwate Prefecture. Out of these, Halysites arisuensis is new to scientific knowledge. Based on halysitids, the Okuhinotsuchi Formation as a whole may be of Late Llandoveryian to Wenlockian in age. In general, the halysitids described are faunistically very much related to those of southwest Japan and Australia. Apart from H. arisuensis n.sp., the following species are described: Falsicatenipora shikokuensis Noda & Hamada 1958, Halysites labyrinthicus (Goldfuss 1829), Halysites cf. cratus Etheridge 1904, Halysites sp. A and H. sp. B.</ABSTRACT>

45432 <ABSTRACT>Eight species of halysitid corals, namely Schedohalysites kitakamiensis (Sugiyama), Falsocatenipora shikokuensis Noda & Hamada, Halysites catenularius (Linnaeus), H. suessmilchi Etheridge, H. kuraokensis (Hamada) and three indetermiabile species, are described and figured from the silurian deposits of Mt. Yokokura region in Kochi Prefecture, Southwest Japan. Among them, Halysites spp. A and B may represent new forms although they are imperfect in preservation. Halysites catenularius (Linnaeus) and H. kuraokensis (Hamada) are recorded from Mt. Yokokura region for the first time. The silurian geology in the Mt. Yokokura region is also briefly described.</ABSTRACT>

45470 <SOURCE>Journ. Geol. Soc. Japan 81, 2: 105-126.</SOURCE>
45471 <ABSTRACT>History of the research on Japanese Palaeozoic corals is
briefly stated. Stratigraphical and geographical distribution of corals
in the Japanese Palaeozoic deposits is briefly described. A total of
281 species is listed up from various horizons ranging from the Late
Silurian to the Upper Permian. Worldwide correlation and
palaeobiogeographical situation of the coral faunas and problems
related to the palaeoclimatology are discussed. * Certain amount of
horizontal movement of the present day Japan probably occurred during
the Palaeozoic, it is also discussed in combination with palaeomagnetic
study and coral fauna. * In spite of the fact that Japan has always
been located in the eastern end of the Tethys Sea, certain minor
elements are found indicating a relationship with the boreal sea, the
Durhaminidae province of Carboniferous time for example, and Eastern
Australia in various ages.</ABSTRACT>

45522 <SOURCE>Hokkaido University, Faculty of Science Journal, ser. 4, 17, 4: 555-573.</SOURCE>
45523 <ABSTRACT>[crinoid and not a tabulate - see Minato et al. 1982] A new tabulate coral named Ohnopora hayasakai is described. It somewhat resembles Syringolites but may genetically be distinguished from the latter in having two straight hollow tubes in each corallite which are connected with smaller tubules in the central part of the tabulae. The corallites are contiguous, with common walls; polygonal, more or less rectangular in cross sections. Mural pores are present.</ABSTRACT>

45536 <ABSTRACT>The Fukuji area, in the Hida Gaien belt (HGB), is one of the most significant areas for Paleozoic stratigraphy in Japan. The Devonian Fukuji Formation of this area yield abundant, well-preserved coral fossils, however, the biostratigraphy and paleobiogeographical significance of this fauna still remain unclear and precise details of the Devonian situation of the HGB have yet to be revealed. In order to understand the Paleozoic history and geological framework of the HGB better, the stratigraphy and faunal assemblages of this formation have been reexamined. Limestone and muddy limestone samples amounting to

some 420kg from seven horizons (Locs. 1 to 7) along the Ichinotani Valley, Fukuji area, Gifu Prefecture, central Japan have been studied here. The tabulate coral fauna from the Loc. 1 (N36°13.17' E137°31.37') comprises the following 17 species: Favosites goldfussi, *F. flexuosus*, *F. sp. A*, *Squameopora hidensis*, *S. zhanwaensis fukujiensis* subsp.nov., *S. cf. zhanwaensis*, *Sapporipora kamitakaraensis* sp.nov., *Sa. karatanioum* sp.nov., *Heliolites wenxianicus*, *H. cf. gemina*, *H. ichinotaniensis* sp.nov., *H. ? sp.*, *Helioplasma takayamaensis* sp.nov., *Pseudoplasmopora okuhidaensis* sp.nov., *P. cf. arguta*, *Striatopora* sp., *Gertholites ? sp.* This paper describes these tabulate corals from the Loc. 1.  45561 <SOURCE>Bulletin of National Science Museum Tokyo, Ser. C, 31: 13-29.</SOURCE>
 45562 <ABSTRACT>Five tabulate coral species of the superfamily Pachyporoidea are described from the Lower Devonian (Emsian?) of the Fukuji Formation, Gifu Prefecture, Central Japan. They include pachyporids consisting of *Hillaepora* sp. cf. *H. altaica* Dubatolov in Dubatolov and Spasskiy, 1964, *Isurugiopora obesa* gen. et sp.nov., *Striatopora takayamaensis* sp.nov. and *Thamnopora hayasakai* sp.nov., and a parastriatoporid of *Parastriatopora innae* Dubatolov, 1963. Among the previously known pachyporid genera, a new genus *Isurugiopora* is most similar to *Gertholites*, differing mainly in its exceptionally inflated median dark line. *Dendropora dubrovensis* Dubatolov, 1959 from the Givetian of the Kuznetsk Basin, southwestern Siberia is assigned to *Isurugiopora*. The conspecific and closely related species are reported from the Kuznetsk Basin and Altai of southwestern Siberia. The tabulate coral faunas from Salair and the Kuznetsk Basin of southwestern Siberia, Inner Mongolia, the Urals, Tarim, and Belgium also have comparable species with the Fukuji fauna. From a paleobiogeographic point of view, this fauna shows most strong affinities with those in southwestern Siberia. [original abstract] </ABSTRACT>

45743 <SOURCE>Science Reports of the Institute of Geosciences, Univ. of Tsukuba, Section B, 1: 149-162.</SOURCE>
45744 <ABSTRACT>Three interesting corals were discriminated from the Mitsuzawa Limestone, near Itsukaichi, west of Tokyo. These corals are Lithostrotion (Siphonodendron) mitsuzawensis Yamagiwa, Diphyphyllum delicatum nishitamensis Igo & Kobayashi n. subsp., and Heterophyllia (?) tokyoensis Igo & Kobayashi n.sp. * Peripheral increase is very rare in the genus Lithostrotion, but commonly observed in Lithostrotion (Siphonodendron) mitsuzawensis. Although the indentification of generic position was reserved, the occurrence of the genus Heterophyllia from this limestone is also worthy of note to consider the paleobiogeography of corals in Carboniferous. 45755 <TITLE>Reef-forming Algal-Chaetetid Boundstone found in the Akiyoshi Limestone Group, Southwest Japan.</TITLE>
45756 <SOURCE>Bulletin Akiyoshi-Dai Museum of Natural History 20: 1-17.</SOURCE>
45757 <ABSTRACT>This paper deals with the detailed reconstruction of a reef framework newly found in the upper part of the Millerella yowarensis Zone of the Akiyoshi Limestone Group. The reef framework, developed on a calc-arenitic sedimentary mound, consists mainly of chaetetids, calcareous algae and rugose corals with minor amount of encrusting foraminifers, bryozoans and annelid worms. Chaetetes, the most dominant group of organisms in this framework, played an important role as a framebuilder and a sediment trapper. However, hard mass is indispensable for the growth of Chaetetes. In relation with this problem, calcareous algae played as a sediment binder at an early stage of the framework-growth. And then the soft bottom became consolidated, providing the best condition for the growth of Chaetetes. After the growth of Chaetetes rigid framework for the organic reef was formed. 45769 <SOURCE>Bulletin of the Tohoku University Museum 1 [Proceedings of the 8th International Symposium on Fossil Cnidaria and Porifera]: 134-143.</SOURCE>
45770 <ABSTRACT>Strata and organisms underlying (substrate) and overlying (cover) chaetetids on polished vertical slabs from the Pseudostaffella antiqua and Millerella yowarensis zones of the Akiyoshi Limestone Group are here recorded. A total of six slabs have been examined. Two slabs were of encrusting chaetetid algal framestone, and two of algal bindstone; one of each lithology was from each biostratigraphic zone. The remaining two slabs, both from the back reef slope, were of algal chaetetid boundstone from the P. antiqua Zone. Slabs of encrusting chaetetid algal framestone were collected from the reef crest and those of algal bindstone from the reef flat. The facies and environment from which we have the most data over the greatest area, are the algal chaetetid boundstones from the back reef slope. Algal bindstone from the reef flat was next and the encrusting chaetetid algal framestone from the reef crest was least represented. Using reference grid, five by five centimeters, transects at one centimeter intervals were made parallel to the inferred direction of chaetetid growth, i.e. as near as possible to the direction paralleling the long dimension of the chaetetid tubules. Where transects crossed a chaetetid mass, the substrate of that chaetetid and what covering the chaetetid mass was recorded. The greatest diversity in substrate and cover occurred in the back reef slope environment. In all polished surfaces examined, algal/microbial mats are the dominant chaetetid substrate, and also covering strata, irrespective of reef environment or limestone facies. These results suggest that from upper Serpukhovian into middle Bashkirian time (the interval reflected by the two foraminiferal zones noted above), algal/microbial mats overgrew chaetetid sponges, but the mats also provided a suitable substrate for subsequent chaetetid sponge colonization and growth. Although competitive interactions are possible, it is more reasonable to suggest that algal/microbial overgrowth occurred as part of all the sponge tissue died as a result of disease or injury. Additionally, algal/microbial mats, as binding agent of unconsolidated sediment, produced a stable surface for chaetetid colonization.</ABSTRACT>

45782 <SOURCE>Bulletin Akiyoshi-Dai Museum of Natural History 19: 27-67.</SOURCE>
45783 <ABSTRACT>This paper is the systematic paleontological description of a large collection of Heterocorallia from the Lower Carboniferous, Akiyoshi Limestone. Seven species distributed among four genera are described in detail: Heterophyllia cf. H. ornata M'Coy, H. cf. H. oblonga Yu et al., Hexaphyllia yabei sp.nov., H. inflata sp.nov., Pentaphyllia regulare Yu et al., Radiciphyllia akiyoshiensis gen. et

sp.nov., *R. toriyamai* gen. et sp.nov. * The genera of *Heterocorallia* are divided into two groups based on the microstructure of the peripheral edges of septa. Serial transverse sections from a single corallite of *Radiciphyllia akiyoshiensis* gen. et sp.nov. clearly support the system of septal development proposed by Poty (1978a, b; 1981).</ABSTRACT>

45807 <TITLE>Paleontological and biostratigraphical studies on *Heterocorallia* from the Akiyoshi Limestone, southwest Japan.</TITLE>
45808 <SOURCE>11th International Congress on Carboniferous Stratigraphy and Geology, Beijing, China; *Compte Rendu* 2: 344-354.</SOURCE>
45809 <ABSTRACT>In the Shishide-dai area, the Lower Carboniferous part of the Akiyoshi Limestone which contains a prolific fauna of *Heterocorallia* is most widely exposed, and subdivided into six foraminiferal biostratigraphic zones, the CL1 to CL6 Zones in ascending order. A detailed correlation of the lower part of this limestone is given by the foraminiferal assemblage. Among the heterocorallian limestones, the CL3 to CL5 Zones are corelative with the upper Visean (V3b and V3c), and the CL6 Zone with the lower Namurian (E1) in western Europe. Based on the morphological characteristics, the heterocorallian genera from the Akiyoshi Limestone are divided into two groups. One of the groups, which contains *Hexaphyllia*, *Heterophyllia*, and *Pentaphyllia*, is presumed to have had a living habit of attaching, to other organisms or hard objects by cementing tips of the hollow spines. The other group, containing *Radiciphyllia*, has had a sessile habit on the substratum by cementing talon-like attachments.</ABSTRACT>

45873 <SOURCE>Scientific Reports, Institute Geosciences, University of Tsukuba, Sec. B., 24: 1-15.</SOURCE>
45874 <ABSTRACT>The Jurassic Mamba Formation exposed in the Nagakubo area of

the Chichibu district, Saitama Prefecture included many fossiliferous limestone clasts. Abundant fossils in the clasts are rugose corals of which two new interesting species *Yuanophyllum chichibuense* and *Acrocyathus bamberi* are described in this paper. These corals indicate a Bashkirian (early Middle Carboniferous) age. Previously known species of *Yuanophyllum* have been reported mainly from the Viséan to Serpukhovian (upper Lower Carboniferous) of China, hence *Y. chichibuense* is considered being a relict of this genus. Another new species *Acrocyathus bamberi* is also one of the survivors of this genus that is common in the upper Lower Carboniferous.

45886 <SOURCE>Trans. Proc. Palaeont. Soc Japan, N. S. 148: 228-245.</SOURCE>
45887 <ABSTRACT>Corals are abundant in the lowest part of the Omi Limestone, Central Japan. An assemblage of corals obtained from the lowest part in the Fukugakuchi area comprises more than 13 forms, from which the following five species including three new species are herein described and illustrated: *Cyathaxonia* cfr. *C. cornu* Michelin, *Clisiophyllum kurohimense*, sp.nov., *Akiyosiphyllum stylophorum* Yabe et Sugiyama, *Carcinophyllum hasegawai*, sp.nov. and *Hiroshimaphyllum simplex*, sp.nov. This coralline fauna is correlatable with that one of the *Nagatophyllum satoi* zone of the Akiyoshi Limestone, Southwest Japan, and indicates Late Viséan age.</ABSTRACT>

45911 <TITLE>Carboniferous rugose corals from the Nanmoku area, northeastern part of the Kanto Mountains, Gunma Prefecture, Japan.</TITLE>

- 45912 <SOURCE>Science Reports of the Institute of Geoscience University of Tsukuba, Section B (Geological Sciences) 19: 29-42.</SOURCE>
- 45913 <ABSTRACT>Interesting Carboniferous rugose corals are discovered in a limestone block embedded in the Jurassic accretionary complex exposed in the Nanmoku area northwestern part of the Kanto Mountains, Gunma Prefecture. The limestone is light gray to gray and massive, and its microfacies suggests that the block represents a part of reefal facies. Identified rugose corals from this limestone are *Cystophorastraea sinensis* Wu & Zhao, *Petalaxis sondoi*, sp.nov., and *Amygdalophylloides wuwangshii*, sp.nov. Moreover, *Beedeina* and some other fusulinaceans, smaller foraminifers, *Chaetetes*, calcareous algae, and other organisms constitute main framework of this coral limestone and its geological age is assigned to a Moscovian of the Middle Carboniferous. </SOURCE>
45965 <ABSTRACT>Two rugose corals Nagatophyllum satoi Ozawa and Carcinophyllum enorme (Ozawa), both of which are from the Nagatophyllum satoi Zone of the Akiyoshi limestone Group are redescribed in the present paper; they occur in the Middle Visean. * Nagatophyllum satoi Ozawa is a compound rugosan with the dendroid form. It is characterized by the following points: 1) a large-sized corallite, 2) a large number of septa in two orders, which have the trabecular microstructure, 3) conical tabulae, 4) a wide dissepimentarium with the regular dissepimental rows, and 5) a tendency of change in axial structure of several types throughout corallite ontogeny. * Carcinophyllum enorme (Ozawa) is also a compound rugosan with the dendroid form. It is characterized by the following characters: 1) a medium-sized corallite, 2) a large number of septa in two orders, which have stout trabecular microstructure, 3) septa dilated in both peripheral and inside ends, 4) dense tabulae of nearly horizontal direction, 5) extremely thick stereozone with large lonsdaleoid dissepiments, and 6) carcinophylloid axial structure. * Nagatophyllum satoi and Carcinophyllum enorme generally form composite colonies. 45978 <ABSTRACT>The Ichionotani Formation exposed in the Fukuji area of central Japan, yields abundant corals from various levels. The formation is subdivided into lower, middle, and upper members, and its geologic age is well controlled by fusulinacean biostratigraphy and is of Late Early to Late Carboniferous age. The basal part of the Lower member (late Visean to Serpukhovian) contains a prolific coral fauna, including Heterocanina, Kueichouphyllum, Arachnolasma, Yuanophyllum, Koninckophyllum, Lithostrotion, Siphonodendron, Dibunophyllum and others. Neokoninckophyllum, Lonsdaleia, and Axophyllum are also above those, still part of the lower member but dated just above the Mid-Carboniferous boundary, yield Cladochonus and Cyathaxonia. The middle member (early to middle Moscovian) yields Amplexocarinia, Dorlodotia, Kionophyllum, and other taxa below, in the lower part, and Ivanovia (s.l.), Fomichevella, Pseudozaphrentoides, and Dibunophylloides above, characteristic of the upper. The lower part of the upper member (late Moscovian) yields abundant Dibunophylloides and Fomichevella, both of which occurred earlier, in the middle member. The middle and upper parts of the upper member (Kasimovian to Gzhelien) include two distinct coral faunas: Carinthiaphyllum and Koninckocarinia, associated with a dendroid type of Chaetetes (B) in the middle; and notably abundant Bothrophyllum in the upper part. The uppermost part of the member yields Sestrophyllum. Coral faunas in the Ichinotani (except the Onimaru-type fauna of the lower member) have not been found in other Carboniferous sections in Japan. 46067 <TITLE>Growth Forms of Auloporidid Corals in the Akiyoshi Limestone Group, Southwest Japan. Paleoeological Studies of Reef-building Organisms in the Akiyoshi Organic Reef Complex I.</TITLE>
46068 <SOURCE>Bulletin Akiyoshi-Dai Museum of Natural History 25: 7-25.</SOURCE>
46069 <ABSTRACT>This paper deals with two growth forms of auloporidid corals collected from the Middle Carboniferous limestones in the Minamidai area of the Akiyoshi Limestone Plateau, Southwest Japan. Numerous auloporidid corals are found in many types of boundstones distributed in the reef core facies of the Akiyoshi organic reef complex in this area. The auloporidid corals usually adhere to the main reef builders or rarely to the hard substrate. The present corals are apparently divided into two forms, form A and B. The form A grows up to be a shrub-like dendroid corallum. The form B, on the other hand, reveals an encrusting corallum. These two forms, however, have the same characteristics in their corallites, such as the size of corallite, the microstructure and thickness of wall, the shape of tabulae (horizontal to convex and complete), the presence of short spinose ridges, and the absence of mural pores and connecting tubes. Furthermore, these two forms have a similarity in their young growth form, in which the corallites closely contact with each other and encrust on the surface of other organic skeletons. It is obvious from the above that these two forms represent two morphological varieties in the growth form and belong to one and the same species. Two forms of auloporidid corals are respectively found in the different types of boundstones built up under the different environments. The form A discriminated by shrub-like dendroid corallum occurs in the framestone and the bafflestone, which are mainly constructed by rugose corals. The form B characterized by encrusting corallum occurs in the framestone and the bindstone, which consist of encrusting reef-builders, such as calcareous algae and chaetetids. Accordingly, it might be stated that the two variant growth forms are recognized as the ecophenotypes in the same species of auloporidid corals. Two growth forms of the present corals show some resemblances to those of the several genera among the different families of the Order Auloporida. The convex and complete tabulae of the Minamidai species are different from those of the other genera among the Carboniferous auloporidid corals. As the result of this study, it can be stated that the variant growth form must be taken into consideration to classify the auloporidid corals.</ABSTRACT>

46080 <TITLE>Description of some Carboniferous corals from the Ichinotani Formation, Fukuji, Hida Massif, central Japan - Upper Paleozoic corals from Fukuji. Southeastern part of the Hida Massif, Part 7.</TITLE>
46081 <SOURCE>Scientific Reports, Institute Geosciences, University of Tsukuba, Sec. B., 21: 41-69.</SOURCE>
46082 <ABSTRACT>The Ichinotani Formation, exposed in the Fukuji area, Hida

Massif, central Japan, was studied by many specialists and assigned to one of the most continuous late Early to late Carboniferous sections in the Japanese Islands. This formation yields abundant corals along with prolific faunas including fusulinaceans and other smaller foraminifers. Recently, the authors have summarized the stratigraphic occurrence of corals in this formation and listed many coral species including several new species. These new and some other interesting species are newly described or scrutinized herein: *Cyathaxonia weyeri* Igo and Adachi, n.sp., *Actinophrentis?* sp., *Fomitchevella japonica* Igo and Adachi, n.sp., *Bothrophyllum domheri* (Fomichev), B. sp., n.sp.?, *Koninckophyllum?* nipponalpinum (Igo and Adachi), *Arachnolasma ichinotaniense* Igo and Adachi, n.sp., *Yuanophyllum pauciseptatum* Igo and Adachi, n.sp., *Dibunophylloides mizuyagadaniensis* (Kamei), *Sestrophyllum fedorowskii* Igo and Adachi, n.sp., *Ivanovia* (*Ivanovia*) *podolskiensis* Dobrolybova, and *Ivanovia* (*Protoivanovia*) *eguchii* Igo. 46106 <TITLE>The Lower Carboniferous Odaira and Onioaru Formations in the Setamai-Yukisawa district, southern Kitakami Mountains, northeast Japan.</TITLE>
46107 <SOURCE>Journal of Geological Society of Japan 91, 12: 851-866 [in Japanese, with English abstract].</SOURCE>
46108 <ABSTRACT>Stratigraphy, paleontology and sedimentary petrology of the transitional part of the Odaira and Onimaru Formations which represent the upper sequence of the Lower Carboniferous of the Setamai Subbelt are re-examined in the Setamai-Yukisawa district in detail. The upper part of the Odaira Formation consists of slate, sandstone and limestone. Besides, the uppermost part of the formation is mainly composed of limestone and grades upward conformably to the Onimaru Formation mainly represented by black fossiliferous limestone. Corals obtained from the upper and uppermost parts of the Odaira Formation include *Kueichouphyllum* and *Yuanophyllum* in its upper horizon, *Pseudouralinia* and *Siphonophyllia* in lower horizon. The former two genera are common to the coral fauna of the Onimaru Formation which is Upper Viséan in age. So, biostratigraphic gap is not recognizable between the two formations. 46120 <SOURCE>9th International Congress on Carboniferous Stratigraphy and Geology; Washington - Champaign - Urbana 1979, 3: 256-262.</SOURCE>
46121 <ABSTRACT>Tournaisian faunas of Japan possess certain elements closely related to stratigraphically equivalent faunas of Australia, the USSR, the United States, and northern China. Upper Visean coral faunas show strong resemblance to corals of the same age from southern China and are of the Kueichouphyllutn province of HILL (1948). Corals of the Japanese Silesian include both Tethyan and Boreal elements as well as many endemic forms, but fusulinids appear to be similar to those of the Boreal fauna of the Urals, Moscow basin, northern China, and Korea. Volcanic rocks are dominant in the Japanese Tournaisian. There are also Lower and Middle Carboniferous granites, the former dated by Rb-Sr as 339-332 m.y.B.P. Angular unconformities are present at the base of Tournaisian and upper Visean deposits, and a paraconformity is present between the upper Visean and Silesian deposits. From paleomagnetic studies, the Japanese Islands are inferred to have shifted from north to south during the time span ranging from Early Carboniferous until Early Permian, and thereafter have moved generally northward. 46147 <ABSTRACT>The Akiyoshi Limestone Group (Lower Carboniferous to upper Middle Permian) is a huge exotic limestone mass containing abundant reef-building shallow marine fossils and resting on a basement composed of basaltic lava and volcaniclastic rock. Tectonic, sedimentologic, and

- paleoecologic characteristics of the limestone sequence indicate that it represents an organic reef complex developed on top of an oceanic seamount. Rugose corals are among the important reef-builders and are mainly distributed on the outer side of the reef complex. They present various growth forms in response to habitat differences in a well defined reef facies zonation</ABSTRACT>

- 46211 <SOURCE>Bulletin Akiyoshi-Dai Museum of Natural History 38: ...</SOURCE>
- 46212 <ABSTRACT>Abundant euhedral of quartz were found in the reef limestone from seven localities in the Akiyoshi Limestone area. Quartz crystals occurred in an grainstone has an average length of 0.261 mm and width of 0.121 mm, and the average ratio between length and width is 2.149, which means the quartz crystallized in elongate shape under ahydrothermal environment. The quartz crystals have different size distributions and inside structures among their host limestone textures. Large crystals grew up in trabecula tissue of reef building organisms, such as rugose corals and chaetetids, and small ones in micritic matrix of coated grains. It might depend on density of fine clucks and solubility to the hydrothermal liquid in each host limestone texture. Quartz usually has solid calcite inclusions as inside layers. These solid inclusions are come from remains of host calcite tissues which unsolved during crystallization in hydrothermal liquid. Mineralogical identification of inside layers of quartz was done by the laser Raman microprobe. Homogenization temperatures of primary fluid inclusions in quartz veins (from 150-220 °C.) and a calcite vein (169,5 °C) talked that the origin of these euhedral crystals of quartz came from a hydrothermal activity which possibly occurred in Late Cretaceous after the intrusion of quartz porphyry in the Akiyoshi Limestone area.

46250 <SOURCE>Bulletin Akiyoshi-Dai Museum of Natural History 28: 59-78. </SOURCE>
46251 <ABSTRACT>More than 82 species included in 56 genera of Rugosa, Tabulata, Dividocorallia, and chaeteids described and illustrated from Akiyoshi Limestone Group and some derived limestone blocks located near the Akiyoshi Limestone area are compiled in this checklist. The checklist is based on a computer database composed of 287 occurrence data sheets derived from publications that have coral and chaetetid descriptions and illustrations. Generic range are given in terms of Tethyan standard stages for the Carboniferous and Permian. The list contains some duplicate reports based on the same material. Many of corals are figured without any description, and some of them have no precise biostratigraphic information. Further study is needed to determine precise ranges of the taxa. </ABSTRACT>

46353 <TITLE>A Permian rugose coral, Yatsengia kuzuensis, from the Kiryu in the Ashio Mountains, Gunma Prefecture, Japan.</TITLE>
46354 <SOURCE>Bulletin of National Science Museum (Tokyo), ser. C, 26, 1-2: 79-86.</SOURCE>
46355 <ABSTRACT>A Permian rugose coral, Yatsengia kuzuensis (Yabe) was collected from limestone and calcareous sandstone beds exposed in Umeda, north of Kiryu City in the Ashio Mountains, Gunma Prefecture. This species was originally described as the type species of the genus Pseudoyatsengia Yabe, 1951 from the Kuzu Limestone, which is exposed in the Aisawa Quarry, about 30 km east of the present locality. The coral is described here because Pseudoyatsengia is considered to be a synonym of Yatsengia Huang, 1932, and the occurrence of rugose corals in the Ashio Mountains is rather rare. 46367 <SOURCE>Bulletin of National Science Museum (Tokyo), ser. C, 26, 1-2: 33-43.</SOURCE>
46368 <ABSTRACT>Permian limestones designated as the Nabeyama Formation are exposed in the Kuzu area, Tochigi Prefecture. The limestones are particularly abundant in fusulinaceans but uncommon in rugose corals. The limestone pebbles in the conglomerate that unconformably overlies the Nabeyama Formation commonly yield rugose corals. Yatsengia suzukii sp.nov., and waagenophyllum (Waagenophyllum) akasakense (Yabe) from the limestone pebbles are here described. These corals were recycled from the Nabeyama Formation. 46380 <SOURCE>Science Reports of the Institute of Geoscience University of Tsukuba, Section B (Geological Sciences) 15: 125-133.</SOURCE>
46381 <ABSTRACT>Upper Middle Permian rugose corals are newly collected from limestone clasts in chaotic rocks of the Gozenyama Formation exposed along the Akigawa River, Hinohara Village, Nishitama County. The corals are identified as waagenophyllum (waagenophyllum) pulchrum Hamada and Praewentzelella nishiatmaensis Igo, Adachi and Igo, n.sp. The geologic age of these corals is assigned to the Midian (Yabeina Zone) of the late Middle Permian. [original abstract]</ABSTRACT>

- 46510 <SOURCE>Facies 54, 4: 529-547.</SOURCE>
- 46511 <ABSTRACT>Microfacies of the Early to Middle Norian reefal limestone of the Sambosan Accretionary Complex (SAC) at Kamase locality, southwest Japan, are classified into seven major facies types in stratigraphic order: peloidal grainstone-packstone, unfossiliferous lime-mudstone, tubular problematica-rich wackestone, sponge-coral floatstone, sponge bafflestone, coral rudstone, and peloidal-bioclastic packstone-grainstone. The SAC records patch reef development on a mid-oceanic seamount in the Panthalassa Ocean. Because most examples of Triassic reefs come from the former Tethys, counterparts such as those from the SAC are pivotal in resolving paleogeographic issues as well as clarifying the depositional patterns between the eastern Tethys and adjacent western Pacific (Panthalassa). We also reveal that the primary stratigraphy of the reefal limestone was disrupted by submarine landslides of the seamount in an open-ocean realm during the late

- Middle to Late Jurassic time. [original abstract] </ABSTRACT>

- 46524 <ABSTRACT>The catalogue gives a systematic overview on the Mesozoic corals reported from the territory of Japan. The data were taken from the literature and have been improved by data on the type material at the Tohoku University Museum (Sendai) and additional information on the stratigraphy of various localities. It is subdivided into two parts. The taxonomic part encompasses an alphabetical list of all taxa with their types, type locality and type level, the citations in the literature and the occurrence of the corals. The second part is a list of localities from which the corals are reported, with data on the localities' geographical position, their stratigraphy and lithostratigraphy, additional literature, notes and the list of corals indicated there. - 46536 <SOURCE>Bulletin of the Tohoku University Museum 2: 77-110.</SOURCE>
- 46537 <ABSTRACT>The Jurassic corals described by Eguchi, Mori, Murata, Sugiyama and Yabe between 1933 and 1963 held at the Tohoku University Museum (Sendai, Japan) have been revised. The material comes from 44 localities and represents 87 coral species. The revision encompasses the proof of the generic assignment and a profound comparison to Jurassic corals described from localities outside Japan. The high number of endemic species was found to be justified. Only the generic composition of the faunas are comparable to other (mostly European) faunas.</ABSTRACT>

46600 <TITLE>Late Jurassic cnidarian and poriferan fossils from the
Torinosu-type limestones in the Kurosegawa Terrane, western Kii
Peninsula, Southwest Japan and their geological significance.</TITLE>
46601 <SOURCE>Fossils 72: 5-16.</SOURCE>
46602 <ABSTRACT>Cnidarian and poriferan fossils were reported from the

Torinosu-type limestones in the middlemember of the Ikenoue Formation, Kurosegawa Terrane, western Kii Peninsula, Southwest Japan. They include 16 species belonging to 13 genera (nine Scleractinia, one Spongiomorpha, one Sclerospongia, and two Stromatoporoidea). The recorded cnidarian and poriferan fauna shows Late Jurassic in age, and the age estimation is consistent with the radiolarian chronostratigraphic data of the fine-grained clastic rocks enclosing the Torinosu-type limestones. Field observations suggest that the Torinosu-type limestone bodies were originally formed as laterally discontinuous carbonate mounds in shallow marine environment, and they were broken in part into blocks and transported downwards. Torinosu-type limestones associated with fine-grained clastic rocks are widely distributed in the Tithonian to Berriasian strata of both the Kurosegawa and Southern Chichibu terranes in the western Kii Peninsula. It has been discussed that shallow marine carbonate environment was formed as a result of uplift of the fore-arc basin caused by collision of seamounts. Furthermore, thrust movement of the Kurosegawa nappe over the Southern Chichibu Terrane accumulated thick olistostrome on the fore-arc basin during the middle Oxfordian to Kimmeridgian, resulting in the formation of shallow marine environment. </ABSTRACT>

46614 <SOURCE>Facies 50, 2: 217-227.</SOURCE>

46615 <ABSTRACT>Tethyan microencrusts and microbial crusts, most of them previously unknown in Japanese Mesozoic biotas, are present in the uppermost Jurassic-lowermost Cretaceous Torinosu Limestone distributed in southwestern Japan. They construct reefal facies together with reef-forming metazoans. *Bacinella irregularis* and *Lithocodium aggregatum* are quantitatively most important, while subordinate constituents include *Thaumatoporella parvovesiculifera*, *Koskinobullina socialis*, *Iberopora bodeuri*, *Girvanella* sp. and *Tubiphytes morronensis*. They are especially common in the shallow-water reefal facies, but appear micritic in outcrops. Microencrusts and microbial crusts can only be recognized in thin sections, and they grow around the reef building metazoans and form bindstone. Each microencruster exhibits some specific spatial distribution associated with its paleoecology. Similarities with the taxonomic composition of the upper Jurassic Tethyan microencruster association imply that the community extended geographically at least to the Tethyan gateway where the Japanese Island Arc was located. 46666 <SOURCE>Sci. Pap. Coll. Gen. Educ., Univ. Tokyo 19, 2: 251-262.</SOURCE>
46667 <ABSTRACT>The Pleistocene Ninomiya Formation yields the ahermatypic corals such as *Oulangia stokesiana miltoni* Yabe & Eguchi, *Fotocyathus* (*Paradeltocyathus*) *orientalis* (Duncan), *Flabellum* cf. *distinctum* M.-E. & H., *Dendrophyllia cribrata* M.-E. & H., *Flabellum transversale* Moseley. Among them, *Dendrophyllia* is excellently preserved in arborescent shape. Occurrence of the Recent *Dendrophyllia* species in the Japanese waters is reviewed in this occasion.</ABSTRACT>

46691 <TITLE>Fossil Freshwater sponges from the Middle Pleistocene Tsumori Formation in Mashiki-machi, Kumamoto Prefecture, Japan.</TITLE>
46692 <SOURCE>Scientific Reports of the Toyohashi Museum of Natural History 14, pp 1-7</SOURCE>
46693 <ABSTRACT>Fossils of spongillid sponges, *Eunapius fragilis* and *Ephydatia muelleri* occur in the Middle Pleistocene Tsumori Formation in Mashiki-machi, Kumamoto Prefecture, Japan. This is the 2nd record of *Eunapius fragilis* and *Ephydatia muelleri* from the Pleistocene in Japan. The Tsumori Formation consists of a lacustrine sediment which contains fossils of diatoms, plant fragments, sponges, molluscs, insects, and fish. The fossil sponges occur in the lower part of the Tsumori Formation that is subdivided into the lower and upper parts with lithological characters. The fossils are found on the surface of plant fragments and in massive mudstone. Those occurrences suggest that the sponges were rapidly deposited after death of the sponge. If the habitat of the sponges have not changed over time, the fossil sponges from the lower part of the Tsumori Formation is inferred to have been formed in shallow lake with waters of high mineral and organic contents.

46704 <TITLE>A fossil freshwater sponge (Porifera; Spongillidae) from the Pliocene Hitoyoshi Formation in the Hitoyoshi Basin, Kumamoto Prefecture, Japan.</TITLE>
46705 <SOURCE>Science report of the Toyohashi Museum of Natural History 16: 31-37.</SOURCE>
46706 <ABSTRACT>Fossils of spongillid sponge, *Eunapius sinensis* (Anmandale) were discovered from the upper part of the Pliocene Hitoyoshi Formation of the Hitoyoshi Basin, Muamoto Prefecture, Kyushu, Japan. They constitute the second occurrence record of *Eunapis sinensis* as fossil. The Hitoyoshi Formation consists of lacustrine deposits, which contain diatoms, water plant, insects, cyprinid fishes, and molluscs besides the sponge. Gemmules of fossil sponges occur as rounded spots, which encrust the surfaces of molluscan shells and massive mudstones. The spicular components consist of megascleres and gemmoscleres, and the latter are more abundant. This mode of occurrence of fossil sponges suggests only gemmules were left after death on the surface of molluscan shells and mud.</ABSTRACT>

46717 <TITLE>Pleistocene reef development and stratigraphy on Ie-jima, the
Ryukyu Islands, southwestern Japan.</TITLE>
46718 <SOURCE>Proceedings of the 10th International Coral Reef Symposium
(Okinawa), 536-546.
http://www.reefbase.org/resource_center/publication/pub_26765.aspx
</SOURCE>
46719 <ABSTRACT>Sedimentological investigations were conducted on Pleistocene
reef-complex deposits of the Ryukyu Group, recovered in 30 drill cores
from Ie-jima, off Motobu Peninsula, the Ryukyu Islands, southwestern
Japan. Four depositional units are identified by lithologic changes and
numbered sequentially from the base upwards. Unit 1, the lowest unit,
commonly begins with marine conglomerate or coral limestone, both of
which grade upward into detrital limestone containing abundant larger
foraminiferal tests (*Operculina* spp. and *Amphistegina* spp.). Units 2
and 3 are composed of shallow-water coral limestone overlain by
deep-water detrital and rhodolith limestones. Unit 4, unconformably
overlying Unit 3 at elevations exceeding 50m, consists of coral
limestone grading upward into detrital limestone rich in coral rubble.
These units clearly display a deepening-upward stratigraphic
succession. Calcareous nannofossil biostratigraphy indicates that Unit
1 mostly correlates with the Early Pleistocene between 0.85 Ma and 1.65
Ma and that Units 2 to 4 range in age from 0.41 Ma to 0.85 Ma. Thick
deposits of carbonates and siliciclastics (Unit 1) formed in response
to tectonic subsidence of this area before 0.85 Ma. Subsequently,
reefal and shelf carbonates (Units 2 to 4) accumulated in response to
glacioeustatic sea-level changes. The change is likely to be related to
the Mid-Pleistocene Transition (MPT). The MPT at the Ryukyus is marked
by increased amplitude of sea-level changes and a subsequent enhanced
mode of coral-reef deposition. [original abstract]</ABSTRACT>

46769 <TITLE>A study of Fossil Corals from Tateyama city and its Environs and Recent Coral Fauna of Chiba Prefecture, Central Japan.</TITLE>
46770 <SOURCE>Bulletin Tokyo College of Domestic Science 13: 41-52. [in Japanese, with English summary]</SOURCE>
46771 <ABSTRACT>Numa coral bed of Tateyama city is famous for Japanese Geologists, because of its well studied fossil corals and known as only one Pleistocene reef formation in Honsyu. Since July 1969 we have often chances to study the localities and obtained several fossil and recent specimens of corals. Some 100 species of corals were known to occur there, judging from the growth form, especially abundant Echinophyllia, Pectinia and other thin explanate delicate forms it belongs evidently [to] calm inland bay facies. Among them following two species of southern form were discovered as first fossil occurrence. Palauphyllia hataii is a Lobophyllid coral and its distribution is now restricted in the tropical or subtropical sea (Loc. Palau Islands, Pracer Islands and Ogasawara Islands). Koseleya sp. is similar to Moseleya latistellata of the Great Barrier Reef, but much smaller in size and much larger than M. minor Ma (nom. nud.). Echinophyllia, Acropora, Caulastrea are illustrated here as fossil. Several ahermatypic corals thriving the continental shelf of Chiba pref. were listed here for the future study of fossil corals of the younger cenozoic formations of Kwanto district, and others.</ABSTRACT>
