shore to the reef edge was depicted along an approximately 420-m transect on the Hirota Coast of this island. A total of 20 quadrats (1m x 1m) were analyzed along the profile at 10- or 20-m intervals to clarify distribution of macrobenthos inhabiting the reef. The Hirota Reef is divided into four geomorphologic zones according to their depth, gradient, surface roughness, substrate and characteristic macrobenthos. They are, from shore to offshore, shallow lagoon, seaward reef flat, reef edge and reef slope. The shallow lagoon comprises a shoreward depression (~160m wide on the transect) with a sand/gravel bottom that inclines gently toward offshore, and a seaward patch zone (~70m wide). The patches (~2m high) are covered with fleshy algae, coralline algae and hermatypic corals. The seaward reef flat (~190m wide) is a flat plane that is constructed by biogenic carbonates and is covered with turf algae, with hermatypic corals scattered. Although the seaward reef flat of the Hirota Reef cannot be differentiated into different geomorphologic zones, similar seaward reef flat areas in the Central and South Ryukyus can be clearly subdivided into inner reef flat, reef crest and outer reef flat. This difference may be attributed to a lower reef growth rate and/or the later reef formation of the Hirota Reef in Holocene time than the southern examples. The coral fauna on the Hirota Reef is delineated by low diversity and characterized by taxa typical of high-latitude, non-reefal communities. The algal flora consists of tropical to subtropical species associated with warm-temperate species. These faunal and floral characteristics may be related largely to lower water temperature in Tane-ga-shima than those in typical coral-reef regions. [original abstract] </ABSTRACT>

46912 <TITLE>Introductory perspective on the COREF project.</TITLE>
46913 <SOURCE>Island Arc 15, 4: 393-406.</SOURCE>
46914 <ABSTRACT>Coral reefs are tropic to subtropic, coastal ecosystems
comprising very diverse organisms. Late Quaternary reef deposits are
fossil archives of environmental, tectonic and eustatic variations that
can be used to reconstruct the paleoclimatic and paleoceanographic
history of the tropic surface oceans. Reefs located at the latitudinal

limits of coral-reef ecosystems (i.e. those at coral-reef fronts) are particularly sensitive to environmental changes - especially those associated with glacial-interglacial changes in climate and sealevel. We propose a land and ocean scientific drilling campaign in the Ryukyu Islands (the Ryukyus) in the northwestern Pacific Ocean to investigate the dynamic response of the corals and coral-reef ecosystems in this region to Late Quaternary climate and sealevel change. Such a drilling campaign, which we call the COREF (coral-reef front) Project, will allow the following three major questions to be evaluated: (i) what are the nature, magnitude and driving mechanisms of coral-reef front migration in the Ryukyus? (ii) what is the ecosystem response of coral reefs in the Ryukyus to Quaternary climate changes? (iii) what is the role of coral reefs in the global carbon cycle? Subsidiary objectives include: (i) the timing of coral-reef initiation in the Ryukyus and its causes; (ii) the position of the Kuroshio current during glacial periods and its effects on coral-reef formation; and (iii) early carbonate diagenetic responses as a function of compounded variations in climate, eustacy and depositional mineralogies (subtropic aragonitic to warm-temperate calcitic). The geographic, climatic and oceanographic settings of the Ryukyu Islands provide an ideal natural laboratory to address each of these research questions. [original abstract] </ABSTRACT>

46925 <TITLE>230Th/234U and 14C dating of a lowstand coral reef beneath the insular shelf off Irabu Island, Ryukyus, southwestern Japan.</TITLE>

46926 <SOURCE>Island Arc 15, 4: 455-467.</SOURCE>

46927 <ABSTRACT>High-resolution seismic reflection profiles delineated the distribution of mound-shaped reflections, which were interpreted as reefs, beneath the insular shelf western off Irabu Island, Ryukyus, southwestern Japan. A sediment core through one of the mounded structures was recovered from the sea floor at a depth of -118.2m by offshore drilling and was dated by radiometric methods. The lithology and coral fauna of the core indicate that the mounded structure was composed of coral-algal boundstone suggesting a small-scaled coral reef. High-precision α -spectrometric 230Th/234U dating coupled with calibrated accelerator mass spectrometric 14C ages of corals obtained reliable ages of this reef ranging from 22.18 ± 0.63 to 30.47 ± 0.98 ka. This proves that such a submerged reef was formed during the lowstand stage of marine oxygen isotope stages 3-2. The existence of low-Mg calcite in the aragonitic coral skeleton of 22.18 ± 0.63 ka provides evidence that the reef had once been exposed by lowering of the relative sealevel to at least -126m during the last glacial maximum in the study area. There is no room for doubt that a coral reef grew during the last glacial period on the shelf off Irabu Island of Ryukyus in the subtropical region of western Pacific. 46938 <TITLE>Latitudinal changes in larger benthic foraminiferal assemblages in shallow-water reef sediments along the Ryukyu Islands, Japan.</TITLE>
46939 <SOURCE>Island Arc 15, 4: 437-454.</SOURCE>
46940 <ABSTRACT>The variations in foraminiferal abundance in reef sediments from three latitudinally different islands exhibit two contrasting trends along reef flats: a shoreward decrease on Ishigaki and Tane-ga-shima Islands and a shoreward increase on Kudaka Island. A total of 25, 24 and 13 foraminiferal taxa were identified in Ishigaki, Kudaka and Tane-ga-shima Islands, respectively. Baculogypsina sphaerulata, Neorotalia calcar and Amphistegina spp. were dominant (i.e. >3% of foraminiferal assemblages) in the three islands. Calcarina gaudichaudii and Calcarina hispida were common on Ishigaki and Kudaka Islands but were absent on Tane-ga-shima Island. Larger foraminiferal assemblages from three different reef-flat environments on Ishigaki Island can be distinguished, whereas those from the three environments on Kudaka and Tane-ga-shima Islands are similar in composition. These latitudinal changes in larger foraminiferal assemblages in reef sediments may possibly be caused by variations in the topography of reef flats, distributions and standing crops of living foraminifers on reef flats, and the northern limit of some calcarinid species in the northern Ryukyus. 46951 <TITLE>Holocene sea-level change and tectonic uplift deduced from raised reef terrace, Kikai-jima, Ryukyu Islands, Japan.</TITLE>
46952 <SOURCE>Sedimentary Geology 159, 1-2: 5-25.</SOURCE>
46953 <ABSTRACT>Kikai-jima (Kikai Island) is surrounded by four Holocene raised coral reef terraces, which are thought to be an offlapping sequence of reef deposits caused by combined effects of seismic uplift and Holocene sea-level change. Many studies in this region have investigated Holocene sea-level changes and reef growth, but there are relatively few in which reliable sea-level indicators are given. We have found that Pocillopora verrucosa, one of the most abundant coral species on the upper-reef slopes of fringing reefs in the Ryukyus, has its peak abundance at a depth of 1.5m. Therefore, this species is considered ideal for the analysis of relative sea-level change and can be used as a dipstick for the Holocene reef deposits in this area. Based on the distribution of P verrucosa on the four Holocene raised terraces, we calculate relative paleo-mean sea levels to be 10.8-11.1 and 8.5-8.9 m for Terrace I, 5.0-5.3 m for Terrace II, 4.0-4.3 m for Terrace III and 1.9-2.5 m for Terrace IV. These results, combined with hitherto known and newly measured radiometric dates (103 total), clearly show that the four terraces formed in response to repeated seismic uplifts at 6.3, 4.1, 3.1 and 1.4 ka, and that sea level was higher than present between 7.0 and 6.3 ka. 46964 <TITLE>Anatomy of a modern coral reef flat : A recorder of storms and uplift in the late Holocene.</TITLE>
46965 <SOURCE>Journal of Sedimentary Research 71, 2: 295-304.</SOURCE>
46966 <ABSTRACT>Cores from the Kabira Reef, Ishigaki Island, southwest Japan, reveal the internal structure and temporal changes in sedimentary process of a complete coral reef flat. The reef crest caught up with sea level at about 4000 yr BP. Since then, it expanded oceanward and the reef pavement has grown landward. The backreef structure is composed of bioclasts derived from the reef framework. Of all the bioclasts, corals and coralline algae are most abundant. Coral fragments coarser than - 3,0 Ø have dominated the backreef sediments since 2000 yr BP. Benthic foraminiferal tests first occurred at about 4000 yr BP, and their abundance increased significantly starting around 2000 yr BP. Shallowing of the reef crest is also indicated by the presence of the shallow-water benthic Foraminifera Baculogypsina sphaerulata tests after 2000 yr BP. The date 2000 yr BP is coincident with tectonic uplift at Kabira Reef (Kawana 1989). We consider this uplift to have caused a relative sea-level fall that aided the deposition of coral fragments transported from the reef pavement by storms. The relative sea-level fall also caused subaerial exposure of the reef crest during low tides and the transition of reef-building organisms from corals to shallow-water species of benthic Foraminifera, resulting in a change noticeable in the constituents of backreef sediments. The results of this study suggest that the coral reef flat, and especially the backreef, can be a faithful recorder of relative sea-level changes.</ABSTRACT>

- 47096 <ABSTRACT>The species Echigophyllum giganteum Yabe and Hayasaka is here redescribed from the Omi Limestone, Niigata Prefecture, central Japan. The systematic position of the genus Echigophyllum within the Clisiophyllinae is discussed. It is concluded that Echigophyllum should be restored as an independent genus, having been regarded previously as junior synonym of the genus Amygdalophyllum Dun and Benson by Hayasaka (1939). - 47173 <SOURCE>Facies 34, 1: 239-256.</SOURCE>
- 47174 <ABSTRACT>This contribution emphasizes the significant rock-building role of microbial encrusting organisms including Tubiphytes, filamentous cyanobacteria (mainly Girvanella and Ortonella), and Archaeolithoporella in the Carboniferous to Permian buildups that formed on seamounts in the Panthalassa ocean. The description concentrates on the paleontological characters of these microbes and the petrographic properties of the microbial bindstones and related cryptomicrobial fabrics. Comparisons of major rock-building biotas in the Carboniferous-Permian Panthalassan buildups and Parigean reefs are briefly discussed. The Lower Carboniferous (Visean) to upper Middle Permian (Murgabian) limestone units and the upper Lower to upper Middle Permian (Artinskian to Murgabian) limestone units in southwest Japan were examined. All these limestone units are underlain by oceanic island-type basalts and are totally free from terrigenous materials. The limestones are lying in disrupted accretionary terranes of Japan and are regarded as relicts of oceanic buildups upon seamounts in the Panthalassan open-ocean realm. [first fragment of extensive summary]

- 47212 <SOURCE>Geological Magazine 132, 4: 367-373.</SOURCE>
- 47213 <ABSTRACT>Middle and Late Cambrian reefs were built mainly by cyanobacterial communities. A few reefs with a metazoan as well as an algal component, however, are known from this interval. A Middle Cambrian reef formed primarily by spicular demosponges is described here from the Mila Formation in the Elburz Mountains, northern Iran. The reef is enclosed within calcareous grainstones which contain terminal Middle Cambrian (late Mayan) trilobites. The Mila Formation reef was constructed by sponges of the family Anthaspidellidae and bacterial (algal?) sheaths, and is the earliest metazoan reef to be documented from the interval after the demise of archaeocyath sponges. The reefal community is typical of subsequent reefal communities of Early-Middle Ordovician age. The Ordovician examples differ only by the incorporation of additional metazoan elements.</ABSTRACT>

- 47225 <SOURCE>Bulletin of the Tohoku University Museum 1 [Proceedings of the 8th International Symposium on Fossil Cnidaria and Porifera]: 125-133.</SOURCE>
- 47226 <ABSTRACT>Middle to Upper Cambrian sponge mounds occur in shallow marine carbonates, (the Mila Formation) of the southern Elburz Mountains, northern Iran. The mounds are up to 6m thick, with a 30m diameter, and have low, rigid frameworks formed by a single species of the demosponge genus Rankenella and microbial micrite. The mound bearing unit mainly consists of coarse grained crinoidal grainstone, less than 70m in thickness, and includes brachiopod shell beds and oncoids. Cross stratified and lenticular grainstone units indicate shoaling. During the development of the carbonate shoal, water energy increased and the shoal was cut off from terrigenous influx. Stabilization by brachiopods or early lithification may have provided favorable substrates for sponge colonization. The sponges probably adapted to a clear, strong water flow, which provided an effective nutrient supply, thus inhabiting the environment previously occupied by archaeocyaths. These Iranian mounds represent the oldest reef building by a non archaeocyath sponge community (Hamdi et al., 1995). Middle to Late Cambrian reef building in other localities generally is by microbial thrombolites and stromatolites. Although the Iranian mound

- community is very simple, it is regarded as an ancestor of Early Ordovician sponge microbial reefs. [original abstract] </ABSTRACT>

- 47252 <ABSTRACT>Auf Grund der Rugosen-Fauna des Type- und des Reference-section der Niur-Formation Ost-Irans sowie einiger anderer Rugosenfunde aus dieser Formation aus den Gebieten Ozbakuh und Shirgesht kann diese Formation in zwei "Faunenzonen" gegliedert werden. Die tiefere ist durch das Auftreten von Streptelasma, Tenuiphyllum, Paliphyllum etc., die hoehere durch cystiphyllide Rugosa, Spongophylloides etc. charakterisiert. Ihre Verteilung geht aus Abb. 5 hervor. Die Rugosengenera erlauben im Verein mit einigen Altershinweisen, die durch andere Tiergruppen (Stromatoporen, Conodonten, Brachiopoden) gewonnen wurden, eine Einstufung der unteren "Zone" in das Llandovery, der oberen "Zone" in den Bereich Ludlovium bis Lochkovium. Da es sich fast durchwegs um neue Arten handelt, koennen keine zoogeographischen Aussagen gemacht werden.</ABSTRACT>

- 47278 <ABSTRACT>La première partie est consacrée à la présentation de la série paléozoïque observée dans chacun des deux gisements avec son contenu faunistique et les attributions d'âge. Cette série qui atteint 2000m à Robat-e-Garabil, est perturbée en son milieu et comprend du Silurien à Polypiers et Brachiopodes (Llandovery à Wenlock), des dépôts détritiques et évaporites (Dév. inf.?) du Dévonien moyen (Eif.-Giv.) et supérieur (Fras.) marin richement fossilifère. A Khochaïlagh, des séries marines marno-calcaires très riches en Brachiopodes rappelant celles d'Afghanistan occidental représentent le Dévonien moyen (Eif.-Giv.) et supérieur (Famen.), elles reposent sur des formations volcaniques et détritiques (Dév. inf.). * La seconde partie comprend la description des principaux fossiles de la série, en particulier celle des coraux siluriens (Jean Lafuste). Ceux-ci sont représentés par les genres de Tabulata suivants: Palaeofavosites, Mesofavosites, Plasmopora.</ABSTRACT>

- 47330 <ABSTRACT>From collections made in the seventies, coming from different localities in eastern Iran (Tabas and Kerman regions; de Lapparent collection) and central Iran (Soh region, Zahedi collection), fourteen species are described. From Silurian, one species is attributed to *Araeopoma* (first citation outside the type-area: Gotland) and on to *Axolasma*. Ten are Devonian and have been yielded by the same stratigraphic level which is Lower to Middle Frasnian in age (Brachiopod zone 6 of Brice 1977). They are: two *Disphyllum* species (one is *Disphyllum caespitosum tricyclicum* von Schouppé, 1965); two *Hexagonaria* species also found in Afghanistan; one species of *Cystihexagonaria* with, where septal thickening is noticeable, large monacanth of *Hexagonaria*- type; two *Macgeea* species; *Temnophyllum lapparenti* nov. sp.; *Sinodisphyllum* sp. and *Peneckiella* ? cf. *cylindricum* (Yoh, 1937). From Carboniferous, *Sinophyllia cylindrica* and from Permian *Polytehcalis* cf. *denticulatus* are also included. Affinities of the Devonian corals are with those of Afghanistan and Chitral.</ABSTRACT>

47342 <SOURCE>Senckenbergiana lethaea 68 1/4: 263-303.</SOURCE>
47343 <ABSTRACT>As an introduction to the geology of the Devonian of the area of the town of Adapazari, NW Turkey, the geological position of the Alabalik Member at the base of the Yilanli Formation is outlined by reference to its type section (O. Kaya). At its type locality the Alabalik Member contains a relatively well-preserved fauna of rugose and tabulate corals which are described herein for the first time (R. Birenheide). The majority of the 16 currently recognized species are conspecific with described taxa or comparable with such species, of which the bulk of occurrences have been recorded from the Middle Eifelian of Eurasia and N Africa; therefore the Alabalik Member is very probably of the same age. The following species are new: Xystriphyllum kayai n.sp., Dohmophyllum bulbosum n.sp., Favosites dorotheae n.sp., Mariusilites osmanicus n.sp., Mesolites interruptus n.sp. and Heliolites asiaeminoris n.sp.</ABSTRACT>

47368 <SOURCE>Annales de la Societe geologique du Nord 8 (2eme serie): 67-71.</SOURCE>
47369 <ABSTRACT>Three rugose coral species are described from collections made in the two biostromes of Kuh-e-Kaftar section n°2, at Chariseh, Esfahan province, central Iran: Disphyllum sp. 1, Hexagonaria cf. magna

(Fenton & Fenton, 1924), sensu Brice, 1971 and *Temnophyllum lapparenti* Rohart, 1999. This coral level is an interesting stratigraphic marker since it also occurs in eastern Iran and in Afghanistan with the same coral species and with brachiopods characteristic of the 6th Brachiopods Zone of Brice (1977), as here. In central Iran, *Hexagonaria* cf. *magna* was formerly found in the Soh area (Rohart 1999) but without associate fauna. The age is lower to middle Frasnian according to the brachiopods; according to the conodonts, it is inside the interval "middle to late Frasnian (jamieae Zone to rhenana Zone)"; (Ghomalian 1998).</ABSTRACT>

 47380 <TITLE>Rugose Korallen des Givetium und Frasnium im Elburz-Gebirge (Nord-Iran).</TITLE>
 47381 <SOURCE>Diss. Univ. Hamburg 171 pp., 11 figs.; Hamburg. [German, English summary]</SOURCE>
 47382 <ABSTRACT>Givetian and Frasnian corals (Rugosa) of four sections from the Devonian Khoshyeilagh-Formation in North-Iran (Elburz) were palaeontologically studied. 16 genera and 25 species were systematically described. 12 species belong to the Givetian and 10 species to the Frasnian. Three species indicate upper Givetian to lower Frasnian range. By these species definite Givetian was identified and definite Frasnian was confirmed in the Khoshyeilagh-Formation. Eifelian age could not be identified because none of the examined sections delivered any definite Eifelian coral. The Devonian corals manifest an evolution from lower Givetian to upper Frasnian in the Elburz. The sections were correlated according to the biostratigraphic and lithological facts. Ontogenetic studies demonstrate that species within one genus have similar ontogenetic development. Studies of phylogenetic evolution indicate that species within one genus (f. ex. *Disphyllum*, *Heliophyllum*) derive from each other or replace one another. Ecological circumstances permit relatively good conditions for the evolution of Devonian corals in the shelf-region. [original summary]Described are the following species: *Disphyllum caespitosum*, *D. cf. geinitzi*, *D. virgatum*, *D. lazutkini*, *D. caespitosum caespitosum*, *D. hsianghsienense kostetskae*, *Ceratophyllum dohmi*, *Charactophyllum nanum*, *Heliophyllum halli*, *H. shinnery*, *H. aiense*, *Temnophyllum* cf. *richardsoni*, *T. cf. difficile*, *Columnaria sulcata*, *Donia laxa*, *Hexagonaria* cf. *philomena*, *H. cf. hexagona*, *Macgeea* cf. *proteus*, *M. cf. bathycalyx kasimiri*, *Stringophyllum* cf. *inflatum*, *Thamnophyllum caespitosum*, *Spongophyllum imperfectum*, *Aulacophyllum vesiculatum*, *Tabulophyllum gracile*, *Scenophyllum* sp.</ABSTRACT>

47445 <TITLE>New data on distribution of brachiopods, rugose corals, and stromatoporoids in the Upper Devonian of central and eastern Iran. Paleobiogeographic implications.</TITLE>
47446 <SOURCE>Annales de la Societe geologique du Nord 7 (2eme serie): 21-32.</SOURCE>
47447 <ABSTRACT>The Upper Devonian (Frasnian and Famennian) of Iran is briefly reviewed, as is the geologic setting of specific sections sampled in eastern and central Iran in the 1970s by A. F. de Lapparent. Recent study or revision of the fauna from these sections in relation to the program of IGCP 421 has included Frasnian and Famennian rhynchonellid and spiriferid brachiopods (Brice, 1999b), stromatoporoids (Mistiaen, 1999) and rugose corals (Rohart, 1999). Taxa discriminated and their stratigraphic distribution are tabulated. Ages, affinities and paleobiogeographic distribution of these faunas are discussed.</ABSTRACT>

47459 <SOURCE>Societe geologique du Nord</SOURCE>
47460 <ABSTRACT>Volume 1 is largely stratigraphic but its 6th part includes a summary of the biostratigraphy of the 28 stromatoporoid taxons that occur in these sections. Volume 2 is devoted to the stromatoporoids and discusses their stratigraphic distribution in Afghanistan and the relationship of the fauna to other Frasnian and Givetian faunas. In the systematic section species of the following genera are described and figured: Actinostroma (5), Atelodictyon (4), Bifariostroma (1), Anostylostroma? (1), Pseudostictostroma (1), Clathrodiction (1), Clathrocoilon (2), Stictostroma (3), Stromatoporella (1), Geronostroma (1), Atopostroma (1), Stromatopora (2), Salairella (1), Taleastroma (3), Habrostroma (2), Hermatostroma (3), Stachyodes (3), Euryamphipora (1), Labechia (1). Only two of the species are new (Atelodictyon dewalense, Hermatostroma afghanense). Most genera are discussed at length and several are placed in synonymy.</ABSTRACT>

47471 <TITLE>On some Devonian (Frasnian) stromatoporoids from Kerman province, eastern Iran.</TITLE>
47472 <SOURCE>Annales de la Societe geologique du Nord 7 (2eme serie): 33-44.</SOURCE>
47473 <ABSTRACT>The present study is based on material consisting of twenty or so stromatoporoid specimens collected by de Lapparent at the beginning of the seventies in Kerman Province (Bidu River and Ab-Bid sections) in east-central Iran. Although stromatoporoids have been

noted several times in the Devonian of Iran, until now, no systematic studies have been published. However, *Actinostroma stellulatum* Nicholson 1886a was identified from the Tabas area by Flügel (1961) and *Amphipora* sp. was cited from the Kerman area by Wendt et al. (1997). The following stromatoporoid species have been recognized and are here described: *Actinostroma filitextum* Lecompte, 1951, A. sp., *Stictostroma saginatum* (Lecompte, 1951), S. brylkini (Yavorsky, 1955), *Clathrocoilona* cf. *inconstans* Stearn, 1962, C. sp., *Dendrostroma* sp., *Hermatoporella* cf. *pertabulata* (Zukalova, 1971), *Habrostroma dubia* (Lecompte, 1952), H. sp., *Stachyodes costulata* Lecompte, 1952, and *Stachyodes australe* (Wray, 1967). This stromatoporoid fauna clearly shows very close relations with the Frasnian Afghan stromatoporoid fauna recognized by Mistiaen (1985) in the Central Mountains and in the Axial zone, and more generally with the well-known very cosmopolitan Frasnian stromatoporoid fauna of the Old World Realm (Brice et al. 1999).

 47498 <SOURCE>Annales de la Societe geologique du Nord 9 (2eme serie): 81-91.</SOURCE>
 47499 <ABSTRACT>Stromatoporoids and tabulate corals were collected in the Kuh-e Kaftar section n° 2, Chahriseh area, Central Iran, in two biostromal horizons, middle Frasnian in age (apparently) situated just below the jamieae Conodont Zone). The stromatoporoid fauna of Chahriseh, with *Stictostroma saginatum* (Lecompte, 1951), *Clathrocoilina* cf. *inconstans* Stearn, 1962, *Habrostroma dubia* (Lecompte, 1952), *Stachyodes australe* (Wray, 1967) and probably *Hermatoporella* cf. *pertabulata* (Zukalova, 1971), is very similar to the Frasnian stromatoporoid fauna previously observed in the Kerman area, Eastern Iran, and characteristic of the cosmopolite Frasnian stromatoporoid fauna. The tabulate corals are represented by numerous alveolitids, *Scoliopora* sp. and some *Auloporids*, with *Thecostegites bouchardi*

- (Michelin, 1846) a characteristic and interesting Franian species.

47538 <ABSTRACT>En Afghanistan central des Bryozoaires Fistuliporides sont
très abondants à plusieurs niveaux du Dévonien. * Cette note précise le
cadre géographique et stratigraphique où ils ont été observés. L''
étude est centrée sur trois niveaux particulièrement riches, elle
insiste sur les variations constatées dans l''abondance, la
morphologie des Bryozoaires, la composition des associations fauniques,
la nature des microfaciès. Les remarques paléocéologiques apportent des

- éléments en vue d'une reconstitution paléogéographique d'une partie de la région au Frasnien supérieur. L'originalité de ces niveaux construits par des Bryozoaires est soulignée. </ABSTRACT>

- 47564 <ABSTRACT>Three Upper Palaeozoic corals from three different horizons are first described from the Sainbeyli region of Turkey. Waagenophyllum (W.) kueichowense Huang horizon is probably the Permian Khachik age. Kueichouphyllum yabei Minato horizon is the Visean and Caninia cornucopiae Michelin horizon may be the Tournaisian in age. Both Waagenophyllum and Kueichouphyllum are the elements of old Tethyan faunal realm in the Permian and in the Carboniferous respectively, thus indicating that in general Turkey was a part of that palaeobiogeographical province during most of the Upper Palaeozoic. - 47590 <ABSTRACT>Material collected during the fieldtrip of the 4th IGCP 421 meeting (December 1998) in the Palaeozoic (Frasnian, Famennian, Permian) of Kuh-e Kaftar section 2, Chahriseh area, as well as complementary material from Kuh-e Kaftar section 1 are studied. In the concerned area, the Frasnian succession can be divided into two successive units, a lower detrital unit and an upper carbonate unit. Few charophytes come from the lower Frasnian unit (Middle falsiovalis to Late ? hassi Conodont Zone). - Most of the collected material (stromatoporoids, tabulate and rugose corals, bryozoans, brachiopods, ostracods) come from the lower and middle part of the upper carbonate Frasnian unit, especially from two biostromal horizons, apparently located just below the jamieae Conodont Zone. - Some elements (brachiopods, ostracods, trilobites) come from the upper Famennian succession (probable expansa Conodont Zone). - Finally, some of the studied samples (trilobites) are from Permian. The following fossil groups are concerned with by this study: charophytes, carbonate microproblematica, stromatoporoids, tabulate and rugose corals, probable annelids, bryozoans, brachiopods, ostracods, trilobites and ichnofauna. Six of them are concerned with a separate systematic analysis (carbonate microproblematica, stromatoporoidea, tabulate and rugose corals, probable annelids, brachiopods). </ABSTRACT>

47640 <TITLE>First record of *Heterocorallia* (*Hexaphyllia* Stuckenberg 1904) from the Lower Carboniferous (Viséan), west-central-Sinai, Egypt.</TITLE>
47641 <SOURCE>*Senckenbergiana lethaea* 86, 1: 1-21.</SOURCE>
47642 <ABSTRACT>The first record of *Heterocorallia* anywhere in Egypt is in Early Carboniferous (Viséan) shallow-marine carbonates of the UM Bogma Formation in west-central Sinai. These strata contain the small, single heterocoral species *Hexaphyllia marginata* (Fleming), for which we statistically document marked intraspecific morphological variations. *Hexaphyllia marginata* has a global geographical distribution longitudinally but occurs only in the tropical and sub-tropical regions within a latitude range of about 30° N to 30° S. This first Egyptian *Hexaphyllia* occurs with a particular association of exclusively nondissepimented, small, solitary rugose corals, brachiopods, bryozoans, and other organisms. Small-sized *Hexaphyllia marginata* might have been resistant palaeoecologically that they survived even in the unfavourable habitat conditions on an open, subtropical platform.</ABSTRACT>

47654 <SOURCE>Geologica et Palaeontologica 26: 13-27.</SOURCE>
47655 <ABSTRACT>Solitary rugose and tabulate corals are described from the Middle Visean carbonates of the Um Bogma Formation. Corallites belonging to Amplexizaphrentis Vaughan and Syringopora Goldfuss, though most abundant, are not diversified enough to be useful for zonation. Amplexocarinia sp. and Pleurosiphonella sp. are new for Egypt and may represent an undescribed species. Similarly, a marine fauna including the brachiopod Orthotetes subglobosus Girty and a velellid hydrozoan belonging to Plectodiscus Ruedemann is newly discovered from the Carboniferous clastics of Wadi Khaboba. This further indicates a nearshore shallow marine environment and a Late Visean-Early Namurian age for the kaolin-producing horizon Abu Thora Formation.</ABSTRACT>

47706 <SOURCE>Earth Science [Chikyū Kagaku] 60, 2: 85-92.</SOURCE>
47707 <ABSTRACT>Paleozoic stratigraphy of the Shahmirzad area in the east Elburz Mountains, north Iran is described. The Carboniferous Mobarak Formation consisting of banded limestone and shale is divided into ten lithological units and correlated with the Tournaisian and Lower Visean. A tabulate coral *Vaughania* sp. occurs from the lowest unit (Unit A) of the formation, which is correlated with the lowermost Carboniferous biozone. Geological ages of *Kueichouphyllum* and *Keyserlingophyllum* that were formerly described as the Upper Visean rugose corals in this area or north Iran are revised to the Upper Tournaisian.</ABSTRACT>

- 47731 <TITLE>Revision of the late Visean - Serpukhovian (Mississippian) calcareous algae, foraminifers and microproblematica from Balia-Maden (NW Turkey).</TITLE>
- 47732 <SOURCE>Geobios 43, 5: 531-546.</SOURCE>
- 47733 <ABSTRACT>The taxonomic revision of the carbonate microbiota of the limestone lenses intercalated into the Carboniferous siliciclastic series of Balia-Maden (Turkey) shows that most lenses are early or middle Brigantian in age (latest Visean), only a single lens being of younger age (late Serpukhovian). Calcareous microbiota are abundant in the Balia-Maden lenses carbonates. Microfacies analysis shows the dominance of shallow water environments. The Brigantian assemblage is accurately illustrated. The new foraminiferal taxon *Cribrospira baliamadeni* nov. sp. is morphologically similar to type-material of *Cribrospira panderi* von Moller, but has a porous wall with wider pores, almost keriothecal. *C. baliamadeni* nov. sp. corresponds to the misinterpreted *Bradyina* and *Janischewskina* of the previous literature on Balia-Maden lenses. These limestones show a great diversity of algaesponges (carbonate microproblematica). Among them, (1) small, atypical *Fasciella* previously confused with *Eosigmoilina*; (2) an abundant form described for the first time, *Frustulata reticulata* nov. sp.; and (3) typical *Falsocalcifolium punctatum* (Maslov), important for the biostratigraphic implications, are also mentioned. The single Serpukhovian lens consists of a grainstone and contains the age-sensitive alga *Archaeolithophyllum johnsoni* Racz, and the foraminifers *Monotaxinoides gracilis* and *Janischewskina* sp. - 47746 <ABSTRACT>The marine macrofauna from the Um Bogma Formation (Egypt) is mainly composed of small corals, brachiopods, some bryozoans and a few molluscs. An early Carboniferous age of the fossiliferous carbonate deposits is confirmed and substantiated by either revised or additional material. Littoral marine deposits of both similar age and related biofacies occur in Libya, Morocco and to some extent even in Western Europe, indicating benthonic communities which flourished on an agitated Tethyan shelf in moderately deep and rather warm water.</ABSTRACT>

</SOURCE>

47759 <ABSTRACT>The Lower Carboniferous (Visean) succession of the Um Bogma Formation at Gabal Nukhul, west-central Sinai is subdivided into lower, middle and upper members. Integrating field observations and microfacies analysis led to the recognition of six microfacies as follows: wackestone/packstone, packstone/grainstone, grainstone, bafflestone, calcareous quartz arenite and paleokarst breccia. The paleokarst breccia is the first record to indicate an Early Carboniferous karstification in the Gabal Nukhul area. During the Early Carboniferous (Visean) marine transgression, the lower member of Um Bogma Formation was deposited in intertidal to shallow subtidal environments. A marked drop in sea level and/or syndimentary block faulting (uplifting) led to subaerial exposure of the lower member and followed by karstification process (paleokarst surface). The middle member was deposited in an open platform environment followed by shallow subtidal facies of the upper member. The uniform stacking pattern of the middle and upper member's facies implies a characteristically regressive trend throughout the studied area. The abundance of oolitic deposits together with chlorozoan assemblage within the Um Bogma Formation indicates that the Lower Carboniferous sediments of Sinai were deposited in the lower subtropics region.

47784 <SOURCE>Journal of African Earth Sciences 20, 1: 37-51.</SOURCE>

47785 <ABSTRACT>The study of Carboniferous successions in the Um Bogma and Abu Durba areas of west-central Sinai yielded 70 species of brachiopods, corals, bryozoans, molluscs and trace fossils, 10 which are new to Sinai. The distribution of these fossils suggests the presence of three macrofaunal biostratigraphic units within distinctive lithofacies: a Middle-early Late Visean coral/brachiopod assemblage in the Um Bogma formation, a Serpukhovian-Bashkirian brachiopod/trace fossil assemblage in the Abu Thora Formation and an Early Moscovian brachiopod/bryozoan assemblage in the Abu Durba Formation. The fossil Associations indicate that the Carboniferous sequence of Sinai was deposited in a subtropical epicontinental sea inferred to have covered a greater area in northern Africa. The palaeoecological conditions and

- the palaeobiogeographic relations of this macrofauna to the Carboniferous Palaeothethys Realm are discussed. [the following corals of the Um Bogma formation are figured (pl. 4): Clisiophyllum garwoodi (Salee 1913), Amplexizaphrentis ennikilleni (Edwards & Haime 1851), A. palmatus (Easton 1944) and Sochkineophyllum sp.]</ABSTRACT>

47836 <SOURCE>Neues Jahrbuch fuer Geologie und Palaeontologie, Abhandlungen 155, 3: 374-397.</SOURCE>
47837 <ABSTRACT>A fauna from the middle Murghabian contains Rugosa waagenophyllidae: Pseudohuangia lapparenti n.sp., waagenophyllum (w.) pulchrum Hamada 1962, Iranophyllum (I.) tunicatum Igo 1956, and Durhaminidae: Heritschioides columbicum (Smith 1935) and Tabulata, Syringoporidae: Multithecopora omaniensis n.sp.). Praewentzelella of Matrah, Oman, described in a contribution by H. Fontaine, corresponds to P. honjoi Minato & Kato. Biogeographic relations exist with the waagenophyllidae-association mentioned by Minato & Kato, only Heritschioides is exceptional. Multithecopora is characterized by diameters ranging from 2.1 to 2.5 mm, tabulae are frequent.</ABSTRACT>

47849 <SOURCE>N Jb. Geol. Palaont. Abh. 211/1/2: 113-131.</SOURCE>
47850 <ABSTRACT>Rugosa and Tabulata represented by about 30 taxa played a specific role in Late Permian limestones of the Oman Mountains. Growth form, colony size, skeletonization, abundance of colonies, and stabilization by biotic or inorganic processes triggered the reefbuilding potential of the corals. Solitary Rugosa and Tabulata colonized the shelf as dwellers and had no reefbuilding potential. In reefs, waagenophyllum and similar taxa developed a limited reefbuilding potential; Praewentzelella and compound taxa contributed as members of the constructor guild significantly to reef accretion, while platform representatives of Praewentzelella and waagenophyllum were only dwellers. The extraordinary skeletonization of Praewentzelella gives evidence of a symbiosis by algae.</ABSTRACT>

47915 <ABSTRACT>Ceriod and thamnasterioid rugose corals are described from reworked boulders of the Hamrat Duru Group of the Murghabian (Neoschwagerina-zone) of the Hawasina basin, Oman. The fauna consists of Yokoyamella (Maoriphyllum) christofi n.sp., wentzelella (Wentzelella) annae n.sp., Paraipciphyllum sp. and Omaniphyllum hawasinum n.g., n.sp. Omaniphyllum is provisionally included within the family Petalaxidae Fomichev. Diagnostic criteria of the new genus are a thamnasterioid corallum, more than two orders of septa and a septal, bar-like columella. The fauna is part of the waagenophyllid biogeographic province of the Paleotethys. It characterizes probably the southern shelf of the Paleotethys north of Gondwana.</ABSTRACT>

47939 <TITLE>Bioerosion in Late Permian Rugosa from Reefal Blocks (Hawasina Complex, Oman Mountains): Implications for Reef Degradation.</TITLE>
47940 <SOURCE>Facies 35: 133-142.</SOURCE>
47941 <ABSTRACT>Rugose corals are known from allochthonous Late Permian reefal blocks of the Al Jil and Ba#039;id Formation (Hawasina Complex), Oman Mountains. In contrast to many Late Permian Rugosa found elsewhere in the Tethys, they occurred in sponge reefs and contributed to reef construction. The waagenophyllid warm water coral fauna is moderately diverse comprising cerioid, thamnasterioid, and fasciculate taxa. In contrast to sponges, chaetetids, and low-growing reefbuilders, the corals secreted diagenetically stable, most probably Mg-calcitic skeletons. Borings in coral skeletons are consequently well preserved providing important data for the interpretation of reef destructive processes. Thin-section analysis revealed three taxa of infaunal borers including Entobia Bronn 1837, uncertain thallopiphyte borings, and borings of unknown bioeroders. Macroborers were more important than microborers, because of the dominance of clionid sponges. Good evidence exists also for the occurrence of two types of undetermined grazers which destroyed the coral surfaces. The amount and distribution of bioerosion is variable among different coral taxa. The fasciculate coral Praewentzelella regulare Fluegel 1995 was the favorite substrate. Up to 33% of the calices were bored. Dendroid and compound corals were

bored subordinately. Bioerosion of these colonies does not exceed 2%. There is good evidence for substrate preference amongst the borers. Major controlling factors affecting borer distribution are believed to be variations of skeletal density and gross morphology. The borer assemblage could not limit reef accretion significantly. Factors controlling boring activity might have been quality of substrate, sedimentation rate, rapid incrustation of substrates, and competition for food with reef constructors including sponges, chaetetids, and rugose corals.

47952 <TITLE>The last representatives of Rugosa in Abadeh and Julfa, Iran: survival and extinction.</TITLE>
47953 <SOURCE>Courier Forschungsinstitut Senckenberg 164: 75-80. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 1]</SOURCE>
47954 <ABSTRACT>Solitary rugose corals (plerophyllids) are known to have flourished in the Upper Permian in the Abadeh and Julfa regions of Iran. They are phylogenetically one of the last representatives of Rugosa. Among them, of special interest are the two small-sized and simply constructed species (*Pentaphyllum brevisseptum* and *P. minimum*). Morphological changes during ontogeny, intraspecific variability, and their comparisons with those of other species, suggest that both species are phylogenetically related to *P. leptoconicum* from which they were independently derived. During the Late Permian, both *Pentaphyllum brevisseptum* and *P. minimum* followed an adaptive strategy: paedomorphosis, in order to survive under unfavourable conditions. The heterochronic change and the resultant variability closely interacted with palaeoecological conditions. Each species showed different morphological modifications within the inherited phylogenetic constraint characteristic of Rugosa. No further improvements finally appeared to combine adaptation to the prevailing, unfavourable environments. The latest Permian rugose corals failed to break through the phylogenetic constraint, resulting in their extinction.</ABSTRACT>

47978 <TITLE>Sequential disappearance of Permian Rugosa in Iran and Transcaucasus, West Tethys.</TITLE>
47979 <SOURCE>Bulletin Geol. Surv. Japan 44, 7: 447-453.</SOURCE>
47980 <ABSTRACT>At the end of the Permian, many Palaeozoic organisms, including the Rugosa, became extinct. The marine Upper Permian yields relict groups within Rugosa. The Abadeh and Julfa regions, Iran and Transcaucasus in the West Tethys are the important case areas for elucidating the end Permian extinction patterns of Rugosa. Permian Rugosa in those areas showed distinct disappearance patterns morphologically and taxonomically. The disappearance of Yatsengia and wentzelellinae was succeeded by that of waagenophyllinae, and Plerophyllidae were last to disappear. Each event boundary is marked by changes in sedimentary conditions and is associated with prominent biofacies changes in fusulinids, smaller foraminifers and so on, some of which were global and coeval. The disappearance pattern of corals in Iran and the Transcaucasus was sequential in abundance and composition, owing to successive selection caused by progressively more adverse, local habitat changes under pelagic to littoral [conditions]. However, similar faunal successions appeared in different places and synchronous geological events, such as sea-level changes and volcanism, were prevailing over areas. Not only single and/or local environmental conditions, but global factors having multiple interactions could produce such characteristic faunal successions.</ABSTRACT>

48004 <TITLE>Untersuchungen über Rugosa aus dem Perm Afghanistans.</TITLE>
48005 <SOURCE>FC&P 13, 2: 30.</SOURCE>
48006 <ABSTRACT>Olaf Otto Dillmann arbeitet im Rahmen einer Dissertation an der Untersuchung permischer Rugosa aus Afghanistan. Das zu untersuchende Material stammt aus dem Mittelperm Ost-Afghanistans. Es

handelt sich um eine Aufsammlung von Prof. G. Mennesier, Amiens. * Im folgenden soll ein kurzer Zwischenbericht über den Stand der bisherigen Arbeit gegeben werden. Die Untersuchung beschränkt sich auf kolonial auftretende Rugosa. Dabei handelt es sich ausnahmslos um Formen aus der Familie der waagenophyllidae. So konnten bislang mit Sicherheit folgende Arten festgestellt werden: (1) Unterfamilie wentzelellinae - Lonsdaleiastraea typica Gerth, L. cf. vinassai Gerth, wentzelella (Wentzelella) wynnei (Waagen & Wentzel), wentzelella (Szechuanophyllum) szechuanensis Huang, W. (S.) kitakamiensis Yabe & Minato, wentzelloides (Battambangina) frechi (Volz), W. (Multimurinus) n.sp., Polythecalis chinensis (Girty); Arten der Gattung wentzellophyllum Hudson sind ebenfalls vertreten. Ihre artliche Zuordnung steht jedoch noch aus. * Bemerkenswert aber ist, dass die Gattung wentzelloides Yabe & Minato ausserhalb Ost- und Südostasiens erstmals nachgewiesen wurde. Auffallend ist auch der hohe Anteil dieser in der Literatur nur wenig beschriebenen Gattung in der zu bearbeitenden Fauna. (2) Unterfamilie waagenophyllinae - Ipciphyllum flexuosum (Huang), Paraipciphyllum n.sp., Yokoyamaella (Yokoyamaella) tertioseptata (Yokoyama), ? Yokoyamaella (Maoriphyllum) sp. [preliminary note]</ABSTRACT>

48018 <SOURCE>J. Fac. Sci. Hokkaido Univ. 23, 1: 53-146.</SOURCE>

48019 <ABSTRACT>This paper mainly concerns the systematic palaeontology of some Middle to Upper Permian corals from the Abadeh and Julfa regions, Iran. The fauna consists of 35 species of 15 genera belonging to eight families. Two different kinds of faunas are clearly to distinguish. One is from the Middle Permian and is characterised by such typically Tethyan elements as waagenophyilids and by several species of Ufimia and micheliniids. It is followed by an Upper Permian fauna, terminal phylogenetic representatives of the Rugosa, composed mostly of solitary corals (Pentaphyllum). The Permian fauna corresponds well to that of the Transcaucasus, USSR, reported by Iljina (1962, 1965a). Many of the Middle Permian corals are known from South China, whereas Upper Permian corals indicate high endemism. Each species of Pentaphyllum shows a wide range of morphological variation, phylogenetically irrespective of Scleractinia. Inter- and intraspecific variability as well as ontogenetic changes are especially documented to clarify the distinctness of each species. Tabulata mentioned are: a species of Sinopora (S. asiatica) and some species of the genus Protomichelinia (P. microstoma, P. favositoides, P. laosensis, P. allata, and P. sp.).</ABSTRACT>

- 48031 <SOURCE>Jahrb. Geol. B.-A. 115: 49-102.</SOURCE>
- 48032 <ABSTRACT>The coral-fauna of the Jamal-formation of Eastern Iran can be subdivided in a "Cyathaxonia"-fauna and a "Waagenophyllum "-fauna. The first mentioned faunal-type occurs in the lower Jamal-Formation, the last type in the upper Jamal-Formation (faunal-list Table 1). The age of the Cyathaxonia-fauna is probably the Pseudofusulina-or the lower Parafusulina-Zone, the age of the waagenophyllum-fauna is the Parafusulina-Zone and perhaps the Neoschwagerina-zone. The environment of the Cyathaxonia fauna was the deeper part of a shallow water, probably 50 or 60m. under the sea level, whereas the waagenophyllum-fauna indicates a high wave energy environment of a litoral zone.</ABSTRACT>

- 48045 <ABSTRACT>Late Permian reefal blocks exposed in the Ba'id area of the Eastern Oman Mountains yield a sphinctozoan assemblage that has not been studied previously. The sphinctozoan fauna described here is the first report of such an assemblage from the Arabian Peninsula. Approximately 70 samples were studied with respect to systematic paleontology, as well as frequency of taxa based on presence / absence lists. The Sphinctozoans include 14 genera and 25 species. One genus (Rahbahthalamia) and five species (Amblysiphonella omanica, Salzburgia? irregularis, welteria? hawasinensis, Thaumastocoelia? irregularis, and Girtyocoelia gracilis) are described as new. Amblysiphonella Steinmann (1882), Colospongia Laube (1865), and Sollasia Steinmann (1882) have the highest species diversity. On a generic level, Sollasia, Amblysiphonella, and Parauvanella Senowbari-Daryan and Di Stefano (1988) occur most frequently in the investigated samples. The described fauna exhibits close relationships to sphinctozoan faunas known from the Middle and Late Permian of China and Tunisia.</ABSTRACT>

- 48058 <ABSTRACT>The Internal architecture of Upper Permian calcisponge reefs, Upper Triassic coral thickets, and Upper Triassic coral reef communities of the Oman Mountains have been investigated. In order to gain comparable data sets, investigations were carried out at different scales comprising quantitative data from outcrops and descriptions from thin-section. Methods of quantitative outcrop investigations were modified with reference to standard investigations techniques used in the study of communities of modern reefs. Data evaluation comprises

mapping of reef fabric in natural scale on plastic sheets in the field. Data calculation was carried out utilizing the digitized image analysis system Vidas. Measurement parameter are the total detrital framework coverage, coverage of reef builder taxa, mean diameter of taxa, and mean distance. In addition, measured plastic sheets were printed for paleoecological interpretation. Thin-section analysis reveal microfacies types, sedimentological criteria and taxonomic inventory of reef organisms. Based on quantitative field data five Upper Permian and four Upper Triassic communities were differentiated. Late Permian communities are represented by a (1) Low-diversity sphinctozoan community, (2) Radiotrabeculopora Archaeolithoporella community, (3) Cerioid coral community, (4) Solitary coral community, and (5) waagenophyllid coral community. Upper Triassic communities comprise (1) Diverse coral community, (2) coral Spongostromata community, (3) Solenporacean dendroid coral community, and (4) Crinoid community. The synthesis of both quantitative field data (plot technique with quadrats as sampling units) and the study of thin sections (microfacies analysis, taxonomy) is believed to result in data sets which could be used in comparative reef research with a higher degree of reliability than up to now.</ABSTRACT>

48069 <TITLE>Attempted Reconstruction of Permian and Triassic Skeletonization from Reefbuilders (Oman, Turkey): Quantitative Assessment with Digital Image Analysis.</TITLE>

48070 <SOURCE>Abhandlungen der Geologischen Bundesanstalt 50: 31-56.</SOURCE>

48071 <ABSTRACT>Upper Permian and Upper Triassic reefbuilders from different tectonic units of the Oman Mountains and Turkey were analyzed quantitatively with respect to skeletonization (skeleton in area percent) and skeletal mass (skeleton in g/cm³). Data were derived from thin-sections using the digital image analysis system Vidas. The quantitative data were combined with taxonomy, description of gross morphology and microfacies analysis in order to understand the influences of diagenesis in the different sizes and orientations of thin-sections. The investigated skeletons exhibit a wide range of preservation, ranging from unaltered to recrystallized with relic structures. Reefbuilders studied were sponges, sphinctozoans, inozoans, chaetetids, rugose corals, scleractinians, and hydrozoans. The measured parameters vary considerably for higher taxa (e.g., skeletonization of sphinctozoan sponges is 21-54%) as well as for species (e.g., the skeletonization of the sphinctozoan *Alpinothalamia bavarica* is 29-51%). The variation is regarded to be triggered by three main factors: a) differences in morphotypes, b) intraspecific variability, and c) variation of skeletal elements within the colony. well-skeletonized and weakly skeletonized higher taxa were observed in the mean skeletonization and the mean skeletal mass. These data help refine the guild concept proposed by Fagerstrom (1987). The quantitative assessment of the skeletonization and skeletal mass may provide data for the discussion about paleoproductivity of reefbuilders and the sedimentary net budget of ancient reefs.</ABSTRACT>

48082 <TITLE>Supersequence and composite sequence carbonate platform growth: Permian and Triassic outcrop data of the Arabian platform and Neo-Tethys.</TITLE>
48083 <SOURCE>Sedimentary Geology 158, 1-2: 87-116.</SOURCE>
48084 <ABSTRACT>Correlation of maximum flooding surfaces with published data suggests that supersequences P1, P2, and Tr4 can be traced across the Arabian platform into the Neo-Tethys basins, while supersequences P3, P4, and Tr1-Tr3 resulted from local tectonic events at the margin of the Arabian platform (Hulw half-graben). The presented sea level curve corresponds therefore to the Tethyan sea level curve during the Cisuralian and Guadalupian, but differs significantly during the Lopingian, as a result of the dispersal of Pangea. The Middle and Upper Triassic sea level curve from Oman is again in good correlation with published data. The Permian and Triassic sequence architecture on the Arabian plate and adjacent Neo-Tethys was predominantly triggered by the global warming after the Permian-Carboniferous glaciation, the initial rifting of Neo-Tethys, and subordinately by eustatic sea level changes. 48096 <SOURCE>Geobios 28, 2: 163-174.</SOURCE>
48097 <ABSTRACT>Four spicule-bearing chaetetid sponges are described from Upper Triassic (Norian) reef carbonates of the western Taurids (Antalya-Region, SW Turkey): *Atrochaetetes alakirensis* Cui & Fisher, *Blastochaetetes dolomiticus* Bezarini & Braga, *Ptychochaetetes* sp. and *Bauneia* sp.. Spicules are preserved as calcitic pseudomorphs. They are either short or long and slender, corresponding to typical styles; oxes are rarely present in *Atrochaetetes alakirensis*. The styles are mainly embedded in the secondary rigid skeleton, but their rounded ends appear to be attached to the primary wall. In *Blastochaetetes dolomiticus* and *Bauneia* sp. styles are also embedded in the primary wall. A comparison of these spicule-skeletons with those of other chaetetids, especially Paleozoic species, confirms the polyphyletic origin of the Chaetetida.</ABSTRACT>

48110 <ABSTRACT>Jusqu'alors inconnu entre le Permien et le Lias, le

phylum Chaetetida se trouve pour la première fois identifié avec certitude dans un niveau triasique. L''excellente conservation du matériel, fossilisé en aragonite originelle, se révèle très favorable pour l''étude histologique et géochimique. Du point de vue biosédimentaire, les conditions de gisement rappellent très précisément celles des "calcaires de Cipit" des Dolomites italiennes.

48148 <SOURCE>Bulletin du Museum national d'histoire naturelle 275: 293-400.</SOURCE>

48149 <ABSTRACT>L''étude des structures septales des principales espèces triasiques classées jusqu'à présent dans les genres Montlivaltia et Thecosmilia montre que ces deux genres, dont les définitions microstructurales sont maintenant mieux établies, ne sont pas

représentés dans la faune de cette époque. En revanche, la comparaison des types microstructuraux mis en évidence au cours de cette recherche, aussi bien chez les formes alpines que chez les spécimens provenant du Trias de Turquie, fait apparaître des regroupements très significatifs quant aux rapports des faunes de ces deux régions.

48160 <TITLE>Facies architecture of an isolated carbonate platform in the Hawasina Basin: The Late Triassic Jebel Kawr of Oman.</TITLE>

48161 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 252, 1-2: 270-280.</SOURCE>

48162 <ABSTRACT>In the oceanic realm of the southern Tethys, carbonate production of isolated platforms ceased after the end-Permian mass extinction and did not recover until the Late Triassic. The Misfah Formation (MF) at Jebel Kawr in the Oman Mountains is interpreted as a relic of such an isolated Late Triassic platform of the Hawasina Ocean, a part of the Neo-Tethys. Correlation of three sections at Jebel Kawr points to a sequence attached to Arabian platform. The shallow-water carbonates of Jebel Kawr comprise a platform rim reef facies and bedded inner-platform facies characterized by stacked high-frequency cycles with subtidal to intertidal carbonate sequences. The depositional profile of this Late Triassic isolated platform evolved during Carnian and Norian time from a low-relief phase with volcaniclastic interruptions, followed by a carbonate bank stage with a shallow subtidal to peritidal interior and marginal oolite shoals. In the Norian vertical accumulation caused an increase of the platform height and developed a relief along the margins that progressively increased through the aggrading reef stage.</ABSTRACT>

48173 <TITLE>Upper Triassic Reefs of the Oman Mountains: Data from the South Tethyan Margin.</TITLE>

48174 <SOURCE>Facies 34: 41-76.</SOURCE>

48175 <ABSTRACT>The upper Triassic reefal limestones of the Oman Mountains were investigated with respect to their microfacies, palaeontology and community structure. The reef fauna described and figured for the first time occurs in parautochthonous slope deposits of the Arabian platform (Sumeini Group) and in allochthonous reefal blocks (Oman Exotics, Hawasina Complex). The Oman Exotics are tectonically dislocated blocks, derived from isolated carbonate platforms on seamounts in the Hawasina basin or in the South Tethys Sea. The lithofacies and fauna of these blocks comprise a cyclic platform facies with megalodonts, reef and reef debris facies. The reefal limestones are dated as Norian/Rhaetian by benthic foraminiferal associations (Costifera, Siculocosta, Galeanella) and typical encrusting organisms (Alpinophragmium, Microtubus). Some small Oman Exotics are of Carnian age. The shallow-marine organisms

include scleractinian corals of different growth forms, spongiomorphiids, disjectoporids and solenoporacean algae as the main reef builders, various encrusters like microbes, foraminifers, sponges and many different problematical organisms for the stabilisation of the reef framework and a group of dwellers including benthic foraminifers, gastropods, bivalves and a few dasycladacean algae. The reef communities are characterized by the coverage of organisms and distributional pattern. Analogies with the coeval reef deposits from the European part of the Tethys have been recognized. Some species, now collected in Oman, were also reported from American and Asian localities.

- 48214 <ABSTRACT>Upper Triassic reefs and reefal buildups are lacking in Alborz and in the Zagros Mountains (in northern and in southwestern Iran respectively) but some small-scaled Norian-Rhaetian reefs and reef mounds occur in central and eastern Iran, belonging to the central Iranian plate as a part of the Cimmerian Continent. These reefs or bioconstructions are embedded within the Nayband Formation, a mixed siliciclastic-carbonate unit almost 2,800m thick, in the type locality in the Tabas area. Most of the buildups have a biostromal geometry, biohermal constructions are rare. A large number of reef organisms was found in the Iranian reefs and is also known from other Norian-Rhaetian reefs of the western Tethys. However, some organisms seem to be endemic and are not known from other localities. Based on the relative abundance of reef organisms, reefs within the Nayband Formation may be characterized as sponge dominated reefs (sponge reefs), coral-dominated reefs (coral reefs), or sponge-coral or coral-sponge reefs. In comparison with other Norian-Rhaetian reefs, the Iranian reefs are differentiated by their different organisms (especially foraminifera and microproblematica) and by encrustations represented mainly by small brachiopods and worm tubes. Reefs within the Naband Formation were formed on carbonate ramps in subtidal depths below the wave base.</ABSTRACT>

- 48227 <ABSTRACT>92 taxa of scleractinian corals belonging to 50 genera are described from Toarcian to Kimmeridgian rocks of east-central Iran (Tabas-Kerman area). They formed, occasionally associated with calcareous sponges and microbial communities, small patch reefs or reef meadows in siliciclastic-dominated shelf environments of the Tabas and

Lutblocks of the Central-East Iranian Microcontinent. On the large lateMiddle Jurassic to early Late Jurassic Esfandiar Carbonate Platform, situated at the eastern margin of the Tabas Block, corals were surprisingly rare. One of the genera (Irania gen. nov.) is new as are three species: Irania hexagonalis, Dimorphomeandra iranensis, and Thamnasteria iranensis.

48277 <TITLE>Jurassic corals from the Shemshak Formation of the Alborz Montains, Iran.</TITLE>

- 48278 <SOURCE>Zitteliana A46: 41-74.</SOURCE>
- 48279 <ABSTRACT>Nineteen taxa of scleractinian corals are described and figures from the Toarcian-Lower Bajocian part of the Shemshak Formation of the Alborz Mountains. Dominant taxa are Isastrea, Microsolena, Trigerastraea, Periseris, and Collignoastrea. Most of these corals occur near the top of the formation (lower Bajocian), close to the top of a large-scale shallowing cycle. Scattered specimens are found in transgressive lags of small-scaled parasequences in the Toarcian part of the succession. Corals are very rare in the Shemshak Formation with the exception of Rian, NE of Semnan, where strongly reduced sedimentation rate facilitated the establishment of coral meadows and a patch reef in mixed carbonate-siliciclastic setting on the crest of a tilted fault block.</ABSTRACT>

- 48290 <TITLE>Callovian Colonial Corals from the Tuwaiq Mountain Limestone of Saudi Arabia.</TITLE>
- 48291 <SOURCE>Palaeontology 32, 3: 675-684.</SOURCE>
- 48292 <ABSTRACT>The earliest development of coral-bearing strata in Central Saudi Arabia took place during deposition of the Tuwaiq Mountain Limestone (upper Middle-Upper Callovian). It does not appear to constitute a major barrier reef, but rather a series of isolated corals and coral bioherms; coral heads (20-50 cm in diameter) are scattered in life position within an extensive sheet of pure limestone (20-40 m thick) stretching for more than 1000 km along strike in central Saudi Arabia. This sheet could be described as an extensive biostrome. A striking feature of the Tuwaiq Mountain Limestone coral fauna is the low diversity of species that persisted throughout the development of the formation. These species are: Meandraraea gazaensis Alloiteau & Farag, Ovalastraea caryophylloides Goldfuss, Trigerastraea collignoni (Alloiteau), Columnocoenia lamberti Alloiteau and Brachthelia sp. A possible explanation for the low diversity of the fauna is inimical ecological conditions or palaeobiogeographical barriers which could have prevented the historical accumulation of species from neighbouring areas. Similar factors are responsible also for the endemism of the Jurassic Arabian fauna including ammonites, foraminifers, algae, ostracods, nautiloids, brachiopods and echinoids.</ABSTRACT>

- 48303 <TITLE>Free pennulae within Dendraraea sp. (scleractinian coral) from the Callovian of southern Israel.</TITLE>
- 48304 <SOURCE>Courier Forschungsinstitut Senckenberg 164: 199-204. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, vol. 1]</SOURCE>
- 48305 <ABSTRACT>Specimens of the Jurassic branching coral Dendraraea, collected from Middle and Late Callovian beds at Hamakhtesh Hagadol (Negev, Israel), commonly have free pennulae. The pennulae differ from

each other in size and outline according to the space available for their growth. Their elevated rims are continuous all around, and bear numerous, uniform marginal teeth. The space between the pennular rim and the central trabecula remains equal all around. Such a degree of individuality is uncommon among pennular corals which mostly developed menianae (long balconies) by the fusion of the inner and outer flanks of each pennula to those in front and behind. The global formation of free pennulae within Dendraraea was apparently due to the trabecular growth at right angles to the long axis of the branch.

 48316 <TITLE>Madréporaires simples du Dogger d'Afghanistan; étude sur les structures de type Montlivaltia.</TITLE>
 48317 <SOURCE>Mém. Soc. géol. France, n. sér., 50, Mém. 115: 1-40.</SOURCE>
 48318 <ABSTRACT>A study of several Jurassic solitary Corals from Afghanistan led us to a detailed examination of structural features in Montlivaltia. The septa were found to consist of two distinct components: an axial structure formed by fibrous trabeculae rhombic in transverse section, and laminar layers which thicken secondarily the axial structure on both sides. The same sort of architecture for several genera is deduced from Kobayashi's work and is confirmed in Stereophyllia All., Thecosmilia M.-E. & H. and Cyclostraea All. The septal structure of recent Fungia seems to be closer to the aforementioned structure than to those of typical Mesozoic Fungidae. The authors believe that corals having a Montlivaltia-type septal composition should be introduced as such in the classification (Superfamily Montlivaltioidea Alloiteau 1952 emend.). This group seems to have been widely spread geographically and over long periods of time. The presence of clear microstructure in specimens from different parts of the world allows us to deny the existence in Montlivaltia of an axis of divergence for the trabeculae as described in earlier works. An ecological interpretation for Chomatoseris and Montlivaltia is proposed as well.</ABSTRACT>

 48330 <SOURCE>Türkiye Jeoloji Bulteni 41, 1: 99-107.</SOURCE>
 48331 <ABSTRACT>The species of Donacosmilia corallina de Fromental (hermatypic coral) have been defined as Upper Jurassic (Oxfordian-Kimmeridgian, Portlandian?) in age by most European research workers. The presence of this form has also been noted from the reefal limestones of Yukarıköy formation in the Araç-Daday (Kastamonu) region of Turkey. In this study systematic description of this form is presented and the associated reefal limestones are assigned to Upper Jurassic (Upper Oxfordian-Lower Kimmeridgian) in age. 48342 <TITLE>A new depositional model and sequence stratigraphic interpretation for the Upper Jurassic Arab "D"; reservoir in Qatar.</TITLE>
48343 <SOURCE>Journal of Petroleum Geology 24, 3: 243-264.</SOURCE>
48344 <ABSTRACT>Deposition of the Arab Formation on the Arabian Plate followed a eustatic sea-level high during the Oxfordian that deposited the open-marine shelfal carbonates of the Hanifa and Jubaila Formations. Oolite/peloidal shoals and local coral-algal stromatoporoid banks were subsequently deposited on the platform margin. These acted as barriers and led to the differentiation of intrashelf basins from open-marine (Tethyan) waters to the east. During the subsequent Kimmeridgian lowstand, gypsum wedges were laid down in the intrashelf basins. Slight changes in water depth, which exposed or flooded these barriers, are believed to be responsible for the cyclic nature of the Arab Formation sediments. Arab Formation cycles show a 4th order frequency but have thicknesses more typical of 3rd order Vail-type sequences. This is probably explained by the 4th order flooding events merely topping-up pre-existing accommodation space of tens of metres water depth in the intrashelf basin. Diagenesis associated with movement of hypersaline brines may have been responsible for the development of widespread dissolution porosity and dolomitization. The laminated, organic-rich, bituminous lime mudstones of the Hanifa/Jubaila Formations are the probable source of oil in the Arab Formation in Qatar. The main reservoir types are oolitic-peloidal grainstones and dolomitized limestones. [original abstract] </ABSTRACT>

48356 <SOURCE>SEPM Special Publication 69: 21-35.</SOURCE>
48357 <ABSTRACT>In wadi Naqab, the Middle Jurassic corresponds to a broadly shallowing succession comprising multiple, meter-scale, fifth-order cycles. The Bajocian is predominantly subtidal, and cycles are commonly terminated by thick, massive oncoidal/peloidal packstones or grainstones. Most of the Bathonian and Callovian cycles start with spicular wackestones and end with cross-bedded peloidal/oolithic grainstones and/or stromatoporoid/coral rudstones. 48382 <SOURCE>Egyptian Journal of Geology 41, 2A: 347-363.</SOURCE>
48383 <ABSTRACT>Eight colonial coral species (Scleractinia) were collected and identified from the Cenomanian strata (Raha Formation) of Gabal Mokattab, west central Sinai. The identified species include Phyllocoenia pediculata, Phyllocoenia sp., Polytremacis chalmasi, Thecosmilia cf. Tommasii, Thamnasteria sp. and Fungiastraea cf. conferta. One species, Fungiastraea mokattabensis is considered to be new. The identified species belong to families Montlivaltiidae, Faviidae, Smitotrochiidae and Thamnasteriidae, with the exception of one species Polytremacis chalmasi which is an octocoral belongs to Family Helioporidae. The studied corals were collected from one horizon composed of argillaceous limestone, at the upper part of the Raha Fm. Corals occur with other fauna of pelecypods, gastropods and echinoids, they are recorded in different areas in Egypt (especially Sinai) as well as some North African and European regions.</ABSTRACT>

- 48407 <TITLE>Scleractinian corals from Lower Cretaceous deposits north of Esfahan (Central Iran).</TITLE>
- 48408 <SOURCE>Facies 48, 1: 199-216.</SOURCE>
- 48409 <ABSTRACT>A new section through Cretaceous deposits was discovered 1 km west of the Dizlu village (approximately 40 km north of Esfahan, central Iran). Lithologically, the section distinctly differs from all other sections exposed in neighboring localities. A scleractinian coral fauna (Upper Aptian-Upper Albian), collected from a reefal limestone, is described in detail. The following taxa were found: Actinastrea aff. pseudominima (Koby), Columactinastrea sp., Eugyra cotteui (d' Orbigny), Pseudomyriophyllia turnsekae Baron-Szabo, Montlivaltia sp., Paraclausastrea pulchra Morycowa, Placocoenia robusta Oppenheim, Columnocoenia ksiazkiewiczzi Morycowa, Styliina micropora 26 Koby, Felixigyra deangelisi Prever, Cyathophora haysensis wells, Diploastrea harrisi wells, Morphastrea cf. ludovicina (Michelin), Meandrophyllia meandroides (Koby), Eocomoseris raueni Löser, Fungiastrea crespoi (Felix), Latiastrea cf. kaufmanni (Koby), Kobya aff. crassolamellosa Gregory. The coral association of the Esfahan region is dominated by forms that are known to be cosmopolitan and semic cosmopolitan in the Lower Cretaceous. It was found that over 40% of the coral fauna had previously been reported from both Lower and Upper Cretaceous strata. A similar pattern has been recognized for other reefal associations (e.g. Albian of Greece and Upper Barremian-Middle Albian of Mexico). In contrast, coral assemblages which developed in rather soft bottom environments have a significantly smaller percentage (15-20%) of taxa extending into the Upper Cretaceous and show closer affinities to Upper Jurassic and Lower Cretaceous faunas.</ABSTRACT>

- 48421 <SOURCE>Revue de Paléobiologie 24, 2: 515-532. ISSN 1661-5468</SOURCE>
- 48422 <ABSTRACT>The Upper Cretaceous (Campanian-Maastrichtian) rocks that are exposed at several localities in the United Arab Emirates and the Sultanate of Oman are rich in macro- as well as microfossils. Solitary corals are found in these outcrops, associated with colonial corals, rudists, gastropods, pelycopods and echinoids. Nineteen species of solitary corals were identified from Jabal Buhays, Al Faiyah range Mountains (United Arab Emirates), Jabal El Rawdah and Jabal Huwayyah (Sultanate of Oman). Of these nineteen species ten species are described from the Qalah Formation (Upper Campanian) of Jabal Huwayyah and ten species are described from the Simsima Formation (Upper Campanian-Maastrichtian) of Jabal Buhays and Jabal El Rawdah where one species *Cunolites profundus* is common in the three localities. One species found in the Simsima Formation belongs to the new species *Cunolites trifurcata* described herein. Two morphotypes are observed in the studied solitary corals. Trochoid morphotypes prevailed during the deposition of the Qalah Formation, these lived on a hard substrate in a shallow marine protected environment. Hemispherical to dome-shaped morphotypes belonging to cunolitid corals prevailed during the deposition of the Simsima Formation. These are better adapted to a slightly higher energy environment with terrestrial supply by having elevated corallites which aided them to lie freely on the soft substrates as well as to free themselves from the fine sands and silts. The absence of costosepta at the basal part of cunolitid

- corals shows that they were immobile during life.</ABSTRACT>

- 48448 <ABSTRACT>A new section through parts of the Middle Aptian to Early Albian Sanganeh Formation at the southwestern margin of the Koppeh Dag, NE-Iran, displays a succession of silty to fine-sandy marl between which limestone boulders and debris layers are intercalated at several levels. These boulders are olistoliths, derived from the edge of a nearby carbonate platform, long since eroded. Most of the olistoliths are reef limestones built of corals and calcareous sponges. At two levels, the reef fauna weathered out from the boulders and could be collected. Fourtyseven taxa of Scleractinia have been described and figured, which considerably extend our knowledge of the biodiversity of Cretaceous corals from the area. The corals show an interesting mixture of taxa known since the Middle Jurassic and those known only from the Cretaceous.</ABSTRACT>

48474 <ABSTRACT>Ten species of scleractinian corals, collected from two localities in the northwestern flank of Oman Mountains have been described and illustrated. The described fauna shows close affinities principally with those of Saudi Arabia, Baluchistan and India, with lesser affinities to those of the Mediterranean realm. The hermatypic nature of these coral associations and their patchy distribution suggests that they were confined to warm-shallow, well lighted water with considerable amount of reworking of mobile strata (bioturbation).</ABSTRACT>

48499 <SOURCE>Senckenbergiana lethaea 73, 2: 269-276.</SOURCE>
48500 <ABSTRACT>The scleractinian coral Stylopsammia judaica Oppenheim 1930 is redescribed by means of topotypical material from Israel and new discoveries from central Jordan. The genus Stylopsammia Oppenheim 1930 is compared to Astrhelia Milne-Edwards & Haime 1849 and Archohelia Vaughan 1919 and assigned to the family Oculinidae. The holotype of the type species of Astrhelia, Madrepora palmata Goldfuss 1826, is re-examined and figured.</ABSTRACT>

48511 <TITLE>Aptian corals from Gabal Abu Ruqum, North Sinai, Egypt: taxonomy and adaptive morphotypes.</TITLE>
48512 <SOURCE>7th International Conference on the Geology of the Arab World, Cairo University, February 2004.</SOURCE>
48513 <ABSTRACT>Colonial and solitary corals of variable morphotypes are abundant in the Aptian rocks of Gabal Abu Ruqum, North Sinai. A taxonomic study on these corals revealed the occurrence of 24 species 11 solitary and 13 colonial species. Six species are established as new: Trochosmia cretacea, Montlivaltia amini, Meandrastraea sinaiensis, Pepsomia gawadi, Acrosmia egyptiaca and Epistreptophyllum manzourensis. The solitary corals belong to genera Montlivaltia, Epistreptophyllum, Ellipsosmia, Paracycloseris, Acrosmia and Rennensismia. Ceratoid and trochoid forms with a narrow base and a curved corallite dominate in these corals. Most corallites are filled with fine sand grains or clogged with large forams (mainly Orbitolina). Discoid solitary corals are rare and are represented by Paracycloseris sp. The dominance of ceratoid and trochoid forms in addition to the small-sized and curved corallites reflects unfavorable conditions with high terrigenous supply. On the other hand, colonial corals belong to the genera Eugyra, Styliina, Thamnastrea, Fungiastrea, Leptoria, Actinastrea and Ellipsocoenia. The colonial forms show a wide range of adaptation to the soft substrate with much terrigenous influx. Most forms are hemispherical to mushroom shaped with wide bases for stability. These forms usually have a long peduncle or are usually elevated above the substrate to avoid being buried by sand and mud. Only two species [Eugyra (P.) rariseptata and Leptoria sp.] have encrusting morphotypes. [original abstract]</ABSTRACT>

48524 <TITLE>Upper Cretaceous rudist and stromatoporoid associations of Central Oman (Arabian peninsula).</TITLE>
48525 <SOURCE>Facies 32: 189-202.</SOURCE>
48526 <ABSTRACT>Rudist and stromatoporoid associations of the Campanian from Central Oman are nearly monospecific. They are dominated by Durania aff. nicholasi, Vaccinites vesiculosus, Torreites milanovici or phaceloid and massive stromatoporoids. Several other rudist genera play a secondary role. The thickness of the associations is rarely more than one metre. Solitary corals do not occur in the associations. Colonial corals are less common, although they are up to 1m high and show considerable diversity. There are no binders. The reef structure indicates variable hydrodynamic conditions. They are always associated with very shallow water. The pure Durania aff. nicholasi patches with large colonial corals and Torreites milanovici are presumably the most rigid structures. The near monospecific associations of Vaccinites vesiculosus are widely distributed. Although mostly preserved in situ, strong currents, presumably caused by tropical storms, have repeatedly impaired and interrupted growth. The specific growth characteristics of the shell of some rudists, especially the radiolitids, enable an estimation of the individual lifespan. Frameworks of approximately 1m

thickness probably developed in \pm 100 years. The sediments of the complete sections are predominantly bioclastic. [original abstract]

48538 <SOURCE>Goettinger Arbeiten zur Geologie und Palaeontologie, Special Volume 2 [Reitner J., Neuwiller F. & Gunkel F. (eds): Global and Regional Controls on Biogenic Sedimentation I. Reef Evolution]: pp ???</SOURCE>

48539 <ABSTRACT>Complete in situ rudist associations are preserved in the Campanian of Central Oman. They developed during a transgression onto the Arabian Plateau. Microfacial analysis reveals that vigorously turbulent conditions prevailed throughout the Lower Campanian. The development and preservation of in situ rudist associations are obviously rare events. As a rule, turbulence prevents the development of such structures. The absence of vast rudist reefs is not a consequence of an inherent inability of rudists to build reefs, but can be attributed to exogenous, abiotic factors. The associations investigated here inhabited restrictive shallow-marine environment. Rapid growth of a few rudists has been verified. Vertically growing rudist associations of 5-8 in situ generations represent a period of only 100-200 years.</ABSTRACT>

48550 <TITLE>Growth rates of Early Campanian rudists in a siliciclastic-calcareous setting (Pontid Mts., North-Central Turkey).</TITLE>

48551 <SOURCE>Geobios. Memoire Special 22: 385-401.</SOURCE>

48552 <ABSTRACT>Rudist communities that developed on the southern slope of the Pontid magmatic arc during the late Cretaceous thrived in a tectonically unstable setting, and in environments that were strongly influenced by siliciclastic sedimentation. Strontium isotope stratigraphy indicates an early Campanian age of the investigated association at Hobek Tepe, near Amasya. Stable isotope analyses of: sclerochronological profiles of several shells of the three dominating hippuritid species yielded cyclic variations of δ180 that delineate seasonal variations in palaeotemperature. This allowed for the determination of individual life spans, skeletal growth rates and the reconstruction of the living growth fabric. Annual vertical shell growth of 35-40mm was maintained by cylindrical morphotypes of Vaccinites ultimus during several successive years, while adult annual shell accretion of conical morphotypes was only 27 to 30mm. Vertical growth of the co-occurring Yvaniella alpani was considerably slower and rarely exceeded 10mm/year. Differential growth rates of the two most abundant species, and morphological characters of Yvaniella which indicate that skeletal growth capacity was similar to sediment

accumulation, allowed for a consistent reconstruction of the original growth fabric. CaCO₃ production of the rudist communities amounted to 20 kg x year⁻¹ x m⁻² and contributed significantly to the sedimentary budget. Large-scale formation of fine-grained calcareous sediments by bioeroders occurred only in environments of less rapid burial, indicated by associations of slowly-growing geniculate rudist morphotypes and patellate corals. The implications of these results for the distribution of rudists and corals in Cretaceous shallow-marine environments are discussed.</ABSTRACT>

48563 <TITLE>Scleractinian corals from the Oligocene of the Qom Formation (Esfahan-Sirjan fore-arc basin, Iran).</TITLE>

48564 <SOURCE>Courier Forschungsinstitut Senckenberg 239: 5-55.</SOURCE>

48565 <ABSTRACT>Sixtyone scleractinian species of 39 genera are described from the section of Abadeh, central Iran. Nine of these species and one genus are new. The section comprises sedimentary rocks of the Qom Formation located on the Iranian Plate (Esfahan-Sirjan fore-arc basin). The age of the section ranges from latest Rupelian to Chattian (late Early to Late Oligocene) based on planktonic and larger foraminifers. The coral fauna belongs to three different assemblages: 1) a solitary coral assemblage, 2) a Leptoseris-Stylophora assemblage of a low light environment, and 3) a Poritid-Faviidae assemblage forming patch reefs. This study presents a detailed description of a previously unknown Oligocene coral record from this region. The study area is located palaeogeographically between the well known coral occurrences of the Mediterranean Tethys and the coral bearing Nari series of Sind, Pakistan and eastwards following Indopacific localities, and is therefore of prime importance for palaeobiogeographical reconstructions. Comparisons at the species level show that the coral fauna from central Iran represents a mixture of Mediterranean Tethyan and Indopacific elements. Nevertheless, the majority of the species are unknown from the Mediterranean Tethys indicating a beginning of faunal separation despite an open Tethyan Seaway which still connected both regions during this time.</ABSTRACT>

48577 <SOURCE>M.E.R.C. Ain Shams University, Earth Sci. Ser. 15: 61-78.</SOURCE>

48578 <ABSTRACT>A highly fossiliferous Lower Oligocene (Rupelian) section is well exposed on the flanks of Gabal Hafit anticline near Al Ain City, United Arab Emirates. The section contains different kinds of macro- and microfossils. Corals are the most abundant faunal element in that area and are represented by colonial and solitary forms where colonial forms dominate. Colonial corals are the main target of the present work

and are studied here for the first time. The present work focuses on the taxonomic and stratigraphic aspect of these colonial corals. The study includes the identification and description of 21 species of which two species are believed to be new. These are *Tarbellastraea hqfitensis* and *Siderastraea osmani*. The paleoecologic aspect of the studied faunas and their relation to other Tethyan faunas are also discussed. [original abstract]

48589 <TITLE>Oligocene and Early Miocene coral faunas from Iran: palaeoecology and palaeobiogeography.</TITLE>
48590 <SOURCE>International Journal of Earth Sciences 88, 3: 571-581.</SOURCE>
48591 <ABSTRACT>Oligocene and Early Miocene coral assemblages from three sections of central Iran are investigated with respect to their palaeoecological and palaeobiogeographic implications. These corals are compared with faunas from the Mediterranean Tethys and the Indopacific. Associated larger foraminifers are used for biostratigraphy and to support the palaeoecological interpretation. The studied sections are situated in the foreland basins of the Iranian Plate which is structured into a fore-arc and a back-arc basin separated by a volcanic arc. The coral assemblages from Abadeh indicate a shallowing-upward trend. Infrequently distributed solitary corals at the base of the section indicate a turbid environment. Above, a distinct horizon characterised by a *Leptoseris*-*Stylophora* assemblage associated with *lepidocyclinids* and planktonic foraminifers is interpreted as maximum flooding surface. Small patch reefs with a *Porites*-*Faviidae* assemblage are a common feature of Late Oligocene to Early Miocene coral occurrences and indicate water depths of less than 20m. The diversity of the coral faunas shows marked differences. Oligocene corals from the Esfahan-Sirjan fore-arc basin comprise more than 45 species of 32 genera and occur in a wide range of environments. Early Miocene corals from the Qom back-arc basin are less frequent, show a lower diversity (13 genera with 15 species) and occur in single horizons or small patch reefs. [original abstract]

48615 <TITLE>Miocene corals from Wadi El Hommor, Sinai, Egypt.</TITLE>
48616 <SOURCE>Neues Jahrbuch für Geologie und Palaeontologie Abhandlungen
229, 2: ...</SOURCE>
48617 <ABSTRACT>Eighteen species of colonial scleractinian corals and two
solitary ones have been described and identified from wadi El Hommor,
Sinai, Egypt. The colonial species belong to the genera Astrocoenia,
Stylocoenia, Stylophora, Porites, Goniopora, Plesiastrea, Favia,
Goniastrea, Montastrea, Leptastrea, Solenastrea and Tarbellastraea. The
solitary species belong to the genera Fungia and Flabellum. One
colonial species (Tarbellastraea hommorensis) is described as new.
During Miocene rifting which started in the Late Oligocene, the Gulf of
Suez was divided in faulted blocks, each was rising and subsiding with
different magnitude and intensity on both sides of the Gulf. The
presence of corals in certain exposures along the Gulf shoulders may
reflect shallow clear water and relative tectonic stability. The
majority of the studied corals belong to family Faviidae (thirteen
species), followed by Astrocoeniidae and Poritidae (two species each).
The other families (Pocilloporidae, Fungiidae and Flabellidae) are
represented each by one species.</ABSTRACT>

48630 <ABSTRACT>The nature and distribution of syntaxial cements in
Scleractinian corals and their growth in optical continuity with the
skeletal carbonate fibres combined with simultaneous recrystallization
allow a comparison with similar structures in Palaeozoic corals. Marked
thickenings of the septa are due to cementation fabric, as syntaxial
cements for instance. Moreover, these are also the cause of the
development of pseudoskeletal elements, as for example the
stereoplasmatic cones in the case of Cystimorpha. These studies of
diagenesis of scleractinians from the Pleistocene of the Sinai
Peninsula led to an analysis of the elements Ca, Sr, Mg, Na, Si, and Al
in the skeletal carbonate as well as in syntaxial cements. The amount
and distribution of these elements enable the identification and
delimitation of organic and diagenetic carbonates, if no
recrystallization has taken place. The results of the investigation
demonstrate again that mere observation and graphic description of
microstructures is not sufficient. Rather, the diversity of hitherto
described microstructural units necessitates an interpretation which
takes into account the diagenesis of the fossil. This leads to the
conclusion that while the skeletal architecture of Paleozoic corals has
in most cases been preserved, the microstructure may have suffered
recrystallization. [an English version of this paper has been published

48641 <TITLE>Carbonate Deposition in Accretionary Prism Settings: Early Miocene Coral Limestones and Corals of the Makran Mountain Range in Southern Iran.</TITLE>
48642 <SOURCE>Facies 31: 141-178.</SOURCE>
48643 <ABSTRACT>The regional mapping of the Makran mountain range on behalf of the Geological Survey of Iran represents a unique coverage: the entire area of the mountain range was compiled in a unified programme. During this mapping, Miocene limestones containing rich coral and foraminiferal faunas were recorded over a strike length of several hundred kilometres, as minor developments within thick neritic clastic sequences which in turn overlie great thicknesses of Eocene-Miocene flysch. These limestones include rigid bioconstructional frameworks, loosely compacted coralline assemblages and foraminiferal calcarenites: they include in situ reefal deposits and material redeposited quite close to their original site of depositions. Most are Burdigalian, as shown by the benthonic position foraminifera, but some are Aquitanian. The geotectonic setting was an accretionary prism in a zone of plate convergence. The limestones and enclosing clastic sediments comprise an intensely folded, reverse-faulted and locally dislocated sequence, the duplex structure being the result of a major Late Miocene-Pliocene episode of regional deformation. This concentration of the intense tectonic deformation in a late major episode requires a different model for this zone of plate convergence to the model widely applied to such zones. The possible controls on limestone deposition are discussed: tectonic uplift and shallowing of the sea, climatic warming and eustatic factors. Depositional features of reefal formations in the late Jurassic of the Caucasus, the Pliocene-Recent of Halmahera, and the early Miocene of SE France are discussed in comparison with the Makran model.[part of extensive summary]</ABSTRACT>

48667 <TITLE>Monsoon Climate and Arabian Sea Coastal Upwelling Recorded in
Massive Corals from Southern Oman.</TITLE>
48668 <SOURCE>Palaios 11: 347-361.</SOURCE>
48669 <ABSTRACT>Corals living in the coastal waters of southern Oman
experience the influence of the seasonally reversing Asian monsoon
system. The objective of the research reported here is to assess the
potential for using the skeletal chemistry of these corals to
investigate past variability in the monsoon climate. To this end,
20-year long, monthly resolution geochemical records are presented for
cores from two massive Porites corals, located 20 km apart near Marbat
on the Arabian Sea coast of southern Oman. We consider four aspects of
skeletal chemistry: oxygen and carbon isotopic composition, barium
content and the nature and occurrence of annual fluorescent bands
within the coral skeletons. Coral skeletal [948;180](#) documents
variations in sea surface temperature which have regional and
basin-wide significance. In particular, the [948;180](#) of coral skeleton
precipitated during the period of the NE monsoon is strongly correlated
with annual rainfall anomalies in India, whilst that precipitated
during the period of the SW monsoon appears to provide information on
variability in the strength of coastal upwelling. The stable carbon
isotope composition and barium content of these particular corals
display strong annual cycles, but do not appear to directly record
interannual climatic oceanographic variability. It is concluded that
corals on the coast of southern Oman have great potential to provide
high-resolution, century-long records of oceanographic and climatic
variability associated with the operation of the monsoon climate system.

48693 <TITLE>Dated coral reefs of southern Sinai (Red Sea) and their
implication to late Quaternary sea levels.</TITLE>
48694 <SOURCE>Marine Geol. 108: 29-37.</SOURCE>

- 48695 <ABSTRACT>Coral reefs of Sinai constitute four morphological terraces: three emergent fossil reefs and one submergent modern fringing reef [labeled: I (28-35m above sea level), II (13-18m), III (5-8m) and IV (-1 to +1m)]. Four genetic reef complexes which do not necessarily correspond to the morphological terraces were identified and dated. The reef / terrace age relationship are as follows: (1) Ophira (Terrace I): 330-290ka; (2) Mureikha (Terrace II and/or III): 215-170ka; (3) Naama (Terrace II and/or III): 141-81ka; Umm-Sid (Terrace IV): 6,5-2,5ka. The age groups correspond to the oceanic oxygen isotope stages 9, 7, 5e and 1. The vertical uplift of the Southern Sinai coast which is situated along the western margin of the Dead Sea Transform did not exceed 28-35m during the last 300.000 years.</ABSTRACT>

48760 <ABSTRACT>An oligotropic archaeocyathan fauna, consisting entirely of Regulares occurs in the upper Sellick Hill Formation and lower to middle Fork Tree Limestone. In the upper Sellick Hill Formation thin laterally persistent archaeocyath - rich bioclastic packstone has eroded pioneer bioherms but succeeding biohermal buildups are present. Regular Archaeocyaths with extensive outgrowths held together an open framework also occupied by sponges, Epiphyton and encrusting Girvanella. Anaptyctocyathus sellicksi (Taylor) is revised and 13 additional taxa described (among them 3 new species). 3 species allow correlation with the lower Wilkawillina Limestone (Flinders Ranges). The fauna is not older than mid-Attdabanian and arguably Botomian in age.</ABSTRACT>

48810 <TITLE>Ordovician biogeography of Australasia</TITLE>
48811 <SOURCE>In: Wright A.J., Young G.C., Talent J.A. & Laurie J.R.
(eds): "Palaeobiogeography of Australasian faunas and floras".-
Memoir Association of Australasian Palaeontologists 23: 63-126.</SOURCE>
48812 <ABSTRACT>webby describes the distribution of Ordovician
stromatoporoids on pages 69 and 70. The earliest assemblages are
labechiids best represented in the middle Ordovician of Tasmania which
show affinities with Chazyan and Blackriveran forms of Laurentia. Late
Darriwilian faunas from New South Wales show relationships to north
China and Korea. The diverse labechiid fauna of earliest Eastonian
(mid-Caradoc) age includes species with relationships to Tasmania,
Malaysia, north China, Mongolia, Tuva and Siberia. Clathrodictyids
first appearing in late Caradoc rocks also have Asian connections but
appear about the same time in Australia, east Canada, and north
China. The most diverse Ordovician faunas occur in early Ashgill rocks.
Aulacera is common in late Ordovician rocks in Tasmania, the Siberian
platform, Urals, Novaya Zemlya, etc. but not in New South Wales. The
affinities of island-arc assemblages from New South Wales are closest
to SE Asia and China. The affinities of the Tasmanian shelf fauna is
dominantly Asian, but at least twice had influxes of North American
stocks.</ABSTRACT>

- 48837 <SOURCE>Historical Biology 15, 1-2: 41-60.</SOURCE>
- 48838 <ABSTRACT>The biostratigraphic distribution of the Silurian Tabulata and Chaetetida of Australia can informally be described in terms of four successive coral assemblages. * The earliest Bridge Creek Assemblage (Rhuddanian-Aeronian) contains abundant halysitids and is not geographically widespread. Species of this assemblage tend to be holdovers from Late Ordovician faunas. * A major radiation event occurred at the time of the Quarry Creek Assemblage (Telychian-early Sheinwoodian), involving favositids, heliolitids, halysitids, and other groups. This may indicate the onset of conditions favourable to corals over widespread areas of eastern Australia. * The late Sheinwoodian-earliest Gorstian Dripstone Assemblage is characterised by a continued expansion in the number of species of favositids, the appearance of auloporids, and a contraction in the number of species of sarcinulids, multisoleniids, and halysitids. * Favositids continued to dominate the youngest Hatton's Corner Assemblage (Gorstian-Pridoli), but halysitids almost became extinct by the end of the Ludlow. * Faunas of Pridoli age are neither abundant nor well studied, but appear to be reduced continuations of earlier faunas. A number of tabulate taxa are identified as possibly useful biostratigraphic indicators in Silurian sequences. [original abstract]

- 48850 <SOURCE>Acta Palaeontologica Sinica 37, 3: 359-379.</SOURCE>
- 48851 <ABSTRACT>The highly diverse Early Devonian rugose corals characterized by the occurrences of Carlinastraea, Martinophyllum and Pradisphyllum of the late Lochkovian-Pragian faunas and of Chalcidophyllum. Macgeea and Protomacgeea of the Emsian faunas are widely distributed in eastern Australia, and exhibit a high ratio of newly evolved generic taxa. Philipsastreids and endophyllids made their first appearance in the Pragian and became common in the Emsian. The earliest elements of the stringophyllids occur in the various rock units of Emsian age. While in the other provinces of the Old World Realm, these three families are recorded mainly from the Middle or even Upper Devonian. This pattern of distribution suggests that many of the common genera belonging to these families originated in eastern Australia during the Early Devonian. Middle Devonian rugosan faunas of eastern Australia are characterized

by endemic Sanidophyllum and Blysmatophyllum. The Eifelian faunas seem to exhibit gradational changes from the earlier faunas. In contrast to a strong northwestwards dispersal from eastern Australia to south China and other provinces of the Old World Realm during the Early Devonian, the diverse Givetian faunas of Australia were less provincial, and exhibit a major influx of elements from south China, central Asia, Europe, northwestern Canada and other provinces of the Old World Realm. The Upper Devonian of eastern Australia is dominated by red-beds and associated facies of non-marine depositional setting with only rare records of rugose corals. Western Australian Frasnian faunas consist of both shelf and basin dwelling forms and show a long diversity and a strongly cosmopolitan nature.

 48863 <SOURCE>Records of the Western Australian Museum, Supplement 58: 273-277.</SOURCE>
 48864 <ABSTRACT>Biostratigraphical distribution of Australian Devonian tabulate corals appears to be influenced by episodes of transgression and regression both locally and world wide. Decrease in species diversity can be related to local regressive phases. Examination of contemporaneous sequences unaffected by regression is needed before a strong cause and effect relationship can be established.</ABSTRACT>

 48875 <TITLE>The Tabulate Coral Families Syringolitidae Hinde, Roemeridae Pocta, Neuroemeridae Radugin and Chonostegitidae Lecompte, and Australian species of Roemeripora Kraicz.</TITLE>
 48876 <SOURCE>Roy. Soc. of Victoria Proc. 83, 2: 171-190.</SOURCE>
 48877 <ABSTRACT>The genera Roemeria E. & H., Roemeripora Kraicz (and its possible synonym Vaughanites Paul 1937, non Woodring 1928), Roemerolites Dubatolov, Armalites Chudinova, Pseudoroemeripora Koksharskaya, and Bayhaium Langenheim & McCutcheon are considered to have syringoporid affinities and to form a family Roemeridae Pocta. The three Australian Lower or early Middle Devonian species Michelinia progenitor Chapman, Syringopora thomii Chapman and Roemeria ocellata Hill are revised, transferred to Roemeripora, and considered probably synonymous. Pseudoroemeria Chekhovich and Syringoporinus Sokolov are possibly better grouped with Troedssonites Sokolov than in the Roemeridae. Neuroemeria Radugin and Thecostegites E. & H. have syringoporid affinities and are grouped in the family Neuroemeridae while Chonostegites E. & H., also with syringoporid affinities, is considered the sole member of its family Chonostegitidae Lecompte. Haimeophyllum Billings is shown to be a synonym of Chonostegites. Gorskyites Sokolov, Neosyringopora Sokolov and Roemeripora wimani Heritsch form a group of Upper Carboniferous and Permian Tabulates that

appears to deserve syringoporid subfamily status. Syringolites Hinde is considered more closely related to Favosites than to Syringopora, and is treated herein as the only genus in the family Syringolitidae Hinde of the Favositoidea.

48888 <TITLE>Spur and groove morphology from a Late Devonian reef.</TITLE>
48889 <SOURCE>Sedimentary Geology 133, 3-4: 185-193.</SOURCE>
48890 <ABSTRACT>Spur and groove structures form on the windward side of modern coral reefs in response to wave action. Hitherto, no examples have been confirmed in the Palaeozoic record. We confirm here ancient spur and groove morphology from the Teichert Hills, an exhumed platform atoll from the Upper Devonian (Frasnian) reef complex of the Canning Basin, western Australia. Oriented growth of the reef-building metazoans (laminar tabulate corals and stromatoporoid sponges) proves an organic and constructional origin for the spurs. Grooves acted as sediment traps that filled with coarse bioclastic sand and winnowed brachiopods derived from the back reef and reef flat. Geometry and style of ancient spurs and grooves may provide indications of ancient synoptic hydrodynamic regimes: on the basis of the relationship between modern coral reef spur orientation and incoming wave direction, these ancient spurs are inferred to have formed normal to refracted waves. The presence of these structures offers unequivocal evidence for the active growth of mid-Palaeozoic reefs in wave-dominated hydrodynamic regimes, and demonstrates that reef-building biota can show a common morphological response to wave energy independent of taxonomic position. 48903 <ABSTRACT>[Stromatoporoid faunas are described by Webby and Zhen on pages 196 to 198. They discuss whether stromatoporoids were restricted to latitudes 40°N and 35°S as suggested by Heckel & Witzke or show a wider spread (60°N to 45°S) as supported by Stock. Several Pragian-Emsian genera found in eastern Australia show affinities with the Kuznetsk basin, Siberia and the Tien Shan, Altai mountains, Uzbekistan, Salair, arctic Canada, and south China. The Eifelian record of north Queensland is linked to the Urals and the early Devonian of the Czech Republic and the Reefton occurrences of New Zealand, Givetian-Frasnian faunas of Queensland and western Australian basins are much more cosmopolitan and have many species in common with European faunas. The dramatic reduction in diversity at the Frasnian-Famennian boundary led to a relict fauna of Labechiids,

- 48915 <SOURCE>Alcheringa 31, 4: 365-373.</SOURCE>
- 48916 <ABSTRACT>The pachastrellid genus Brachiaster Wilson (Pachastrellidae, Demospongiae, Porifera) has had until now no known fossil representatives. Here we describe its first known fossil representative from the late Eocene of southwestern Western Australia, assigned to Brachiaster claudellevii sp.nov. Brachiaster claudellevii has well-developed axial canals in the mesotriders, which points to it being intermediate in character between the typical tetraxial desmas of lithistids, and tetraxial spicules of non-lithistid demosponges. This further supports the position of Brachiaster among the Pachastrellidae. The geographic and bathymetric distribution of the extant and newly described fossil representatives of Brachiaster indicates that the Eocene sponge described here is important in understanding the evolution of Indo-West Pacific sponges because it points to a long evolutionary history and complex biogeographic distribution of this lineage of pachastrellid sponges. National Museum of Victoria, Melbourne, and the Fisheries Laboratory, Queensland Fisheries Service, Mourilyan Harbour, Queensland. The material contains 67 species, 20 being found in Australian waters for the first time. Forty-five are known species, but nine of these are more or less completely redescribed. Twenty-two species are new, including eight new species of *Capnella*. A key to the species of this genus is given.

48955 <ABSTRACT>A total of 237 species of azooxanthellate Scleractinia are reported for the Australian region, including seamounts off the eastern coast. Two new genera (*Lissotrochus* and *Stolarskicyathus*) and 15 new species are described: *Crispatotrochus gregarius*, *Paracyathus darwinensis*, *Stephanocyathus imperialis*, *Trochocyathus wellsi*, *Conocyathus formosus*, *Dunocyathus wallaceae*, *Foveolocyathus parkeri*, *Idiotrochus alatus*, *Lissotrochus curvatus*, *Sphenotrochus cuneolus*, *Placotrochides cylindrica*, *P. minuta*, *Stolarskicyathus pocilliformis*, *Balanophyllia spongiosa*, and *Notophyllia hecki*. Also, one new combination is proposed: *Petrophyllia rediviva*. Each species account includes an annotated synonymy for all Australian records as well as reference to extralimital accounts of significance, the type locality, and deposition of the type. Tabular keys are provided for the Australian species of *Culicia* and all species of *Conocyathus* and *Placotrochides*. A discussion of previous studies of Australian azooxanthellate corals is given in narrative and tabular form. This study was based on approximately 5500 previously unreported specimens collected from 500 localities, as well as a re-examination of most of the types and previously reported specimens from the Australian region. Fifty-six species are recorded as new to Australia; 183 state range extensions are listed; and 96 worldwide bathymetric range extensions are noted. In order to characterize the Australian fauna, all 703 known azooxanthellate species were tabulated as to coloniality, method of attachment, and depth range: 187 species are colonial, 516 solitary; 373 are attached, 265 free, and 54 transversely dividing; and 200-1000 m is the most common depth range. Compared to all azooxanthellate species, those from Australia have a slightly higher percentage of species that are solitary and unattached (or transversely dividing), due to a disproportionate number of species in the families *Flabellidae* and *Turbinoliidae*. Bathymetrically they are typical of the worldwide fauna. Sixty-seven species are endemic to the Australian region. Both UPGMA cluster analysis and MDS ordination reveal two main regions: a northern tropical region and a southern warm temperate region, consistent with zonation patterns of shallow-water marine invertebrates.</ABSTRACT>

48968 <ABSTRACT>This is the authoritative source on sponges of Australia and its territorial waters. It is the first comprehensive catalogue of Australian Porifera, and an essential text for those involved with this group. * The Catalogue is being compiled as a public enquiry database and will serve as a directory to the most comprehensive and recent information available on each species of the Australian fauna. * Information on each species includes synonymy, literature citation, location and status of type material, and type locality for each available name, a brief summary of geographical distribution and ecological attributes, and important references on various aspects, especially biology. [the volume deals with some 1400 species in 77 families; it contains numerous taxonomic decisions and includes an historical overview of sponge taxonomy; a synopsis of the location and status of Australian collections is also provided]</ABSTRACT>

49005 <TITLE>Submarine cementation in a high-energy platform reef: One Tree Reef, Southern Great Barrier Reef.</TITLE>
49006 <SOURCE>Journal of Sedimentary Petrology 53, 4: 1133-1149.</SOURCE>
49007 <ABSTRACT>Three major framework facies (algal pavement, coral heads, and branching corals) identified within the Holocene section of One Tree Reef shows varying degrees of cementation. The widest distribution

and greatest variety of submarine cements occur within those facies or subfacies that have extensive encrustation by coralline algae; these are found beneath the windward margin and within the patch reef drilled. Both Mg calcite and aragonite cements exhibit diverse fabrics and textures. Mg calcite is the dominant cement and is present as both an interskeletal and intraskeletal infill, whereas aragonite cement is exclusively intraskeletal. Interskeletal cements are relatively uncommon and are only developed within those facies or subfacies whose particular style of framework construction is capable of trapping significant quantities of fine-grained internal sediment. Lithified crusts, with either a laminated or columnar morphology, are a prominent cavity infill within many of the reef framework facies. Although direct evidence is lacking at this stage, the morphology and other features of these crusts probably indicate some form of organic influence during their formation. Peloids, which are the major component of the lithified crusts as well as many other cavity infillings, are considered to be a particular form of Mg calcite micrite and to have nucleated within the interstitial waters of the reef. Microcrystalline rim cements around the peloids have often cemented them into a coherent mass that resembles detrital lime mudstones. (Original summary)

49019 <SOURCE>CRC Press, Boca Raton, Florida, 356 pp. ISBN/ISSN: 84930833X</SOURCE>

49020 <ABSTRACT>Demonstrating the relevance and need of science in planning the future of the Great Barrier Reef and coral reefs worldwide, Oceanographic Processes of Coral Reefs: Physical and Biological Links in the Great Barrier Reef emphasizes multi-disciplinary processes - physical and biological links - that have emerged as the dominant forces shaping and controlling the ecosystem. The book draws heavily on data from coral reefs in Australia, Indonesia, Thailand, and the Philippines. Oceanographic Processes of Coral Reefs: Physical and Biological Links in the Great Barrier Reef covers: * Climate and global change * Coastal oceanography * Wetlands ecology * Estuaries * Marine biology * Land use management in the tropics * Fisheries management * Coral Reef ecological modeling * Biodiversity and the human impact. Explore how the ecosystem responds to both physical and biological stimuli, and how they interact. Understand processes imperative to create sustainable design strategies Comprehend the connectivity of biotopes - land, mangroves, seagrass, and corals Discover the relationship between managing marine resources and managing adjoining land use Learn how fish behavior and migration patterns control fisheries.</ABSTRACT>

49031 <TITLE>New evidence for the Holocene sea-level high from the inner shelf, Central Great Barrier Reef, Australia.</TITLE>
49032 <SOURCE>J. sediment. Res. A, 64, 4: 881-885.</SOURCE>
49033 <ABSTRACT>Radiocarbon dates from fossil oyster beds of intertidal origin on Magnetic Island, north Queensland indicate that the local Holocene maximum of relative sea level was attained no later than 5660 ±50 B.P. (conventional uncorrected age) and remained at 1.6-1.7m above modern levels until 4040 ± 50 B.P. Given the tectonic stability of the area, this implies that eustatic sea level remained at its Holocene peak for at least ca. 1600 yr. The new high-precision sea-level data indicate sea levels 1-5m higher than those of the same age inferred from buried mangrove deposits on the inner shelf in north Queensland. Uncertainties in deriving relative sea level from such mangrove deposits may be a significant source of error in worldwide attempts to distinguish the eustatic and crustal warping components of relative sea-level change, especially in the tropics.</ABSTRACT>

49085 <ABSTRACT>[Webby describes the distribution of Ordovician
stromatoporoids on pages 69 and 70. The earliest assemblages are
labechiids, best represented in the middle Ordovician of Tasmania,
which show affinities with Chazyan and Blackriveran forms of Laurentia.
Late Darriwilian faunas from New South Wales show relationships to
north China and Korea. The diverse labechiid fauna of earliest
Eastonian (mid-Caradoc) age includes species with relationships to
Tasmania, Malaysia, north China, Mongolia, Tuva and Siberia.
Clathrodictyids first appearing in late Caradoc rocks also have Asian
connections but appear about the same time in Australia, east Canada,
and north China. The most diverse Ordovician faunas occur in early
Ashgill rocks. Aulacera is common in late Ordovician rocks in Tasmania,
the Siberian platform, Urals, Novaya Zemlya, etc. but not in New South
Wales. The affinities of island-arc assemblages from New South Wales
are closest to SE Asia and China. The affinities of the Tasmanian shelf
fauna is dominantly Asian, but at least twice had influxes of North
American stocks.]</ABSTRACT>

49096 <TITLE>Rugose coral diversifications and migrations in the Devonian of
Australasia.</TITLE>
49097 <SOURCE>Historical Biology 15: 61-76.</SOURCE>
49098 <ABSTRACT>The occurrence of approximately 100 rugose coral genera has
been confirmed in the Devonian carbonate dominated successions of
Australasia. Their temporal distribution shows that the largest faunal
turnovers were in the Pragian and Givetian, with profound extinction
events at or near the ends of the Emsian, Givetian and Frasnian. The
evolutionary innovation and diversification of the Early Devonian
rugose corals of eastern Australia are characterized by a high turnover
rate in the late Lochkovian-Pragian and strong dynamism of radiation
from late Pragian to medial Emsian, implying considerable dispersal to
South China, central Asia and Europe. After a high intensity of
origination in the Pragian, maximum diversity was reached in the
Emsian. Phillipsastreids and endophyllids appeared late in the Pragian
and became common in the Emsian; stringocephalids appeared in the
Emsian. As elements of these families are recorded mainly from the
Middle, or even Upper Devonian of other provinces of the Old World
Realm, it appears that they may have originated in eastern Australia
during the Early Devonian. Following a marked decrease in generic
richness in the Eifelian, faunal diversity reached another high peak in
the early mid-Givetian as a result of immigration of coral genera,
probably from South China, central Asia, Europe and northwestern Canada
in the Old World Realm.</ABSTRACT>

49135 <TITLE>Paleobiologic and paleoenvironmental context of coral-bearing Early Cambrian reefs: Implications for Phanerozoic reef development.</TITLE>
49136 <SOURCE>Geology 21: 917-920.</SOURCE>
49137 <ABSTRACT>Early Cambrian corals from South Australia have been found within fossil reefs of unusual biological and paleoecological composition. The framework of these reefs is composed of a diverse assemblage of calcareous sponges (e.g., archaeocyaths and sphinctozoans), calcimicrobes, and at least two species of coral-like organisms, one of which is first reported herein and bears similarities to younger Palaeozoic tabulate corals. Complex growth interactions occur among these organisms, suggesting that space was a limiting factor in Early Cambrian reef ecosystems, as it is today in modern scleractinian reefs. In striking contrast to most Early Cambrian archaeocyath-calcimicrobe reefs, these South Australian reefs

flourished within energetic, mixed siliciclastic-carbonate shallow-marine environments along the margins of arid, coarse-grained, sea-marginal alluvial fans. The implications of these coral-bearing reefs are multifold. First, their existence not only extends the range of tabulatelike corals to the Botomian (middle Early Cambrian), but it adds an additional clade of participants to the Early Cambrian metazoan radiation event. Second, the existence of Botomian-aged skeletonized colonial cnidarians necessitates an earliest Cambrian or Neoproterozoic ancestor for the group. Third, the presence of tabulatelike corals and their involvement in reef building prior to the Toyonian extinction (late Early Cambrian) challenges hypotheses (e.g., lack of a suitable reef builder after the extinction of archaeocyaths until the Ordovician) used to explain the paucity of Middle and Late Cambrian reefs worldwide. The presence of these corals on sea-marginal fans contradicts the perception that early reefs were restricted to low-energy, predominantly carbonate subtidal environments. </ABSTRACT>

49163 <ABSTRACT>Two preliminary volumes tentatively gave the specialists a redefinition of the British Museum collections (1969) and a brief reconsideration of every genus previously established on Australian material either by Taylor T.G., Bedford R., W.R. and J. or by subsequent designation. The aim of this new volume is to give a modern approach of Monocyathina, Dokidocyathina and Ajacicyathina (i.e. regular atabulate Archaeocyatha) present into the whole material collected on Ajax Mine area. The most up-to-date results of anatomic and systematic studies are used and carried further on distinction between wall-canals and simple pores, porous and non porous septa (in connexion with stirrup-pores) are taken into consideration for the definition of new taxa.</ABSTRACT>

49188 <SOURCE>Geobios 24, 6: 697-718.</SOURCE>
49189 <ABSTRACT>The oldest known tabulate, Flindersipora bowmani Lafuste gen. et sp.nov. from the Flinders Ranges of South Australia is described for the first time. The new genus presents all morphological and structural characteristics of Tabulata: cerioid shape, septal ridges, tabulae, wall pores. Its microstructure is nevertheless new, formed by " platelets". Specimens have been found associated with archaeocyaths and calcified cyanobacteria in Lower Cambrian shelf margin buildups in the Orparinna Shale and Moorowie Formation in two different localities: Ten Miles Creek where they are associated with solitary archaeocyaths, and Moorowie Mine, where they built complex bioconstructions associated with colonial archaeocyaths. The archaeocyaths, comprising 11 species indicate a middle Botomian age. One species Robertocyathus brenti Debrenne is new. The buildups were among the last to flourish prior to widespread regression in the Early Cambrian in South Australia. With this discovery, the present opinions on the phylogeny of Tabulate Corals must be modified. In comparison with some Cambrian or even Ordovician forms which have been supposed to have affinities with corals, Flindersipora has a less rudimentary morphology and could not be said more primitive than these previously known genera. Because of its advanced favositid architectural type Flindersipora reinforce the idea that the origin of Tabulata is very ancient and must be looked for in the Precambrian.</ABSTRACT>

- 49215 <ABSTRACT>A rich assemblage of poriferan spicules and sclerites of the Chancelloriidae has been found in Mid Cambrian phosphatic sediments of the Georgina Basin. The hexactinellid spicules are especially diverse, and contain several new types. These include pulvinusactins (nom. nov.) and follipinules, strongly inflated triaxons which probably formed an armouring dermal layer in Thoracospongia, and cometiasters which may be the first Cambrian evidence of the Hexasterophora. Demosponge spicules, especially triaenes, are moderately diverse. Polyactine spicules with central canals are interpreted as proto-aster megascleres, which may have evolved into aster microscleres. Calcarean, heteractinellid spicules are also common. These features suggest an early Cambrian diversification of the Porifera. The systematic position of the Chancelloriidae is still controversial.</ABSTRACT>

- 49228 <ABSTRACT>A biostratigraphic study of coral faunas from the Early to Middle Devonian Fanning River Group has been completed in conjunction with geological mapping of the Burdekin Basin, north Queensland. Ten coral associations are now recognised. Associations A-D from the Laroona Formation (new name) and the Mount Podge Limestone (new name) are late Emsian to early Eifelian in age. Associations E-J occur in the Burdekin Formation and Cultivation Gully Formation and range in age from late Eifelian to middle or late Givetian. The recognition of early Devonian faunas is a significant new discovery and demonstrates that rugose corals are useful for regional biostratigraphic correlation.</ABSTRACT>

- 49241 <ABSTRACT>Upper Frasnian coral-bearing platform deposits are limited in the Devonian reef complexes of the Lennard Shelf, Northwestern Australia. A well preserved fauna from the upper Frasnian Sparke Conglomerate is described herein, together with several collections from the Virgin Hills Formation that are late Frasnian in age as determined by conodonts. *Hillastraea* gen. nov., with type species *H. floriforme* (Hill 1954) and *H. georgeae* sp.nov. are described. *Smithiphyllum coppi* sp. nov is the first species of *Smithiphyllum* described from western Australia. A further specimen of *Tabulophyllum lowryi* Hill & Jell 1970 is noted, and one other species of *Tabulophyllum* is described in open nomenclature. *Phillipsastrea sparkensis* sp. nov is described, *Phillipsastrea delicatula* Hill 1936 is reassigned to *Frechastraea*, *Phacellophyllum kimberleyense* Hill & Jell 1970 to *Thamnophyllum* and *Haplothecia ? laciniosa* Hill & Jell 1970 to *Kuangxiastraea*.</ABSTRACT>

- 49254 <ABSTRACT>The Fanning River Group is among the best exposed marine-dominated Devonian sequences in eastern Australia. It consists of limestone, sandstone and conglomerate of shallow marine origin, which form the basal sequence of the Burdekin Basin. Sixteen species and subspecies (9 new) of rugose corals are described from outcrops of the Fanning River Group exposed in the Kirkland Downs, Boundary Creek and Lime Creek areas; these areas represent the north and northwestern margins of the Burdekin Basin during the early Givetian transgression. The coral taxa are determined as: *Lythophyllum proliferum* sp.nov., *Endophyllum jelli* sp.nov., *lowaphyllum schlueteri* (Etheridge 1898), *Blysmatophyllum isisense* Pedder 1970, *Blysmatophyllum multigemme* sp.nov., *Blysmatophyllum?* sp., *Sanidophyllum kirklandense* sp.nov., *Spongophyllum* (*Beugniesastraea*) *variabilis* sp.nov., *Australophyllum cyathophylloides yohi* subsp.nov., *Xystriphyllum dotswoodense* sp. n., *Xystriphyllum* sp., *Taimyrophyllum crassiseptatum* sp.nov., *Acanthophyllum* (*Acanthophyllum*) sp., *Amarophyllum amoenum* Pedder 1970, *Argutastrea* sp., and *Aristophyllum planotabulatum* sp.nov.</ABSTRACT>

- 49267 <ABSTRACT>Forty-two rugose coral species referable to 18 genera are

described. Two new genera, *Noviphyllum* and *Careophyllum*, are erected and are typified by *N. canningense* sp.nov. and *C. brevilamellatum* (Hill, 1936) respectively. Eleven other new species are described: *Grypophyllum benbowi*, *Sociophyllum homense*, *Disphyllum patulum*, *D. hockingi*, *D.? murum*, *Spinophyllum prolatum*, *Temnophyllum spissum*, *Chostophyllum apertum*, *Peneckiella naniforme*, *P. moniliforme* and *P. capitanea*. New material is described for, or additional observations are made on 13 previously described species: *Smithiphyllum coppi* Brownlaw & Jell, *Disphyllum caespitosum* (Goldfuss), *D. virgatum* (Hinde), *D. incomptum* (Hill & Jell), *Argutastrea hullensis* (Hill), *Temnophyllum turbinatum* Hill, *Hillastraea floriformis* (Hill), *H.? georgeae* Brownlaw & Jell, *Phillipsastrea sparkensis* Brownlaw & Jell, *Frechastraea delicatula* (Hill), *Thamnophyllum kimberleyense* (Hill & Jell), *Peneckiella teichertii* Hill and *Kuangxiastraea laciniosa* (Hill & Jell). Eleven species are left in open nomenclature due to insufficiency of available specimens. [last part of extensive summary]

49279 <SOURCE>Geological Survey of Western Australia Bulletin 129: 1-107.

</SOURCE>

49280 <ABSTRACT>This major monograph in addition to describing and illustrating 27 taxa of Givetian, Frasnian and Fammenian Stromatoporoids also has valuable general discussions of their occurrence in the reefal facies, their shapes, microstructures, basal layers and contained organisms. Three new species are described *Actinostroma windjanicum*, *Hermatostroma ambiguum*, and *Stromatopora lennardensis*. The author supports his determinations with many measurements and adopts a broad species concept that results in many species being placed in synonymy including the widely recognized late Devonian species *Actinostroma clathratum*. Many northern European species are recognized. The genus *Euryamphipora* is reinterpreted as a particular growth form of *Amphipora* and placed in synonymy.</ABSTRACT>

49304 <TITLE>Palaeoecology of a late Devonian back reef: Canning Basin, Western Australia.</TITLE>
49305 <SOURCE>Palaeontology 43, 4: 671-703.</SOURCE>
49306 <ABSTRACT>Back-reef ecologies within the celebrated mixed carbonate-siliciclastic Late Devonian (late Frasnian) Pillara Limestone of Windjana Gorge, in the Canning Basin, Western Australia, are re-interpreted as being dominated by microbial communities. Proposed microbialites are expressed as weakly-laminated, fenestral micrite, that show unsupported primary voids, peloidal textures, disseminated bioclastic debris, and traces of microfilaments. These grew as either extensive free-standing mounds or columns, often intergrown with encrusting metazoans, or thick post-mortem encrustations upon skeletal benthos. In some cases, microbial encrustations are inferred to have developed in protected cavities formed by progressive burial of the reef. The calcimicrobe Shuguria also shows a preferentially cryptic habit, encrusting either primary cavities formed by skeletal benthos, microbialite, or the ceilings of mm-sized fenestrae within microbialite. A further calcimicrobe, Rothpletzella, formed columns up to 0.3m high in areas enriched by very coarse siliciclastic sediment. *Stromatoporoid sponges with a diverse range of morphologies also formed in situ growth fabrics. Monospecific thickets of closely-aggregating dendroid stromatoporoid sponges (Stachyodes costulata), and platy-laminar forms (?Hermatostroma spp.) were common, as were remarkably large stromatoporoids (Actinostroma spp.) that grew as isolated individuals up to 5m in diameter. Such sponges showed impressive powers of regeneration from partial mortality, and individual clones may have been capable of substantial longevities of up to 500 years. Actinostroma spp. showed highly complex growth forms including platy-multicolumnar (A. windjanicum), and a hitherto undescribed inferred whorl-forming foliaceous morphology (Actinostroma sp.) reminiscent of the modern photosymbiotic coral Acropora palmata. These complex morphologies formed abundant primary cavities, previously thought to be only rarely developed in association with stromatoporoids. [original abstract]</ABSTRACT>

49317 <TITLE>Novel paleoecology of a postextinction reef: Famennian (Late Devonian) of the Canning basin, northwestern Australia.</TITLE>
49318 <SOURCE>Geology 28, 11: 987-990.</SOURCE>
49319 <ABSTRACT>Reefs are supposed to be particularly susceptible to mass-extinction events, and to survive only as low-diversity, remnant communities dominated by holdover or disaster taxa. Famennian (Late Devonian) reefs exposed in the Windjana Limestone of the Canning Basin, northwestern Australia, demonstrate, however, that a novel reef ecology

was established in the immediate aftermath of the Frasnian-Famennian mass extinction. Here diverse calcimicrobes (including Rothpletzella spp., Shuguria spp., Ortonella and Girvanella) together with bryozoans, brachiopods and stromatoporoid, sphinctozoan, and lithistid sponges grew as complex framework intergrowths in previously undocumented morphological forms, forming spectacular elevated laminar to platy structures up to 3 m in diameter and 0.35 m thick. At least 15 morphospecies of lithistids are now identified, where only two were previously documented. These communities show no substantial reduction in biodiversity compared to Frasnian counterparts, nor any change in tiering or loss of complex ecological interactions. These observations suggest that where stable carbonate platforms persisted after mass-extinction events, reef-building could continue. More important, they demonstrate that no protracted interval of time was necessarily required either for recovery to ecological stability or for completely new ecologies to assemble. Such studies highlight the need to document ecosystem recovery after mass-extinction events using detailed paleoecological analyses in addition to simple compilations of global biodiversity changes.

 49343 <TITLE>Magnetostatigraphy, Late Devonian iridium anomaly, and impact hypotheses.</TITLE>
 49344 <SOURCE>Geology 18: 291-294.</SOURCE>
 49345 <ABSTRACT>Paleomagnetism, sedimentology, and fine-scale stratigraphy have been integrated to explain the origin of an iridium anomaly in the Late Devonian of western Australia. Thermal demagnetization experiments were carried out on 93 specimens of marginal-slope limestone from the northern Canning Basin. Samples are from a condensed sequence of deep-water (> 100 m) Frutexites microstromatolites. Frutexites is a shrublike cyanobacterial organism that probably precipitated hematite, or a metastable precursor, from sea water. When plotted within the microstratigraphic framework for the study area, the observed characteristic directions from the sampled interval (14.5 cm thick) are in five discrete, layer-parallel, normal- and reversed-polarity zones. The measured northeast-southwest declinations and shallow inclinations probably record Late Devonian magnetostatigraphy on a centimetre scale. The Frutexites bed studied here occurs close to the Frasnian /

Famennian (Late Devonian) boundary, a time of mass extinction of a wide variety of marine organisms throughout the world. Anomalously high iridium concentrations observed in the Frutexites bed have suggested to some authors that the mass extinction was caused by meteorite impact. This study concludes that iridium, which is present over the span of five layer-parallel magnetic reversals, was concentrated over a long period of time by biologic processes. Thus, the Canning Basin iridium anomaly may be unrelated to meteorite impact.</ABSTRACT>

49356 <TITLE>Platform-margin collapse during Famennian reef evolution, Canning Basin, Western Australia.</TITLE>

49357 <SOURCE>Geology 23, 8: 691-694.</SOURCE>

49358 <ABSTRACT>Sedimentological investigations of well-exposed slope strata in the Upper Devonian reef complexes of the northern Canning Basin lead to a sequence-stratigraphic interpretation that differs from others based on predictive models in which coarse carbonate debris deposits are regarded as lowstand deposits. In the upper Frasnian-Famennian Napier Range slope succession, we recognize an important phase of platform-margin collapse during a sea-level highstand in the middle Famennian. At this time the reef-rimmed margin was rapidly prograding, and the platform was producing carbonate grains (notably ooids and peloids) that were being transported by turbidity currents to the slope and basin floor. Periodic collapse of the platform margin led to deposition on the slope of allochthonous blocks of reefal limestone and channelized debris-flow units, intercalated with the ooid-peloidal turbidites and quartzo-feldspathic sandstones. Collapse of the early-cemented margin was probably triggered by gravitational instability caused by oversteepening during rapid progradation and/or tectonic activity, with falling blocks initiating some of the debris flows.</ABSTRACT>

49370 <SOURCE>Goettinger Arbeiten zur Geologie und Palaeontologie, Special Volume 2 [Reitner J., Neuwiller F. & Gunkel F. (eds): Global and Regional Controls on Biogenic Sedimentation I. Reef Evolution]: pp ???</SOURCE>

49371 <ABSTRACT>In the Canning Basin of western Australia stromatolites are very abundant in marine sediments overlying Frasnian reefs. There are stratiform and columnar types in beds of some meters thickness as well as small bioherms of the same size. They are associated with normal marine fossils like sponges, corals, crinoids, brachiopods, ammonoids, and conodonts. Growth rates of stromatolite beds were very low. Stromatolite bearing beds are preferentially red probably due to the presence of hematite indicating oxidizing conditions as a consequence

of low productivity. Crinoidal fastholds are very common at the surface and within stromatolites. They prove a very early lithification as they need a hardground for settling. The syndimentary lithification may be the reason for the preservation of the stromatolites as their potential of fossilization is usually relatively low. </ABSTRACT>

49382 <TITLE>Novel reef fabrics from the Devonian Canning Basin, Western Australia.</TITLE>
49383 <SOURCE>Sedimentary Geology 121: 149-156.</SOURCE>
49384 <ABSTRACT>Large cement-filled cavities (0.2 to 1.5 m wide) are well developed in slope-margin sediments of the spectacular Upper Devonian (Frasnian) reefs of the Canning Basin, Western Australia, where they account for up to 50% of the primary porosity. These are here interpreted as primary reef framework cavities formed beneath a variety of domal, tabular, or laminar stromatoporoid sponges. Of particular note are those created by unusual, very thin (2 to 8 mm) laminar stromatoporoids (mainly Stachyodes australe), that formed arching hollow domes up to 0.3 m in height and 1.5 m in diameter over the sediment surface to enclose flat-based cavities. The free undersurface of these stromatoporoids often supported a hitherto unrecognized cryptic community, dominated by pendant growth of the putative calcified cyanobacterium Renalcis, with rare intergrown lithistid sponges and spiny atrypid brachiopods. The uneven growth surface of the cryptos imparts an irregular stromatactis-like texture to the upper surface of the remaining cavity, which is filled by early marine, finely banded fibrous cements (mainly radiaxial calcite) embedded with often multiple generations of geopetal cement containing peloids and ostracod debris. This ecology yields the tabular stromatoporoid-Renalcis fabric described ubiquitously from the Canning Basin reef complex. Such unusual reef fabrics are a consequence of the ecology of shallow-water marine mid-Palaeozoic reefs which were quite unlike that of modern coral reefs. The frequent preservation of relatively delicate, in situ communities was due to (1) rapid and pervasive early cementation, (2) growth under non-energetic conditions, and (3) the relative insignificance of bioeroders associated with reefs at this time.</ABSTRACT>

(eds)]: 9.1-9.11.</SOURCE>
49410 <ABSTRACT>The Devonian reef belt of the Canning Basin is one of the
best exposed and best preserved ancient reef complexes of the world.
The reefs crop out over about 350 km in a 1.5 to 50km wide zone along
the northern margin of the Canning Basin. This zone, called the Lennard
Shelf is bounded on the north by the Precambrian rocks of the Kimberley
Block and to the south by the deep Fitzroy Trough. A marginal fault
(Pinnacle Fault) with a throw of about 6000 m displaces the Fitzroy
Trough from the Lennard Shelf. * As a result of block faulting
preceding the beginning of reef growth in Middle Devonian times a
relief of locally up to 1000m was formed. The reefs were established on
this rugged topography along the coasts of the Kimberley Block and also
surrounded offshore islands. It is thought that they once also flanked
the shores of the Kimberley Basin to the west and north over a distance
of another 1000km. Thus the "Great Devonian Barrier Reef" as it
was called by Teichert (1943) in analogy to the modern Great Barrier
Reef is quite an appropriate term. [extracted from an introduction]

49447 <TITLE>Palaeoecology of a post-extinction reef; Famennian (Late Devonian) of the Canning Basin, north-western Australia.</TITLE>
49448 <SOURCE>Palaeontology 47, 2: 415-445.</SOURCE>
49449 <ABSTRACT>Reefs were decimated by the Frasnian/Famennian (Late Devonian) mass extinction event (371 Ma) and are assumed to have survived only as depauperate calcimicrobial communities dominated by disaster taxa. Descriptions of Famennian proximal reef-slope communities within the Windjana Limestone, Canning Basin, north-western Australia, show that, notwithstanding the loss of large metazoans, novel ecologies were established in this setting by a rich biota of survivor and progenitor taxa. Diverse calcimicrobes, together with algae, crinoid, bryozoans, brachiopods and abundant sponges (stromatoporoids, inozoans, sphinctozoans, lithistids and hexactinellids) formed a reef framework of either elevated platy structures up to 4m in diameter and 0.35m thick, or mounds up to 15m in diameter. This framework was dominated by a complex intergrowth of calcimicrobes where Rothpletzella formed the primary framework, Ortonella and Girvanella were secondary encrusters, and Shuguria spp. occupied small crypts 2-30mm in diameter. Contiguous columnar stromatolites up to 50mm in height and 1m in width grew upwards from substrate sheltered beneath large sheltered primary cavities; based on minimum growth rates of 50-100 µm/year these are estimated to have been 500-1000 years old. The elevated platy community is inferred to have grown in conditions of episodic siliciclastic sediment input; the reef mounds grew during either episodes, or in localized areas, of low sedimentation. At least 14 species of spicular sponges are now identified from the Windjana Limestone where only two were previously documented. These fore-slope reef communities exposed in Windjana Gorge flourished in high energy carbonate environments dominated by coated grain sediments and, where rapid, early lithification was pervasive. * Such observations demonstrate that no protracted interval of time was necessarily required for post-extinction recovery; in regions where some reef-building taxa survived and suitable carbonate habitats persisted or returned. Moreover, they show that new ecologies, rather than remnants of the pre-extinction community, could be established rapidly. The reef-slope communities of the Windjana Limestone offer little evidence to support the ideas of resurgence or invasion of taxa from deeper waters after the Frasnian / Famennian extinction event. Indeed, there is evidence to suggest that similar microbial-sponge communities were already established in margin and reef slope communities in the latest Frasnian. As such, the most dramatic ecological changes caused by the extinction occurred in back-reef communities, [original abstract]</ABSTRACT>

49460 <TITLE>A new species of Palaeacis from Western Australia.</TITLE>
49461 <SOURCE>Coral Research Bulletin 7: 221-227. [Dieter Weyer's 65th birthday commemorative volume; S. Schröder, H. Löser & K. Oekentorp (eds)]</SOURCE>
49462 <ABSTRACT>Palaeacis irregularis n.sp. is described from the middle to lowermost upper Visean Utting Calcarene from the Bonaparte Basin of Western Australia. The species is characterised by: 1) wedge-shaped corallum; 2) occurrence of all corallites within a single plane; 3) divergence of mature corallites away from each other so as to end up as isolated tubes; and 4) sessile, attached or free-living habits. Palaeacis irregularis n.sp. does not bear close affinities to any described Palaeacis species from the Lower Carboniferous of eastern Australia, although it conceivably could be derived from the P. cuneiformis group, which occurs in eastern Australia. Regardless, the difference between P. irregularis and relatively well known forms in eastern Australia supports the palaeobiogeographic distinction of the two regions. [original summary]</ABSTRACT>

49512 <TITLE>Lake Thetis Domal Microbialites - a Complex Framework of Calcified Biofilms and Organomicrites (Cervantes, Western Australia).</TITLE>
49513 <SOURCE>Goettinger Arbeiten zur Geologie und Palaeontologie, Special Volume 2 [Reitner J., Neuwiller F. & Gunke] F. (eds): Global and Regional Controls on Biogenic Sedimentation I. Reef Evolution]: pp ???</SOURCE>
49514 <ABSTRACT>Lake Thetis is a small saline lake with an increased alkalinity and abundant domal microbialites. These microbialites exhibit a rough stromatolitic structure. The recent growth results mainly from calcifying Entophysalis-biofilms which are forming a more or less laminated crust. Within the deeper parts of the Entophysalis-biofilm the outer basophilic polysaccharide envelopes contain abundant heterotrophic bacteria. Calcification events exactly start at these points. The older, subfossil portions of the microbialites are characterized by plumosely arranged Scytonema-filaments which are enclosed by fibrous aragonite. Within small cryptic primary and secondary cavities clearly laminated organomicrites are lining the cavity walls. The formation of this type of "microstromatolites" is related to organic films, which contain no active microbes. These organic films are composed of degraded organic material (polysaccharides, proteins etc.) acting as matrices and templates for nucleation and growth of organomicrites and fibrous aragonite crystals.</ABSTRACT>

49551 <TITLE>Early Middle Cambrian corals from western New South Wales.</TITLE>
49552 <SOURCE>Alcheringa 01: 181-195.</SOURCE>
49553 <ABSTRACT>Three forms: *Cothonion sympomatum* gen. et sp.nov. with a bi-radially septate operculum, and the new species *lissa* and *daseia* of the genus *Lipopora* gen. nov. are described from the early Middle Cambrian Coonigan Formation in the Mootwingee district of western New South Wales, Australia. They may be representatives of hitherto unknown groups of organisms, but they are tentatively interpreted as coelenterates that reached a level of development comparable with the Anthozoa. *Cothonion* is placed in the new family *Cothoniidae* and questionably referred to the *Rugosa*. *Lipopora* is considered to be similar to *Coelenteratella* Korde; both are grouped in the new family *Lipoporidae* and tentatively referred to the *Tabulata*. 49578 <SOURCE>Palaeontographica A177: 129-212.</SOURCE>
49579 <ABSTRACT>This substantial work deals with a diverse Archaeocyathan assemblage preserved in limestone lenses within a volcanic sequence of the Gnalta Shelf of western New South Wales, Australia. The early Cambrian stratigraphic column commences with basic volcanics (Mount Wright volcanics), which are succeeded by tuffs and cherts (Cymbric Vale Formation) and finally by limestones and shales of the Coonigan Formation. Archaeocyath-bearing lenses are present in the first two

formations. Two successive faunas are evident: a lower, probably later Atdabanian fauna and an upper, more diverse, early Lenian fauna which includes several species previously described from South Australia. Globally, strongest faunal affinities are with the Siberian region. Comments on Archaeocyathan classification, Australian and intercontinental correlation are included. [original abstract; comments by F. Debrenne: the present publication corresponds mainly to P. Kruse's PhD (Sydney 1980) for which he has done patient, careful and skillful work for several years. The results are clearly exposed and abundantly illustrated in a well-produced book published by Paleontographica. We must compliment the author for his well-documented descriptions and clever comments, his interpretative pen-and-ink sketches, essential for the understanding of the anatomic structures, and his extremely good photographs perfectly printed in well-composed plates, and thank the Commonwealth Postgraduate Research Commission to have given him an Award without which such a beautiful piece of work would not exist.]</ABSTRACT>

 49604 <SOURCE>Senckenbergiana lethaea 69, 5/6: 467-521.</SOURCE>
 49605 <ABSTRACT>Morphological characteristics, zoological affinity, and phylogenetic importance of the byroniids have already been discussed by Bischoff 1978b and Glaessner 1984. Taxa from eastern Australia are now formally introduced. The new order Byroniida is established and compared with morphologically similar extinct and extant tube-forming organisms. Morphologically and phylogenetically closest are species of the living scyphopolyp Stephanoscyphus Allman 1874. The new families, the Byroniidae and Prestephanoscyphidae are introduced to accommodate non-septate and septate forms. The new septate genera Prestephanoscyphus and Coadunatoscyphus, and the new species Prestephanoscyphus boreensis, P. devonica, P. cobcreensis, P. rosemariae, Coadunatoscyphus waugoolaensis, and C. sp. A are described. Non-septate Byroniidae are represented by the new species Byronia displosa, B. mirrabookaensis, B. petila, and B. n.sp. A as well as by Byronia sp. a aff. B. mirrabookaensis and Byronia ? sp. b.</ABSTRACT>

49630 <SOURCE>Proceedings of the Linnean Society of New South Wales 100, 4: 231-244.</SOURCE>
49631 <ABSTRACT>Ten species of rugose corals are described and illustrated from the Upper Ordovician (Caradoc) limestones of central New South Wales. They include the new genera *Bowanophyllum* (type species *B. pilatum*) and *Rhadelasma* (type species *R. exigua*), and four other new species, *Palaeophyllum jugatum*, *P. arrectum*, *Palaeophyllum patulum* and *P. laxum*. *Rhadelasma* is one of the earliest rugosans to show rhabdacanth, occurring in an horizon of probably early Bolindian (late Caradoc) age. The New South Wales Ordovician fauna also exhibits representatives of *Helicelasma*, *Streptelasma*? and *Grewingkia*. [original summary]</ABSTRACT>

49733 <TITLE>Ordovician (Bendigonian, Darriwilian to Gisbornian) faunas from the northern Molong volcanic Belt of central New South Wales.</TITLE>
49734 <SOURCE>Alcheringa 25, 2: 211-250.</SOURCE>
49735 <ABSTRACT>Diverse shallow water assemblages dominated by brachiopods, molluscs, sponges and stromatoporoids, and a tabulate coral, in the Warringa Limestone Member (Darriwilian-Gisbornian), and Yuranigh Limestone Member (Gisbornian, or early Late Ordovician) of the Fairbridge volcanics, are documented from the northern Molong volcanic Belt in central N.S.W. New species described include Billingsaria spissa, Shlyginia printhiensis and Sowerbyites? warringaensis. Elements of the Warringa Limestone Member assemblage such as Labechia banksi, Labechiella regularis, and Maclurites cf. M. florentinensis are biogeographically significant in displaying strong similarities with contemporaneous Tasmanian faunas. The brachiopods Ishimia and Shlyginia from the Yuranigh Limestone Member are recognised for the first time outside Kazakhstan and Sibumasu. The presence of the brachiopod Anoptambonites in allochthonous limestone breccia within the lower Fairbridge volcanics provides evidence of a regionally significant hiatus of 10-15 Ma duration separating this unit from the underlying Hensleigh siltstone, of Early Ordovician (Bendigonian) age. The sponge Archaeoscyphia?, from allochthonous limestones in the latter formation, is the oldest macrofossil yet described from the Lachlan Fold Belt in central N.S.W. [original abstract]</ABSTRACT>

- 49761 <ABSTRACT>The Cliefden Caves area of central New South Wales has a well preserved Late Ordovician sedimentary succession that formed in an offshore, near-equatorial, volcanic island setting. Initially fringing deposits (the Fossil Hill Limestone) accumulated, with occurrences of corals such as *Tetradium cribriforme*, *Nyctopora*, *Bajgolia?*, *Dualites*, *Hillophyllum*, and stromatoporoids like *Cystistroma*, *Rosenella* and *Stratodictyon*. These were particularly characteristic of the shoal-type, mid-shelf *T. cribriforme* biofacies, and were contributors to a number of bioherms and biostromes. The succeeding, massive *Belubula* Limestone accumulated mainly in shallow lagoonal phases of the platformed island with only sparse heliolitine corals, *Aulopora*, *Bajgolia?*, the stromatoporoids *Cystostroma* and *Alleynodictyon?* and the sphinctozoan sponge *Belubulaia*. The overlying deeper platform carbonates of the Vandon Limestone have a more diverse fauna with *T. cribriforme*, numerous heliolitines, *Palaeophyllum*, the sphinctozoan *Cliefdenella*, and stromatoporoids (*Ecclimadictyon*, *Clathrodictyon*), but no indubitable reefs. Deep water assemblages of the overlying Malongulli Formation include reworked and in situ siliceous sponge associations. Limestone breccias include; (1) clasts with corals (*Favistina* and *favositids*) and rare silicified sphinctozoans, presumed to be derived from the adjacent shallow platform; and (2) clasts eroded from the slopes, with a diverse assemblage of demosponges, hexactinellids and discrete spicules. The in situ Malongulli assemblage occupied a lower slope / basin position, and includes undescribed hexactinellids and abundant spicules. A striking onshore-offshore faunal differentiation exists, with (1) the corals and stromatoporoids, most diversified and abundant in the mid-shelf island settings above wave base, (2) the sphinctozoans, rare constituents of lagoonal to subtidal level bottom carbonate platform habitats, (3) the demosponges, most common and diversified in the upper slope, and (4) the hexactinellids, well represented in both upper and lower slope / basin habitats.</ABSTRACT>

- 49772 <TITLE>Ordovician faunas and biostratigraphy in the Gunningbland area, central New South Wales, Australia.</TITLE>
- 49773 <SOURCE>Alcheringa 25, 1: 9-52.</SOURCE>
- 49774 <ABSTRACT>The Billabong Creek Formation and overlying Gunningbland Formation within the Northparkes Group in the Gunningbland area, 28km west of Parkes, range in age from late Darriwilian (late Middle Ordovician) to late Eastonian (middle Late Ordovician). These strata provide the most complete sequence through this interval in the central Lachlan Orogen in New South Wales. A biostratigraphic zonation spanning the Darriwilian to Gisbornian is proposed, employing conodonts and corals. This supplements the existing coral / stromatoporoid, brachiopod and trilobite faunal assemblages defining Eastonian and Bolindian shelly fossil zones. The Pygodus anserinus Zone (late Darriwilian) in the basal Billabong Creek Formation is succeeded by the Foerstephyllum-Billingsaria-Stratodictyon Assemblage-Zone (of Gisbornian age) in the middle Billabong Creek Formation. A further five Assemblage-Zones extending through the Eastonian succession are formally defined to replace the existing shelly fossil 'faunas '. New coral species described are Billingsaria domica, Eofletcheria subcerioidea, Foerstephyllum nelungaloo, and ?Paleoalveolites explanatus; a possible new species of the conodont Eoplacognathus is described, but not formally named. 49824 <TITLE>Llandovery rugose corals from the Quinton Formation, Broken River Province, northeast Queensland.</TITLE>
49825 <SOURCE>Memoirs Association Australasian Palaeontologists 21: 1-65.</SOURCE>
49826 <ABSTRACT>Three late Llandovery rugose coral faunas are described from allochthonous limestones near the base of the Quinton Formation in the north of the Graveyard Creek Subprovince, northeast Queensland. The limestones occur within predominantly siliciclastic turbiditic sediments, and consist of large slumped blocks, calcirudites and calcarenites. These were probably derived from contemporaneous shallow marine areas along the unstable northern margin of a small, rapidly subsiding basin, which developed during the Early Silurian in a probably extensional tectonic setting. Twenty-three species referable to 17 genera are described, including the new taxa: Aphyphyllum leprostylum sp.nov.; Dentilasma benestratum sp.nov.; Holmophyllum hadrakainum sp.nov.; Plektelasma eurybykane gen et sp.nov. (Streptelasmataceae); Spinocarina vitilia gen. et sp.nov. (Palyphyllidae); Amplexoides grayense sp.nov.; Amplexoides speciosa gen. et sp.nov. (Arachnophyllidae); and Burota compluvium gen. et sp.nov. (Burotidae fam nov.). Other genera recorded include Tryplasma, Stortophyllum, Rhizophyllum, Cystiphyllum (Cystiphyllum), Palaeophyllum?, Pycnostylus, Lindstroemophyllum?, Grewingia and Cyathactia. The faunas are endemic at the specific level, but have some generic links with faunas of central and southern New South Wales, southern China and to a lesser extent, the Siberian Platform. Age interpretations from the faunas are consistent with associated conodont, graptolite and trilobite age determinations of Telychian (late Llandovery).</ABSTRACT>

- 49837 <TITLE>Coral assemblages in the Silurian of Eastern Australia: a rugosan perspective.</TITLE>
- 49838 <SOURCE>Boletín de la Real Sociedad Española de Historia Natural, Sección Geológica 92, 1/4: 311-323.</SOURCE>
- 49839 <ABSTRACT>Four successive coal assemblages can be recognized in the Silurian of Eastern Australia. The Bridge Creek Assemblage (Rhuddanian-Aeronian) is of limited extent, characterized by species of *C.* (*Cystiphyllum*), *Grewingkia* and *Calostylis* as well as numerous halysitids and *Pseudoplasmodora*. The earliest arachnophyllids and species of *Ptychophyllum* occur in the widespread Quarry Creek Assemblage (Telychian-early Sheinwoodian), in which there is greater rugosan and halysitid diversity. The late Sheinwoodian-earliest Gorstian Dripstone Assemblage is mainly characterized by changes in the tabulate fauna, but is also notable for the appearance of *Entelophyllum*, *Holmophyllia*, and *Zenophila*. The Gorstian-Pridoli Hattous Corner Assemblage is a diversification of older faunas (except the halysitids), and is characterized by such rugosans as *Phaulactis shearsbyi*, *Aphyllum lonsdalei*, as well as *Idiophyllum patulum* and species of *Toquimaphyllum*.</ABSTRACT>

international sur les coraux et recifs coralliens fossiles; Paris,
1975]: 102-107.</SOURCE>
49904 <ABSTRACT>Five distinct coral faunal assemblages have been recognized
in the Lower Silurian of Central New South Wales. Two assemblages are
of late Lower or early Middle Llandovery age whilst the other three
belong to the Upper Llandovery. Differences between largely
contemporaneous faunas are attributed mainly to environmental factors.
Zoogeographic affinities of the Australian faunas are obscured by the
general scarcity of detailed information on Llandovery rugosans
elsewhere in the world, but would appear strongest with those of the
Siberian Platform region. At present distinct rugose coral faunal
provinces in the Lower Silurian cannot be elucidated with any
certainty. [original summary]</ABSTRACT>

- 49943 <ABSTRACT>Rugose corals belonging to the families Cystiphyllidae Milne Edwards & Haime and Goniophyllidae Dybowski from the Middle-Upper Llandoveryan of the Orange district, central N.S.W., are described. Cystiphyllidae represented include Cystiphyllum siluriense cylindricum Lonsdale, C. khantaikaense (Zaprudskaya), "Microplasma" cf. Iovenianum Dybowski, Dentilasma honorabilis Ivanovskiy, D. ramosum n.sp., Holmophyllum confertum n.sp., Hedstroemophyllum crebrum n.sp. and Angullophyllum warrisi n.gen. et sp. Goniophyllidae include Rhizophyllum antiquum n.sp., being the oldest known record of this genus (Upper Llandoveryan). Generic composition of the Cystiphyllidae is reviewed. The affinities of these genera, together with guidelines for distinguishing them, are discussed.</ABSTRACT>

49968 <SOURCE>Palaeontology 17, 3: 715-726.</SOURCE>
49969 <ABSTRACT>*Hattonia* Jones, reinterpreted on type and topotype material of *Hattonia etheridgei* Jones, the type species, is a Silurian and Devonian favositid. It is characterized by distant groups of tabulae developed at the same level throughout the corallum and by pores which are confined to these levels. The genus is endemic to eastern Australia. Two new species, *H. fascitabulata* from the lower Gedinnian of New South Wales and *H. spinosa* from the Emsian of north Queensland, are referred to it.</ABSTRACT>

49980 <TITLE>Early Devonian (mid-Lochkovian) brachiopod, coral and conodont faunas from Manildra, New South Wales, Australia.</TITLE>
49981 <SOURCE>Palaeontographica 273, 1-2: 1-54.
<http://hdl.handle.net/1959.14/32268></SOURCE>
49982 <ABSTRACT>New data are provided for assessing the sedimentary context, palaeoecology and biogeographic affinities of the brachiopod, coral and conodont faunas from Manildra. The deeper-water Maradana Shale shallows upwards into the shallow marine, brachiopod-dominated Garra Limestone. The latter is characterised by angular, poorly sorted allochemical constituents, high mud contents, and encrusting algal mats of *Girvanella*, all implying low-energy conditions with limited post-mortem transport. This is supported by the relatively low degree of valve disarticulation of the silicified brachiopod assemblages. The sedimentological data accord with a shallow (photic zone), open marine environment, with moderate to low-energy conditions of a protected zone within a carbonate platform or shelf-margin. The Garra Limestone is terminated by an influx of clastics and volcanoclastics, the Mandagery Park Formation (redefined). The 55 species of brachiopods from the Garra Limestone at Manildra are referred to 36 genera including two new rhynchonellid genera, *Protodorsis* and *Discamella*, with type species *P. similis* sp. nov. and *D. troparvis* sp. nov. respectively. A new species of the cemented strophomenid, *Colletostracia*, is described but not named. None of the coral and conodont taxa documented appear to be new. 49993 <TITLE>Succession of coral associations during a Givetian transgressive-regressive cycle in Queensland.</TITLE>
49994 <SOURCE>Acta Palaeontologica Polonica 41, 1: 59-88.www.a
pp.pan.pl/article/item/app41-059.html</SOURCE>
49995 <ABSTRACT>The small solitary coral dominated, Grypophyllum-Chostophyllum association, a pioneer coral community, is widely distributed at the base of the Givetian Burdekin Formation of north Queensland in the mixed arkose-carbonate sediments. It is succeeded by fasciculate coral dominated, Dendrostella trigemne association, which is mainly associated with wackestone or bioclastic calcirudite of inner shelf, lagoonal or protected environments. The Australophyllum-Sanidophyllum association, Blymatophyllum-Iowaphyllum schlueteri association, and Spongophyllum association, all dominated by in situ, large massive coral colonies, formed biostromal deposits on the margins of the basin. They developed in nearshore environments during the maximum flooding in the region. The Aphyllum salmoni-Stringophyllum (Neospongophyllum) bipartitum association indicates relatively deeper, mid-outer shelf environments connected with maximum flooding in the depocentre and least terrigenous influx. The massive coral dominated Endophyllum columna-Stringophyllum (Stringophyllum) isactis association, developed in the initial regressive phase, forms a distinctive biostromal unit at the top of the Burdekin Formation. The Lekanophyllum association developed at the base of the Cultivation Gully Formation in a very shallow nearshore environment with a large terrigenous influx as a result of the basin wide, relatively rapid regression. It is characterised by the abundant occurrence of solitary corals and large sized, cerioid Endophyllum columna, which often formed micro-atolls. Rugose corals were better adapted than stromatoporoids to survive of mud influx. [original abstract]</ABSTRACT>

50020 <SOURCE>Proceedings of the Linnean Society of New South Wales 128: 201-208.</SOURCE>

- 50021 <ABSTRACT>The holotype and sole known specimen of the rugosan coral *Microplasma parallelum* Etheridge 1899 is reassessed. This phaceloid species with only sporadic occurrence of isolated dissepiments or presepiments is here selected as type species of the new subgenus *Loyolophyllum* (*Fasciloyolophyllum*), which is erected to accommodate phaceloid species otherwise resembling *Loyolophyllum* (*Loyolophyllum*). Two other species previously referred to *Fasciphyllum*, from the Devonian of China, are also ascribed to this new subgenus. Review of the concept of *Loyolophyllum* sensu stricto leads to a reappraisal of those species assigned to it.</ABSTRACT>

50059 <SOURCE>Courier Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, vol. 2]: 1-6.</SOURCE>
50060 <ABSTRACT>Coral assemblages (A-F) are recognized in the late Eifelian to Givetian Fanning River Group of the Burdekin Basin, west of Townsville, north Queensland. Assemblages (A-D) are recognized in the upper Big Bend Arkose, the Burdekin Formation, and basal Cultivation Creek Formation in the southern half of the Basin; this area was the late Eifelian to early Givetian depocentre of the Basin. Assemblage (A) is the most diverse and widely distributed; it is correlated with late Eifelian and early Givetian faunas of western Canada, southern China, and western Europe. The middle or possibly late Givetian Assemblage (D), the youngest recognized, is confined to the southern margin of the Basin; Assemblages (E) and (F) are latest Eifelian to early Givetian in the condensed Burdekin Formation on the northern flanks of a central basin high. Assemblage (F) is similar to faunas at the top of the Timor Limestone of northern New South Wales.</ABSTRACT>

50097 <TITLE>A new Early Devonian operculate tetracoral genus from eastern Australia.</TITLE>
50098 <SOURCE>Records of the Western Australian Museum, Supplement 58: 21-35.</SOURCE>
50099 <ABSTRACT>Chakeola, a solitary latest Lochkovian to late Emsian (Early Devonian) new genus of the operculate tetracoral family Calceolidae, is characterized by: opercular septa that are present from adjacent to the median septum to the lateral extremities of the operculum; a lack of rootlets on the counter face of the corallite; a weak counter opercular face in mature specimens; and eccentric growth increments on the external opercular surface. The type species, *C. johnsoni* new species, is described from latest Lochkovian (pesavis Zone), early Pragian (sulcatus Zone) and late Pragian (pireneae Zone) strata of the Garra Formation, Wellington, NSW. *C. whitehousei* new species is described from the Ukalunda Beds (perbonus Zone, mid-Emsian), near Ukalunda, Queensland. Specifically indeterminate occurrences of the genus from the Mudgee district in New South Wales are in: the Taylors Hill Formation (?kindlei Zone, late Pragian); the Sutchers Creek Formation (serotinus Zone, late Emsian); and possibly the Mullamuddy Formation (sulcatus Zone, early Pragian). *Rhizophyllum calceoloides* from the Tabberabbera Formation (Emsian), Victoria also belongs to this new genus. *Calceola sinensis* and *Calceola sandalina acuminata* from Emsian strata in northern Vietnam are also assigned to this genus. *Chakeola* thus ranges from the latest Lochkovian (pesavis Zone) to the late Emsian serotinus Zone; it presumably arose from *Rhizophyllum* or a related form, and probably gave rise to *Calceola* in the Emsian in eastern Australia or SE Asia. The occurrence of the genus in eastern Australia and Vietnam provides further evidence of faunal exchange during the Early Devonian. This study concludes that features of the exterior and interior surfaces of the opercula of genera of the Calceolidae are diagnostic at the generic level.</ABSTRACT>

50123 <TITLE>A new Phillipsastraenid tetracoral from the Devonian of New South Wales.</TITLE>
50124 <SOURCE>Palaeontology 24, 3: 589-608.</SOURCE>
50125 <ABSTRACT>Fromeophyllum climax gen. et sp.nov. is a phillipsastraenid tetracoral from the Mount Frome Limestone near Mudgee, New South Wales, Australia, where it occurs over a stratigraphical thickness of 98 m, ranging between Dalejan (Early Devonian) and possibly Eifelian (Middle Devonian) strata. The subfamily assignment is based on a close similarity to Macgeea touti Pedder, which appears to be ancestral to F. climax. Silicified specimens show F. climax to be a polymorphic fasciculate form which undergoes up to three phases of parricidal peripheral increase. When basal structures are preserved, F. climax is mostly found attached to various types of fossil skeletons which offered a firm substrate above the muddy sea floor by sheaths of skeletal material. Calcareous specimens show a well-defined vertical series of horseshoe dissepiments outside which are horizontally disposed ranks which consist alternately of mostly horseshoe dissepiments and flat dissepiments. Outside this zone normal dissepiments are developed which are proximally and outwardly inclined. This outermost array of skeletal material often spreads down the side of the colony over the wall of the trunk, demonstrating the presence of a highly extensile edge zone and everted calyx. Polymorphism is manifest in the diameter and number of septa developed in each of the several generations within a colony. [original summary]</ABSTRACT>

50137 <SOURCE>N. Jb. Geol. Palaeont. Abh. 201, 3: 289-301.</SOURCE>
50138 <ABSTRACT>Rugose and tabulate corals were recovered from two localities in the Anaiwan terrane. Fossils from locality A include Tryplasma sp. aff. T. columnare Etheridge 1907, Tabulophyllum sp., Heliolites sp., and unidentified favositids and syringoporoids, indicating an Emsian age. The only fossil collected from locality B was Thamnophyllum sp., giving a possible Lower to Middle Devonian age for this site. These are the first reported Lower to Middle Devonian fossils from the Anaiwan terrane and provide constraints on the timing of the development of its southern edge.</ABSTRACT>

50150 <SOURCE>Papers & Proc. of the Roy. Soc. of Tasmania 104: 16 pp., 6 pls.</SOURCE>
50151 <ABSTRACT>Of the fourteen species (six new) assigned to eight rugosan and five tabulatan genera, identified in the coral fauna of the Point Hibbs Limestone of the west coast of Tasmania, eleven are systematically examined and illustrated. The genus Endophyllum is discussed in relation to Sinospongophyllum and Tabulophyllum. The microstructure of Silurian and Devonian cystimorphs is considered. The age indicated by the coral fauna is within the range Siegenian to Lower Couvinian and is possibly Emsian.</ABSTRACT>

50163 <SOURCE>Proc. Royal Soc. Queensland 81, 10: 93-120.</SOURCE>
50164 <ABSTRACT>Nine species, Cyathophyllum (Radiophyllum) arborescens, Lyrielasma aggregatum, xystriphyllum sp., Fasciphyllum rugosum sp.nov., Favosites goldfussi, Thamnopora randsi sp.nov., Cladopora sp., Pseudoplasmopora sp. cf. P. gippslandica and Syringopora jonesi sp.nov. are described from the Douglas Creek Limestone of the Clermont District, for the first time, and thirteen previously described species are revised. The lectotype of Acanthophyllum (Acanthophyllum) clermontense is redescribed and thin sections figured. The type specimens of Xystriphyllum dunstani, Australophyllum cyathophylloides, Thamnopora plumosa and Yacutiopora hillae are refigured. The age of the fauna is considered to be late Emsian or possibly early Couvinian.</ABSTRACT>

50188 <TITLE>Marked accumulation patterns characteristic of Lower Devonian stromatoporoid bindstone: Palaeoecological interactions between skeletal organisms and microbes.</TITLE>
50189 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 231, 3-4: 331-346.</SOURCE>
50190 <ABSTRACT>The growth history of stromatoporoid bindstones is as follows: 1) the laminar stromatoporoid "Aculatostroma" first grew laterally, thereby stabilizing bioclastic sediments; 2) the stromatoporoid growths were partly or totally interrupted in relation to deteriorating habitat conditions, where micritization (leiolites with microborings), and encrustation by thrombolites occurred in succession. However, somewhat ameliorated conditions enabled Syringodictyon to temporarily dominate; 3) surviving parts of "Aculatostroma" again spread vertically and laterally upon the recovery of optimum conditions and; 4) the ceilings of cryptic spaces produced within "Aculatostroma" are affected by micritization (leiolites) and then encrustation of thrombolites. Repeated accumulations at various scales indicate antagonistic interrelationships within skeletal organisms and between skeletal organisms and microbes within their habitable ranges. These accumulation patterns thus provide invaluable clues for biotic interactions between skeletal frameworks and microbes, biological successions in accordance with microenvironmental changes, and resultant depositional sequences of bindstones. 50215 <SOURCE>Alcheringa 17: 327-352.</SOURCE>
50216 <ABSTRACT>The fauna of the limestone breccia is interpreted as allochthonous and consists of 11 species including representatives of Actinostroma, Gerronostroma, Schistodictyon, Amnestostroma, Pseudotruperostroma, Salairella, Stromatopora, Atopostroma, and Habrostroma. Details of the microstructure of Amnestostroma and Pseudotruperostroma are presented for the first time. New species include Gerronostroma vergens, Amnestostroma crassum,

- Pseudotruperetostroma jessensis, and P. ripperae. Occurrences of Siberian, S. Chinese and Canadian elements suggest links with these areas. The Jesse limestone has been interpreted as of late Emsian age but the stromatoporoids seem to have been reworked from earlier Emsian beds.</ABSTRACT>

50228 <SOURCE>Royal Society of Victoria Proceedings 105, 2: 113-185.</SOURCE>
50229 <ABSTRACT>Thirty-seven species representing 23 genera are described from the collections of Elizabeth Ripper and new material. New species include: Atelodictyon hicksense, Clathrodiction? heathense, Amnestostroma holmesae, Parallelopora ampla, Habrostroma tyersense, Columnostroma clathratum, Stellopora porecta. The assemblages represent: i) the lower to mid-Pragian of the Lilydale Limestone and the Coopers Creek Limestone that include: Plectostroma altum, Aculatostroma? sp., Schistodiction? cylindriferum, Pseudoactinodiction sp., Atelodiction chapmani, Stromatoporella cf. granulata, Tubuliporella calamosa, Amnestostroma holmesae, Salairella lilydalensis, Syringostromella zintchenkovi, Habrostroma tyerense, Columnostroma clathratum, Dendrostroma? sp.; ii) the basal Emsian of the Buchan Caves Limestone that includes: Clathrodiction? heathense, Pseudotruperetostroma buchanense (and possibly P. ripperae), Syringostromella cf. labyrinthea, Coenostroma sp., Atopostroma distans; iii) the lower to mid-Emsian of the Murrindal Limestone that includes: Petridiostroma delicatulum, Pseudotruperetostroma sp., Parallelopora ampla, Atopostroma sp. Many genera are more typical of Middle rather than Lower Devonian successions in other areas. The Australian Devonian, and the global Lower Devonian succession of stromatoporeid faunas are reviewed.</ABSTRACT>

50292 <TITLE>Paleoecology, biostratigraphy and paleogeography of Favositidae (Tabulata) from the Emsian to Middle Devonian Tamworth Group (New South Wales, Australia).</TITLE>
50293 <SOURCE>Senckenbergiana lethaea [Palaeobiodiversity and Palaeoenvironments] 81, 1: 91-109.</SOURCE>
50294 <ABSTRACT>Different species and species groups of the family Favositidae from the Emsian and Middle Devonian limestones of the Tamworth Group (N.S.W., Australia) were investigated with regard to their paleoecology, biostratigraphy and paleogeography. The Emsian Sulcor Limestone Member yielded Favosites sp. aff. F. basalticus (Goldfuss), Favosites sp. aff. F. salebrosus Eheridge, Favosites stellaris Chernyshev, Squameofavosites nitidus (Chapman), Sq. bryani (Jones), Pachyfavosites rariporus Dubatolov, and P. tumulosus Yanet. The Middle Devonian Moore Creed Limestone Member yielded Favosites ex gr. goldfussi D'Orbigny, exclusively. In the Emsian limestones favositids occur in different lithofacies, but mostly in stratified biostromes, bedded nodular limestones and Amphipora limestones. In the Middle Devonian favositids are found in nodular and lumpy limestones which occur at the base and at the top of some successions. A relationship between sediment composition and the septal apparatus could be detected in F. ex gr. goldfussi. The favositid faunas from Tamworth display faunal ties to eastern Australia and various regions of Asia. Most striking is the similarity to faunas from the southern Tien Shan region. Complex provincial affinities and high diversities are displayed by Emsian favositids, whereas Middle Devonian faunas are of low diversity and consist of cosmopolitan species.</ABSTRACT>

- 50319 <SOURCE>Lethaia 35, 1: 35-50.</SOURCE>
- 50320 <ABSTRACT>Study of 35 systematically collected and 10 semi-random samples (about 100 cm² each) from one outcrop of the Lankey Limestone (Emsian) near Reefton, New Zealand, indicates that it is a reef framestone built by tabulate (4? spp.) and clonal rugose (one sp.) corals, two species of stromatoporoids, a few bryozoans (2? spp.) and crinoids. The guild structure of the reef community and data on skeletal orientation and growth direction further indicate that there was relatively minor biostratinomic alteration of the original community. Skeletons are either in growth position or tipped, toppled, or even overturned, but they have remained in situ. Other clone-rich Lankey Limestones outcrops in the Reefton area support the notion of an upper shelf reef system and stratigraphic and sedimentologic data suggest that it was located near the Gondwana margin at a paleolatitude of about 35°S. (original abstract). The stromatoporoid species identified are Anostylostroma (now Stictostroma) clarum and Stromatopora hupschii. The first is shown in an outcrop photograph.</ABSTRACT>

- 50332 <SOURCE>Facies 39, 1: 1-34.</SOURCE>
- 50333 <ABSTRACT>Biohermal and biostromal buildups were investigated in late Early and Middle Devonian carbonate complexes of the Tamworth Belt. The buildup types and subtypes were studied in three regions (Yarramanbully, Sulcor and, Wyaralong') to clarify their paleo-environmental position. Two stages of development are recognized: Incipient bioherms and bioherms. Incipient bioherms are carbonate buildups with organisms which commonly form true bioherms. They dominate the sediment with small growth forms but are not prolific enough to build large bio-frameworks. Small nodular and globular stromatoporoids characterize the incipient bioherms and are interpreted as stunted growth forms. In one location (,wyaralong') the coarse stromatoporoid calcarenite represents a fore-reef facies, at Sulcor a shallow subtidal setting with moderate water energy can be deduced. The bioherms can be sub-divided into stromatoporoid-, stromatoporoid-Stachyodes-, and stromatoporoid-rugose coral bioherms. Their variable composition probably reflects growth and deposition in different zones of a reef complex and/or different proximity to areas of denudation indicated by high siliciclastic input. In the Tamworth region true bioherms occur only in the Moore Creek Limestone Member (Middle Devonian), and not in older carbonate successions. Biostromes are sub-divided into (1) incipient biostromes with stromatoporoid-heliolitid biostromes and alveolitid biostromes; (2) aggregate biostromes with Amphipora and Stachyodes biostromes; (3) stratified biostromes; (4) mixed aggregate/stratified biostromes. The different types of biostromes are not limited to specific time-intervals, but rather to environmental conditions. (1) Incipient biostromes are characterized by laminar stromatoporoids and tabualte corals. Their forms are interpreted as initial layers of skeletons which were hampered by adverse conditions in growth. The stromatoporoid-heliolitid incipient biostrome (Eifelian Moore Creek Ls.

- Mbr., Yarramanbully) is characterized by abundance of dislodged laminar, ragged and tabular colonies associated with small globular and nodular heliolitids. An unstable substrate may have caused the growth disruptions. Decreasing grain-size of skeletal debris and increasing mud-content suggests deposition on a bathymetric gradient with deepening to the south. The alveolitid incipient biostrome (Eifelian Morre Creek Ls. Mbr., Wyaralong) is composed of nodular limestone with laminar alveolitids, stromatoporoids and Sphaerocodium.

50344 <TITLE>Devonian marine invertebrate fossils from the Port Macquarie Block, New South Wales.</TITLE>
50345 <SOURCE>Proceedings of the Linnean Society of New South Wales 130: 193-217. <http://linneansocietynsw.org.au/recvol.html></SOURCE>
50346 <ABSTRACT>Two assemblages of rugose and tabulate corals, with accessory stromatoporoids and chaetetids, are described from the Touchwood and Mile Road Formations of the Wauchope - Port Macquarie district of northeastern New South Wales. Both assemblages are derived from allochthonous limestone clasts, except that the Mile Road fauna is accompanied at the same level by branching tabulate corals occurring in the matrix, indicating probable contemporaneity. The fauna from the Touchwood Formation indicates an Early Devonian (Emsian) age. Macrofossils from the Mile Road Formation indicate a broad Middle Devonian, probably Givetian age; conodonts accompanying the coral assemblage yield a precise age in the upper part of the early Givetian varcus Zone. Geographic affinities of the assemblages are typically eastern Australian, so that if terranes are represented in the block, these were not remote. Stratigraphic and structural relationships of the units are discussed. The name Mile Road Formation is formally defined. [listed, and mostly illustrated fossils, are: Chaetetes sp., Coenostroma sp., Endophyllum cf. columna Hill, Acanthophyllum sp., Xystriphyllum cf. mitchelli minus Parker, Phillipsastrea cf. maculosa Hill, Sterictophyllum sp., Favosites salebrosa Etheridge fil., Pachyfavosites sp., Squameofavosites squamuliferus Etheridge fil., Cladopora sp., Thamnopora randsi Jell & Hill, Alveolites sp. 50357 <TITLE>The palaeobiogeography of eastern Australian Lower Carboniferous corals.</TITLE>
50358 <SOURCE>Historical Biology 15, 1-2: 91-119.</SOURCE>
50359 <ABSTRACT>Eastern Australian Lower Carboniferous (EALC) corals are characterized by high endemism, with endemism indices of 50 in the Tournaisian and 44 in the Viséan. The most closely related coral faunas occur in the Akiyoshi and Kitakami Terranes of Japan. Less robust

faunal linkages exist with southeast Asia, south China, northern Siberia and Kazakhstan, suggesting east to north Tethyan linkages on most tectonic reconstructions. *Amygdalophyllum* appears to have originated in the eastern Australian-Japanese region and then migrated throughout the Palaeotethys during the late Tournaisian and early Visean. Eastern Australian taxa that lacked such a widespread distribution during the Tournaisian did not spread throughout the Palaeotethys during the Visean. EALC coral distributions can be explained by a palaeobiogeographical model wherein: 1) shallow-water coral faunas were largely depleted following the Frasnian/Famennian extinction event; 2) dispersal occurred during the late Famennian to early Tournaisian from an oceanic centre to the northeast, in western Panthalassa; 3) eastern Australian coral faunas were isolated from the north by the prevailing southerly current direction and possible coastal upwelling in northernmost Australia and New Guinea, and from the south by cooler high latitudes; 4) endemic taxa arose by vicariance subsequent to geographic isolation. * Sampling of EALC corals is incomplete owing to the restriction of most taxa to shallow carbonate facies, which have very limited geographic and stratigraphic distributions. Hence, EALC coral diversity is probably controlled largely by sample density. Better sampling will be required before coral data can be used to independently constrain EALC palaeolatitude, but the limited incidence of coral-bearing facies may preclude a definitive analysis. * High EALC coral endemism is puzzling in light of the apparently cosmopolitan nature of co-occurring shallow benthos. Hence, either EALC corals were particularly subject to genetic isolation for ecological and/or other reasons, or other EALC invertebrates may prove to have higher levels of endemism than has been assumed. Increased emphasis on detailed reconstruction of phylogenies, and the recognition of homoplasy, in particular, in other EALC benthic invertebrates suggest that they may be less cosmopolitan than is currently accepted. 50370 <TITLE>Lower Carboniferous coral fauna of the Rockhampton Group, east-central Queensland.</TITLE>

50371 <SOURCE>Mem. Ass. Australas. Palaeontols. 10 [Jell P.A. (ed.): Devonian and Carboniferous coral studies]: 1-167.</SOURCE>

50372 <ABSTRACT>[...84 coral species are described of which 68 have not been described previously. Included are 3 new genera with type species: *Stereodepasophyllum amplexum*, *Alinkioduncanella crassa*, and *Dinostrophinx hadros*; and 22 new species: *Amplexocarinia pumila*, *Kabakovitchiella? hardingae*, *Amygdalophyllum archeri*, *A. minimum*, *Aphrophyllum edgari*, *A. julli*, *Merlewoodia abnormalis*, *Symplectophyllum densum*, *S. rosewoodensis*, *Siphonodendfon*; *fasdculiseptaturn*, *Schoenophyllum dalmaensis*, *Orionastraea*; *flemingi*, *Michelinia crassispina*, *Tumadpora? hillae*, *Acaciapora jelli*, *Multithecopora minor*, *Pseudomemeripora queenslandica*, *Palaeacis cuneiformis australis*, *P. cuneiformis granvillensis*, *P. grandis*, *P. robusta*, and *P. serrata*. Rockhampton Group corals are grouped into 4 assemblages. Late Tournaisian (*Spirifer sol* Brachiopod Zone) Assemblage A, in the Gudman Formation, includes small solitary corals and abundant *Turnacipora?* with rare colonial rugosans. Although not recognized elsewhere in Queensland, it is similar to that of the Rangari Lst., N.S.W. Middle to late Visean (*Orthotetes australis*, *Delepinia aspinosa*

Brachiopod Zones) Assemblage B, in the Cargoogie Oolite Member, Malchi Formation is a larger fauna of lithostrotionoids, aphrophylloids, and Syringopora. It is recognized in the lower Cannindah Lst. and Washpool Creek Formation. Late Visean (Rhipidomella fortimuscula Brachiopod Zone) Assemblage C, in the Lion Creek Lst., consists of a large fauna of lithostrotionoids, aphrophylloids, and the syringoporoids Multithecopora and Pseudoroemeripora. It is recognized in the upper Cannindah Lst., Liverleigh Lst., Splinter Creek Formation, O'Bil Bil Road Conglomerate, and Mundubbera Sandstone. Late Visean (Marginirugus barringtonensis Brachiopod Zone) Assemblage D, in unnamed limestones on the eastern flank of the Craigilee Anticline, consists of aphrophylloids and Palaeacis and is recognized in the Baywulla and Dakiel Formations and Killala Creek Lst. (fragment of extensive summary)]</ABSTRACT>

 50385 <ABSTRACT>A detailed geological map of the Slaughterhouse Creek area, near Gravesend, New South Wales, Australia, is presented, and the Tournaisian and earliest Visean age of the marine formations established using conodonts. A sequence of six informal coral assemblages is described, all of Late Tournaisian age. The new tabulate coral genus Spinuliplena is described, and two new species. The type horizon of the long doubtful genus Cionodendron Benson & Smith has been identified, and most Australian fasciculate species previously referred to Lithostrotion are transferred to it. The cerioid Roemeripora is reported from the Australian Carboniferous for the first time.</ABSTRACT>

50410 <SOURCE>Proc. Roy. Soc. Queensland 85, 1: 1-26.</SOURCE>
50411 <ABSTRACT>Corals of the genera Aphrophyllum Smith, Aphrophylloides Pickett, Coenaphrodia gen. nov. and Nothaphrophyllum Pickett are described from many localities in the Yarrol Basin of Queensland. with the possible exception of the last genus, all are considered to belong with the Aphrophyllidae, a newly proposed family of rugose corals from Visean beds in Queensland and New South Wales. Amongst the eleven species discussed, the following are newly described: Aphrophyllum diphyrmoche, A. medium, A. latevesiculatum, Aphrophylloides variabilis, and Nothaphrophyllum fasciculatum. Correlations of coral-bearing Visean horizons in Queensland are briefly described and it is suggested that the aphrophyllid corals range through the Lower to Upper Visean Orthotetes aspinosa and Delepineia australis zones of the Carboniferous of eastern Australia.</ABSTRACT>

50448 <TITLE>Quantitative analysis and paleoecology of earliest Mississippian microbial reefs, Gudman Formation, Queensland, Australia; not just post-disaster phenomena.</TITLE>
50449 <SOURCE>Journal of Sedimentary Research 75, 5: 877-896.</SOURCE>
50450 <ABSTRACT>Small (> 30m diameter, ~ 9m thick) reefs in the Gudman Formation of Queensland, Australia are the oldest known Mississippian reefs, occurring very near the Devonian-Carboniferous boundary following Late Devonian extinction events. They occur in high-energy, shallow, oolitic grainstones and consist of ~62% microbialite and bound detritus on the basis of point-count analysis. Skeletal organisms, including potential frame-building rugose and tabulate corals, ramose bryozoans, crinoids, and algae, occur in growth position but account for only 4.4% of sampled framework. The microbial framework was syndepositionally rigid on the basis of: (1) vertical and overhanging relief in a high-energy setting, (2) export of framework intraclasts, (3) hard-substrate-encrusting organisms, (4) abundant hard-rock borings, and (5) neptunian dikes. Unusually for Mississippian reefs, stromatolites make up a large part of the framework (~ 32%), but more typical thrombolites are equally abundant. Interfingering of skeletal organisms and microbialites suggests that they grew in well oxygenated, normal marine waters and that microbial biofilms competed effectively with skeletal organisms for available substrate. Abundant and diverse co-occurring skeletal flora and fauna are inconsistent with interpretations of Gudman stromatolites as post-extinction disaster taxa. Hence, Gudman reefs are stromatolite-rich examples of a larger class of microbialite-dominated Phanerozoic reefs that occurred with abundant skeletal metazoans in normal marine settings. 50461 <TITLE>Earliest known Carboniferous shallow-water reefs, Gudman Formation (Tn1b), Queensland, Australia: Implications for Late Devonian reef collapse and recovery.</TITLE>
50462 <SOURCE>Geology 26, 10: 951-954.</SOURCE>
50463 <ABSTRACT>The Phanerozoic history of reefs extensively has been considered a direct reflection of the history of skeletal reef-building organisms. However, such a relationship does not characterize global mid-Paleozoic reef history. The extinction of most reef-building stromatoporoids and corals at the Frasnian-Famennian boundary correlates with the collapse of North American and European stromatoporoid-dominated reefs, but Western Australian, Russian, and Chinese reefs were much less severely affected until the late Famennian, when algae, calcimicrobes, and nonskeletal microbialites (i.e., stromatolites, thrombolites) declined globally. Additionally, reef recovery was more rapid than previously thought. Small, early Tournaisian (Tn1b) shallow-water reefs in the Gudman Formation of eastern-central Queensland substantially reduce the duration of the reefless lag time following Late Devonian reef decline, essentially confining it to the Strunian. Gudman reefs are dominated by microbialite, but contain a diverse, although volumetrically insignificant, skeletal fauna and flora, including large colonial corals, bryozoans, crinoids, brachiopods, and calcareous algae. Hence,

mid-Paleozoic reef collapse and recovery reflect an amalgam of more-or-less independent histories of skeletal organisms, calcimicrobes, and nonskeletal microbialites, in response to regional and global environmental parameters, a better understanding of mid-Paleozoic reef history will require detailed local- and regional-scale studies to isolate global from nonglobal signals.

50474 <TITLE>Youngest Early Carboniferous (Late Viséan) Shallow-water Patch Reefs in Eastern Australia (Rockhampton Group, Queensland): Combining Quantitative Micro- and Macro-Scale Data.</TITLE>

50475 <SOURCE>Facies 41, 1: 111-139.</SOURCE>

50476 <ABSTRACT>Although skeletal organisms have received most of the emphasis in studies on Phanerozoic reef history, the roles of non-skeletal (non-enzymatic) carbonates (e.g., symsedimentary cements, automicrite, microbialite, etc.) in reef framework construction are becoming increasingly better understood. One problem in understanding the role of non-enzymatic carbonates in reef construction has been the difficulty in recognizing them in reef facies. Whereas skeletal organisms commonly can be recognized and documented in the field, non-enzymatic carbonates may be recognizable only in thin section. This paper describes the application of a new sampling technique that allows the quantitative comparison of skeletal macrofauna and flora with associated non-enzymatic carbonates and other microfaunal/microfloral constituents. The technique involves the point counting of thin sections made from small diameter cores that are systematically recovered from grids and line transects that cover a reasonable area (m²) of reef facies. 50487 <TITLE>Rides septales a organisation de type tetracoralliaire chez Trachypsammia (Tabulate, Permien).</TITLE>

50488 <SOURCE>Lethaia 25, 4: 429-437.</SOURCE>

50489 <ABSTRACT>A rugosan pattern of the septal ridges, formerly described in Kerforneidictyum and Palaeacis, is pointed out in Trachypsammia monoseptata (Permian of Timor) for which only the **Median septum** had been observed. T. monoseptata exhibits a strong cardinal ridge in dorsal or internal position, just opposite a shorter counter ridge, thus creating a plane of bilateral symmetry. The ridges assumed to be alar can be identified by their proximal ends being in contact with the **Median septum**. The major ridges (proto- and metaridges) are obvious, the minor ones show only their very proximal ends. T. monoseptata could be a calicinal young stage of T. dendroides. T. dendroides (Permian of Timor) shows a plane of bilateral symmetry, the cardinal ridge is stronger and longer than the others, the counter shorter, the alar ridges can be identified in tranverse sections, major

and minor ridges are well developed; the number of ridges is often 32. In *T. xizangensis* (Permian of Tibet) only the bilateral symmetry is known, while there are no data for *T. mediterranea* (Permian of Sicily). The systematic affinities between *Palaeacis* and *Trachypsammia* pointed out on the basis of microstructural data are also supported by the septal ridges pattern. Do *Palaeacis*, *Trachypsammia* and other form a special division of Tabulate corals? That is the question.</ABSTRACT>

50501 <SOURCE>Memoirs Association Australasian Palaeontologists 01 [J. Roberts & P.A. Jell (eds): Dorothy Hill Jubilee Memoir]: 275-288.</SOURCE>

50502 <ABSTRACT>Study of structures in septa, wall and tabulae within specimens of *Timorphyllum* from Basleo, Timor, indicates that preservation is excellent. Skeletal structures are original rather than relic, as they are formed by present crystal boundaries rather than being inherited from pre-existing crystal fabrics or compositional changes. Scanning electron micrographs of the corals show little or no modification either of the septal trabeculae or of biogenic carbonate generally, and also indicate several generations of cement. Early cementation by coating skeletal calcite with drusy epitaxial calcite took place shortly after burial, and only sporadic and incomplete deposition of blocky cement took place later, perhaps due to insufficient burial to develop the necessary pressure solution to provide sufficient carbonate.</ABSTRACT>

50514 <SOURCE>Palaeontographica A161 (4-6): 173-226</SOURCE>

50515 <ABSTRACT>The original thin sections of Schoupe & Stacul (1955, 1959) formed a basis for the reinterpretation of majority of genera and families discussed by those authors. The following new taxa were introduced: Asserculiniidae n.fam. with two subfamilies: Asserculiniinae n. subfam. and Duplocariniinae n. subfam. with Duplocarina n.gen. and *D. timorica* n.sp.; wannerophyllidae n.fam. with Productiophyllum n.gen.; Lophbillidium n.subgen. of the genus Lophophyllidium Grabau 1928. The ontogeny and morphology of the axial structure make one possible to introduce a new concept of the genus Verbeekiella Penecke 1908 and the family Verbeekiellidae Schoupe & Stacul 1955. The genus Basleophyllum Schoupe & Stacul 1959 was transferred to Polycoeliidae de Fromentel 1861. The generic name Duplophyllum Koker 1924 and Paralleynia Soshkina 1936 were discussed on a basis of their type species. These type morphologies were compared to those of the species described by Schoupe & Stacul (1959). Some of

these species may belong to new, unrelated genera. Formal generic names were not introduced because of incompleteness of the specimens restudied.

50526 <TITLE>Considerations on most Rugosa and Dividocorallia from de Groot 's (1963) collection.</TITLE>
50527 <SOURCE>Scripta Geologica 127: 71-311.</SOURCE>
50528 <ABSTRACT>Rugose corals reinvestigated herein constitute the main part of the collection described by de Groot (1963). The taxonomy proposed herein differs in several instances from that accepted originally by de Groot. Some changes, such as Petalaxis for Lithostrotionella and Calophyllum instead of Polycoelia, were already introduced in de Groot 's unpublished catalogue. Others were introduced in order to match the recent advances in rugose coral systematics. Most systematic changes were based on new microstructural, diagenetic and hystero-ontogenetic studies. These are described in detail for individual species and briefly discussed in the concluding considerations. Trabecular microstructure of septa and its diagenetic alteration was documented for most species. Presence of two kinds of intercorallite walls (partition and dividing walls) was documented on the basis of their difference in microstructure. This was especially important for the genus Petalaxis, allowing proof of a distinction between species representing its nominative subgenus and that distinguished by de Groot as Hillia. A new name Degrootia was proposed for Hillia, is preoccupied by a lepidopteran. Two genera, one new (Arctocorallium gen. nov.), represented by two species, were transferred to the Calyxcorallia (Dividocorallia), the order and subclass not distinguished by de Groot. Both these species were investigated and documented in particular detail, especially their hystero-ontogeny. The restudied material allowed proof of a distinction between Calyxcorallia and the Rugosa in the insertion of major septa. Also, an uncertain status of minor-like septa that may replace the major septa was demonstrated. Both these determinations are based on the hystero-ontogeny.</ABSTRACT>

50539 <TITLE>Skeletal structure in the rugosan genus Calophyllum from Permian strata of Timor: Comparison with the living deep water coral Lophelia pertusa.</TITLE>
50540 <SOURCE>Coral Research Bulletin 7: 191-207. [Dieter Weyer 's 65th birthday commemorative volume; S. Schröder & K. Oekentorp (eds)]</SOURCE>
50541 <ABSTRACT>Skeletal structures within several species of Calophyllum reflect generic microstructure and its diagenesis, and also impact our understanding of diagenetic modification in other Permian corals from Timor. Most of these microstructural features of the septa, axial dark

line, stereome coating, arcuate growth fronts (stirne), and tabulae (boden) are well-developed. There has been some controversy regarding their origin, whether biogenic or diagenetic. However, they closely resemble skeletal structures in *Lophelia pertusa* (collected live) from deep cold waters, here from the Norwegian Shelf in the Atlantic Ocean. This occurrence, along with the nature and timing of microbial infestations in each, indicates the biogenic nature of identical structures in Permian and living corals. The two groups of corals have much in common in their morphology, living environment and nonzooxanthellate nature (apparently), but no phylogenetic relationship between these genera of Paleozoic and modern corals is here postulated. 50565 <TITLE>Permian corals of Timor (Rugosa and Tabulate): history of collection study.</TITLE>
50566 <SOURCE>Alcheringa 28, 1: 157-183.</SOURCE>
50567 <ABSTRACT>The modern history of collection and study of corals in the Permian strata of Timor began in 1911, with a German expedition (J. Wanner, leader) and a Dutch expedition (H. Molengraaff, leader) to collect Permian and Triassic fossils in the colony of Netherlands Timor, and with a survey by the Swiss geologist F. Weber the same year in Portuguese Timor, the eastern portion of the island. Later expeditions led by Jonker (1916) and Brouwer (1937), both of the Netherlands, greatly increased already huge collections of fossils and additionally, understanding of the island's geology. Monographic studies of these coral collections by Gerth (1921), Koker (1924), Schindewolf (1942), Hehenwarter (1951) and Schoupe & Stacul (1955, 1959) have much enhanced the systematic value of these fossil corals, both Rugosa and Tabulata. Locality information and maps containing collecting localities are somewhat scattered (Wanner 1931, Burck 1923, Marez Oyens 1940, van Bemmelen 1949), but are summarized here. A list of all valid species names (109 Rugosa, 25 Tabulata) is appended to this paper, with type localities and horizon. Serious problems of nomenclature are avoided in this paper by accepting genus names used in Hill (1981), modified by later systematic studies, such as that of Fedorowski (1986), but some unknown number of names in the list of species are to be synonymized, especially since 31 of them are based on a single specimen (e.g. Niermann 1975). The biostratigraphy of these faunas is uncertain, in great part due to the greatest number of corals having been collected from a tectonic melange sequence in the Baun to

Basleo structural region, and additionally because of the purchase of huge numbers of fossils from the indigenous people of Timor, with accompanying uncertainties regarding locality and horizon data. The coral fauna of Permian age from Timor needs serious restudy to insure its stratigraphic and palaeontologic value, but future study will require new field collection of specimens from relatively complete stratigraphic sequences in the northern *Fatu* belt of outcrops. The huge numbers of individuals of some coral species provide great opportunities for understanding population structure in the faunas. [original abstract]

50578 <TITLE>Distribution of the tabulate coral genus *Mirandella Tchudinova* 1986 in the Early Permian.</TITLE>
50579 <SOURCE>Occasional Publications ESRI, new series 8B [Nairn A.E.M. & Koroteev V. (eds) - Contributions to Eurasian Geology, papers presented at the International Congress on the Permian System of the world, Perm, Russia, 1991, part 1]: 57-63.</SOURCE>
50580 <ABSTRACT>The genus *Mirandella Tchudinova* 1986 (Tabulate, Cnidaria) is emended and a new species, *M. greeni*, described from the Artinskian of Tasmania. The microstructure of the genus, observed in ultra-thin sections, is very distinctive, with a dark undulating lamina, surrounded by fibers locally arranged in tufts. The presence of a typical reticulate tissue, along with other morphological features, allows the assignment of the genus to the family Pyrgiidae De Fromentel 1861; a microstructural evolution from mostly *lamellar* forms in the Lower Carboniferous to entirely fibrous ones in the Permian can be observed in this family, corroborating a general trend in the Tabulata. The genus *Mirandella* is present in Lower Permian strata of Kamtchatka, Prekolyma, Australia, Tasmania and New Zealand. Such a geographical distribution suggests that the genus was well adapted to rather *cold* waters.</ABSTRACT>

50591 <TITLE>Late Triassic (Carnian) corals from Timor-Leste (East Timor): their identity, setting and biogeography.</TITLE>
50592 <SOURCE>Alcheringa 29, 2: 287-303.</SOURCE>
50593 <ABSTRACT>Four scleractinian coral taxa are described from limestones within a sandstone-shale sequence correlated with the Late Triassic Babulu Formation, Manatuto township, on the northern coast of Timor-Leste (East Timor). The coral fauna consists of three phaceloid taxa, *Paravolzeia timorica* gen. et sp.nov., *Craspedophyllia ramosa* sp.nov., *Margarosmia confluens* (Muenster), and a generically indeterminate solitary taxon attributed to the family Margarophylliidae. All four corals are related at various taxonomic levels to Carnian faunas from the Dolomites of northern Italy.

Previously, only Norian coral faunas were known from the Triassic of Timor. The fauna exhibits both similarities to and differences from Carnian faunas of the Dolomites and helps confirm palaeogeographic affinities with the western Tethys, although during Late Triassic time Timor lay in the distant southeastern portal of the Tethys. Despite isolation from the western Tethys, the presence of two species found also in the Dolomites indicates that larval dispersal occurred between the two areas.</ABSTRACT>

50604 <TITLE>The Triassic of Timor: Lithostratigraphy, chronostratigraphy and palaeogeography.</TITLE>

50605 <SOURCE>Journal of Asian Earth Sciences 36, 4-5: 341-363.</SOURCE>

50606 <ABSTRACT>The palaeontologically rich and lithologically diverse Triassic successions of Timor provide a key stratigraphic and palaeontological link between northwestern Australia and other terranes of former eastern Gondwana (present-day Southeast Asia). Timor is now located in the zone of collision between the northern margin of the Australian continent and island arc terranes bordering the Eurasian plate, with the Triassic successions exposed in a fold-and-thrust belt and an extensive mélangé complex. In the paper embracing results of multidisciplinary geological investigations managed recently in Timor, paleogeographical and palaeoecological conclusions from examination of Carnian corals (found by F. Da Costa Monteiro.) in the Babulu Formation, East Timor, have been included. [abbreviated abstract; the above mentioned coral fauna from Timor was described in two taxonomical publications: Roniewicz et al. (2005) and Roniewicz et Stanley (2009)]</ABSTRACT>

50617 <TITLE>Late Pleistocene fossils from beneath a high dune near Amity, North Stradbroke Island, Queensland.</TITLE>

50618 <SOURCE>Boolaronga Publ., Geol. 167-177.</SOURCE>

50619 <ABSTRACT>The occurrence of a Pleistocene marine fauna dated at 105,000 yr B.P., from south of Amity, North Stradbroke Island, is described. Its coral and molluscan components are listed. The associated fossil plant fragments and spore/pollen so far identified are also given. All components of the fossil assemblages and the morphology of overlying dune and soil profile are used to make some interpretations of the ecological history of the site. A higher sea level of + 3 m, a slightly warmer climatic regime and greater access to oceanic water in the proto-Moreton Bay are indicated. In addition, both geomorphic and soil evidence imply that the dune overlying the coral has been continuously vegetated since soon after its deposition.</ABSTRACT>

50631 <SOURCE>Alcheringa 05: 71-83.</SOURCE>
50632 <ABSTRACT>An assemblage of hermatypic scleractinian corals occurring landwards of the Pleistocene sandy Inner Barrier system has been referred to the last interglacial period. It comprises at least 20 species, many of which are in growth position, and is accompanied by a substantial association of molluscs. The richness of the assemblage is indicative of good access of oceanic waters at the time of its formation, so the deposit predates barrier emplacement. The coral occurrences are compared with present-day southern ranges of the scleractinian species (all extant), and the implications for climatic and sea-level conditions in the last interglacial are discussed. A sea-level stand of 4-6 m above that at present obtaining (in accord with Marshall & Thom 1976) and a climatic shift towards a cooler regime equivalent to a minimum of 2° of latitude are concluded. 50643 <TITLE>Uplift Rate of Coral Reef Terraces in the Area of Kupang, West Timor: Preliminary Results.</TITLE>
50644 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 068: 259-272.</SOURCE>
50645 <ABSTRACT>A Th/U date of 152,000 years obtained from the prominent fifth step, at 44 m elevation, of a flight of 7 well defined raised reef terraces at Cape Namosain, 5 km west of Kupang, allows inference of a preliminary mean uplift rate of 0.3 mm/yr since the last interglacial. Such a slow uplift rate is supported by the observation of numerous large modern reef platforms and of very limited mid-Holocene emergence - if any - throughout the region. Subject, to confirmation through further dating, this suggests the existence of a more rapid uplift zone in central West Timor, by contrast with the area of Kupang to the west and of northern East Timor and Atauro Island to the east, possibly in relation with the NW-SE seismic tear zone which has been recently pointed out within the subducting plate north of West Timor. One of the main interests in the terraces of Cape Namosain, apart from its neotectonic aspect, resides in the fact that there may be an opportunity to define the 180,000 year old paleo-sea level (terrace VIII of Huon Peninsula): based on the geomorphological interpretation of the series, it could correspond here to the fourth or the sixth terrace. Field investigation and dating in that regard are currently in progress. Another Th/U date of 124,000 years, obtained on the lowest emerged terrace (7 m above low tide) in the southeast of the nearby island of Semau, indicates that this second area has been uplifting little during the last 125,000 years. This, together with the observation of tilts and other structural features, leads to the conclusion that the area to the southwest of Kupang is affected by differential uplifts and block-faulting.</ABSTRACT>

50656 <TITLE>Evidence of high sea level during isotope stage 5c in Queensland, Australia.</TITLE>
50657 <SOURCE>Quaternary Research 24, 1: 103-114.</SOURCE>
50658 <ABSTRACT>Thirty-nine species of scleractinian corals have been recovered from under a high dune on the western (mainland) side of North Stradbroke Island, eastern Australia. The corals are associated with thin intertidal sediments and their good condition implies burial in situ and preservation in a saturated zone. Most likely this occurred as the coast prograded and a large dune advanced into the littoral zone, burying intertidal sediments and coral. The species assemblage indicates a sheltered environment but one open to the ocean without wide fluctuations in salinity. Three species yielded a mean $^{230}\text{Th}/^{234}\text{U}$ age of 105,000 yr B.P. which is significantly younger than the nearest Pleistocene corals at Evans Head, New South Wales. The corals provide evidence of a sea stand near present sea level during isotope Stage 5c, which is considerably higher than previously suggested for this period. Their good condition implies that the overlying parabolic dune is of comparable age and formed during that high stand of sea level. Also, the isotope age provides a maximum period for the development of giant podzols in the podzol chronosequences on coastal dunes in southern Queensland. [original abstract]</ABSTRACT>

50669 <TITLE>Non-river flood barium signals in the skeletons of corals from coastal Queensland, Australia.</TITLE>
50670 <SOURCE>Earth and Planetary Science Letters 237, 3-4: 354-369.</SOURCE>
50671 <ABSTRACT>Two corals from coastal Queensland (Cow and Calf Islands, and Orpheus Island) have been analysed for a suite of trace elements by laser-ablation ICP-MS (LA-ICP-MS). Barium signals in these two corals are 'anomalous' in comparison with Ba behaviour seen in other near-shore corals from this region. The two corals display large sharp peaks in spring which do not correlate with markers of river discharge (Y/Ca and fluorescence). This Ba pattern contrasts with 'normal' behaviour - characterised here by the patterns previously published for two other coastal Queensland corals (King Reef and Pandora Reef), which display Ba peaks in summer associated with flooding of nearby rivers [see: Sinclair & McCulloch 2004 Corals record low mobile barium concentrations in the Burdekin River during the 1974 flood: evidence for limited Ba supply to rivers? 3x Palaeo 214]. Similarities are observed between the anomalous Ba in the Queensland corals and other published patterns of Ba behaviour in corals from South Africa and the Arabian Sea. This non river-flood Ba behaviour is characterized by large sharp spikes of Ba which are resistant to oxidative cleaning and form a continuous horizon within the corals. Curiously, not all corals from a region display anomalous Ba behaviour

despite being in similar environment. The timing of anomalous Ba is consistent within a coral, but may vary from one location to the next. Anomalous Ba spikes are too large to be caused by Ba-rich upwelling, and no single environmental forcing function seems to be able to account for their timing. This combination of observations argues against an exogenous abiotic source for the anomalous Ba signal; instead, it may result from an abiological event triggered by a combination of environmental parameters. Three hypotheses are presented, and critically tested against the observations: barite inclusion following phytoplankton blooms, decaying blooms of the blue-green algae *Trichodesmium*, and physiological perturbations associated with coral mass spawning. None of the three hypotheses are fully consistent with all of the observations and it is concluded that no satisfactory explanation currently exists for the anomalous Ba spikes. </ABSTRACT>

50682 <TITLE>Age accuracy and resolution of Quaternary corals used as proxies for sea level.</TITLE>

50683 <SOURCE>Earth and Planetary Science Letters 253, 1-2: 37-49.</SOURCE>

50684 <ABSTRACT>The accuracy of global eustatic sea level curves measured from raised Quaternary reefs, using radiometric ages of corals at known height, may be limited by time-averaging, which effects the variation in coral age at given height. Time-averaging was assessed in uplifted Holocene reef sequences from the Huon Peninsula, Papua New Guinea, using radiocarbon dating of coral skeletons in both horizontal transects and vertical sequences. Calibrated Δ age ranges varied from 800 to 1060 years along horizontal transects, but weighted mean ages calculated from 15-18 dates per horizon were accurate to a resolution within 154-214 yr. Approximately 40% of the variability in age estimate resulted from internal variability inherent to ^{14}C estimates, and 60% was due to time-averaging. The accuracy of age estimates of sea level change in studies using single dated corals as proxies for sea level is probably within 1000 yr of actual age, but can be resolved to over 250yr if supported by dates from analysis of a statistical population of corals at each stratigraphic interval. The range of time-averaging among reef corals was much less than for shelly benthos. Ecological time-averaging dominated over sedimentological time averaging for reef corals, opposite to patterns reported from shelly benthos in siliciclastic environments.</ABSTRACT>

50721 <TITLE>Stromatoporoid palaeoecology and systematics from the Middle Devonian Fanning River Group, north Queensland.</TITLE>
50722 <SOURCE>Memoirs of the Queensland Museum 43, 2: 463-551.</SOURCE>
50723 <ABSTRACT>Thirty-five Stromatoporoid taxa are described from the Givetian lower Fanning River Group, Burdekin Subprovince. Ten faunal communities are recognized based on the study and distribution of Stromatoporoid and selected molluscan taxa and the distribution of tabulate and rugose corals: Burdikenia, Modiomorpha, Stachyodes costulata-Syringopora, Hermatostroma maculatum-Gerronostroma hendersoni, Clathrocoilona spissa-Aulopora, Ferestromatopora heideckeri-Amphipora ramosa-Stringocephalus, Coenostroma-Hermatostroma episcopate, Amphipora pervesiculata, Endophyttum and cephalopod communities. Analysis of Stromatoporoid shape demonstrates the influence of both genetic and ecologic factors. Zonation of skeletal shape, apparent for both biostromal and biohermal complexes, indicates that strong ecologic influences dominated. Substrate type, sedimentation rate and water depth were important controls. Most taxa display a range of shape. Complex overgrowth phenomena between Stromatoporoid taxa, tabulate corals, chaetetids, and algae produced compound skeletons that are most common within nearshore biostroms, and are interpreted to indicate stress imposed by repeated lethal depositional events or by seasonal variations in salinity. Intergrowth of stromatoporoids with tabulate corals Syringoporella sp., and Syringopora sp., a number of rugose corals, and a ?vermetid are documented. Syringoporella sp. is more common in stromatoporoids with irregular skeletal architecture. For Syringoporella sp. an even distribution of corallites within the host, skeletal response to corallite occurrence, and the absence of micritic envelopes suggests a symbiotic relationship with both the coral and the Stromatoporoid accreting at the same rate and maintaining an even growth surface. Six new species of Stromatoporoid are described comprising Gerronostroma hendersoni, Trupetostroma zheni, Euryamphipora merlini, Ferestromatopora heideckeri, Coenostroma budekinense, and Coenostroma wyatti. Biogeographic affinities of the fauna are strongly with the Old World Realm with species level affinities with Guangxi, Poland and Belgium.</ABSTRACT>

50735 <SOURCE>J. geol. Soc. Australia, 20 (1): 79-84.</SOURCE>
50736 <ABSTRACT>A halysitid coral specimen, doubtfully referred to Quepora, was found in a forsterite-phlogopite marble from near Walang, east of Bathurst. * The rocks are probably of hornblende hornfels facies. Some recent reports of fossils in metamorphic rocks are noted. Alteration of the coral is compared with that seen in less metamorphosed halysitids from elsewhere. Halysitid corals appear to re-crystallize in two stages. First, intertabular and lacunar sparite recrystallize, the former sometimes first developing into *saw-teeth*; (a previously undescribed type of structure); during this phase, walls lose their internal structure. Secondly, tabulae and walls are altered to finely and then coarsely granular calcite. Under certain conditions tabulae are incorporated into recrystallized matrix before the walls.

50747 <TITLE>New genera of Early Devonian calceoloid corals from Australia and France.</TITLE>
50748 <SOURCE>Palaeoworld 15, 2: 185-193.</SOURCE>
50749 <ABSTRACT>Two new Early Devonian genera and species of the family Calceolidae, phylum Cnidaria, are erected; these are Richtereola disruptus n.gen., n.sp., from the Emsian (perbonus conodont zone) of the Taemas area, NSW, Australia and from the Emsian Izarne Formation (gronbergi conodont zone) of the Montagne Noire, southern France; and Savageola unicus n.gen., n.sp. from the Lochkovian (eurekaensis conodont zone) Mandagery Park Formation at Manildra, NSW, Australia. These taxa are essentially defined on opercular characters; well-preserved opercula are essential for confident generic assignment of calceoloid material. Savageola is known only from eastern Australia, but Richtereola is known from the Early Devonian of eastern Australia, southern France, South China (where it is represented by Calceola sandalina naningensis) and north Vietnam. 50773 <TITLE>Proterozoic modular biomineralized metazoan from the Nama Group, Namibia.</TITLE>

50774 <SOURCE>Science 296, 5577: 2383-2386.</SOURCE>

50775 <ABSTRACT>We describe a Proterozoic, fully biomineralized metazoan from the Omkyk Member (~549 million years before the present) of the northern Nama Group, Namibia. *Namapoikia rietoogensis* gen. et sp.nov. is up to 1 meter in diameter and bears a complex and robust biomineralized skeleton; it probably represents a cnidarian or poriferan. *Namapoikia* encrusts perpendicular to the walls of vertical syndimentary fissures in microbial reefs. This finding implies that large, modular metazoans with biologically controlled mineralization appeared some 15 million years earlier than previously documented. [original abstract]</ABSTRACT>

50800 <SOURCE>Zeitschrift der Deutschen Gesellschaft fuer Geowissenschaften 157 [volume in memory of Prof. Franz Lotze]: 611-627.</SOURCE>

50801 <ABSTRACT>The stratigraphic successions analysed with their characteristic archaeocyaths, trilobites, brachiopods, stromatolites,

ichnofossils, and small shelly fossils, allow us to establish the paleontological assemblages in each one of the archaeocyathan zones of the Lower Cambrian in the Iberian Peninsula. We also present a correlation proposal between Morocco, Sardinia, France, and Germany. The Lower Cambrian in the Iberian Peninsula is divided into ten archaeocyathan zones, defined by generic assemblages, with reference to trilobite, brachiopod, and stromatolite genera that are found in these successions. The established zones have precise stratigraphical positions and are correlated with the stages published by Russian authors. Zones I, II, and III are assigned to the Lower Ovetian, and correspond to Atdabanian 1 and 2. Zones IV, V, VI, and VII of the Upper Ovetian are equivalent to Atdabanian 3 and 4, and Botomian 1 and 2. Zones VIII and IX of the Lower Marianian are equivalent to Botomian 3. Zones X of the Lower Bilbilian corresponds to Toyonian 1 and 2.

50826 <SOURCE>Paläontologische Zeitschrift 50, 1-2: 27-33.</SOURCE>

50827 <ABSTRACT>Dans la formation de Bushmann Klippe, attribuée à l'Éocambrien jusqu'à cette découverte, les auteurs décrivent une nouvelle forme rapportée aux Archéocyathes. Depuis 25 ans, des fossiles énigmatiques ont été attribués aux Archéocyathes dans le système de Nama mais les examens ultérieurs par les spécialistes ont jusqu'à maintenant toujours réfuté ces attributions. Dans le cas présent, l'absence de cavité centrale bien définie et de porosité des éléments squelettiques, l'irrégularité des tubes, laissent un très fort doute sur l'appartenance de cette forme aux Archéocyathes. Par contre, elle rappelle les fossiles présentés par le Pr. Sedlak au second Symposium à Paris, dont la position systématique avait prudemment été déclarée incertae sedis. Une comparaison est à envisager.</ABSTRACT>

50839 <SOURCE>Annales de la Société géologique du Nord 05, 2: 117-121.</SOURCE>
50840 <ABSTRACT>In the Ougarta area (western Sahara, Algeria) faunas from the Devonian formations of eight sections have been sampled for biostratigraphic purpose. Fossils (graptolites, goniatites) and microfossils (conodonts, chitinozoans, dactyloconarids) with a pelagic distribution pattern provide reliable ties with the Devonian chronostratigraphy. Additional data provided by benthic faunas (corals, crinoids, brachiopods, trilobites) are also used to better locate some stage boundaries in this Devonian sequence.</ABSTRACT>

50853 <ABSTRACT>In the list of fossils, found by himself, author records one genus of rugose and three genera of tabulate corals from the older Paleozoic sediments of the Bokkeveld group of S. Africa. Besides apparently undefined species, the genera Pleurodictyum (tabulate coral) and Zaphrentis (rugose coral) are represented by the species Pleurodictyum bokkeveldense Gevers 1929, and Zaphrentis zebra Schwarz 1909. * Apparently, a specific assignment of forms of the tabulate genera Favosites and Striatopora proved to be impossible.</ABSTRACT>

50878 <SOURCE>Geologica et Palaeontologica 21: 51-71.</SOURCE>
50879 <ABSTRACT>we propose the new genus Zemmourella, for the species Z. thamnoporoides (Termier & Termier, 1950) on the base of material from the Middle Devonian of Zemmour Noir in Northern Mauretania. It is a branching Tabulate coral, characterized by the development of calicinal platforms with twelve mural ridges and by the presence of crested convex squamulae; these structures are described for the first time. All these characters allow us to bring this new genus close to the family Pachyporidae and to the subfamily Striatoporinae.</ABSTRACT>

50891 <SOURCE>Geobios 24, 1: 47-57.</SOURCE>
50892 <ABSTRACT>The increase in Saouraepora gigantea (Le Maitre) and in a branching specimen of Praemichelinia homofavosa (Le Maitre), studied by serial acetate peels, is basically of lateral type but a corner pore appears in the preblastic stage and allows to define a new category of increase: lateral increase with apical corner pore. Variations on the basic type are exhibited and they concern the apical corner pore (it is more or less precocious, sometimes divided in two, exceptionally missing), the "cella" (cases of filling up by mural lacuna are described) and the connections of the offset with intramural canals whose existence is rehabilitated.</ABSTRACT>

50904 <SOURCE>Annales de la Societe geologique du Nord 06, 2 ser.: 5-23.</SOURCE>
50905 <ABSTRACT>A precise collection in the well known sections of the Devonian of the Ougarta area (Algeria) allows to give new data about the fauna of Pleurodictyum sensu lato previously described by Le Maitre (1952, 1959). Two species, P. saourense Le Maitre and P. rosaceum Le Maitre, are carefully studied and figured for the first time. Morphological, structural and microstructural data are given. The case of P. styloporum sensu Le Maitre 1952 is investigated; the Algerian material does not belong to the american species and may be a new genus. Specimens related to the american species P. crassum are identified in Ougarta. A new genus belonging to the Pleurodictyidae and a new species are described: Pterodictyum lobatum n.gen., n.sp. Representatives of the genus Kerforneidictuym and Petridictyum are scarce but the diversity of the Pleurodictyidae during the Upper Emsian in Ougarta is important. The fauna, within the Old world Realm, belongs

- to the maghrebo-european area.</ABSTRACT>

50956 <SOURCE>Annales de la Societe geologique du Nord 05, 2: 123-128.</SOURCE>
50957 <ABSTRACT>The benthic faunas (corals, crinoids, brachiopods and trilobites) identified in the Lower and Middle Devonian formations of the Ougarta area (western Sahara, Algeria) are used in order to depict the timing and the magnitude of fauna migrations through the Rheic Ocean. Our data show the Rheic Ocean had already started its closure phase at the beginning of the Devonian. In upper Emsian time it was no longer wide enough to prevent the migration of benthic organisms. Indeed, by late Emsian, number of genera and species are common both to the Laurussian and Gondwanan margins of the Rheic Ocean. A new paleobiogeographic entity: the Maghrebo-European realm is defined. It includes the more restricted Ibarmahian Domain and North Gondwana Province.</ABSTRACT>

51034 <SOURCE>Geobios 12, 3: 353-363.</SOURCE>
51035 <ABSTRACT>The microstructure of two species of Cladochonus from the Algerian Carboniferous, C. crassus (McCoy) and C. cf. tenuicollis McCoy have been studied by ultrathin sections. Their walls consist of : 1. an

- external fibrous layer, 2. a median layer of undulating lamellae, 3. an internal zone of slender, elongated elements to which the name of *grundulae* is given here. New data are complementing the generic diagnosis of *Cladochonus* s. str.. Some Permian cladochoid forms show different microstructures and should, therefore, be shifted to new generic units.

51060 <SOURCE>Geologica et Paleontologica 26: 29-33.</SOURCE>
51061 <ABSTRACT>Two tabulate corals described by Stache (1883) from the Lower Carboniferous (probably Late Tournaisian or Early Viséan) of western Sahara are revised. One of them is an undeterminate *Pleurodictyiform*; the other one, called *Favosites africana* by Stache, badly preserved, could be assigned with doubt to *Michelinia* De Konink 1842 sensu lato; we propose to restrict the specific name *africana* to the holotype only.</ABSTRACT>

51072 <TITLE>Depth-related Ecological Zonation of a Carboniferous Carbonate Ramp: Upper Viséan of Bechar Basin, Western Algeria.</TITLE>
51073 <SOURCE>Facies 35, 1: 59-80.</SOURCE>
51074 <ABSTRACT>Following the demise of the stromatoporoid-coral reef community in Late Frasnian time, Lower Carboniferous carbonate shelf profiles possessed a ramp geometry, with major organic buildups represented by mud-rich mounds. Microfacies petrography of the exceptionally well-preserved Upper Viséan (Lower Carboniferous)

carbonate ramp of the Bechar Basin, Algerian Sahara, may well contribute significantly to our understanding of the paleoecological zonation of Carboniferous non-rimmed platforms, and of the still enigmatic mounds commonly referred to as waulsortian banks or mounds. Facies are grouped into two broad groups: (a) a mound facies group which comprises sponge wackestone-bafflestone, sponge-fenestellid bafflestone-wackestone, crinoid wackestone-packstone, and bedded flanks of intraclastic wackestone-packstone, all four facies composing the actual mud-rich mounds, and (b) a supramound facies group composed of coral-microbial framestone, crinoid packstone-grainstone, algal-foraminiferal grainstone and oolite grainstone. Calcareous algae are important bathymetric indicators and are used to delineate three bathymetric zones based on light penetration: the aphotic zone, which contains no calcareous algae; the dysphotic zone, where there is little ambient light, and which is characterized by the presence of red algae (*Fasciella*, *Ungdarella*, *Stacheia*, *Epistacheoides*) and absence of green algae; and the euphotic zone, which receives the full spectrum of sunlight, and is characterized by the occurrence of both green algae (*Koninckopora*, *Kamaenella*, *Kamaena*, *Palaeoberesella*, *Calcisphaera*, *Anthracoporellopsis*, *Issinella*, *Exvotahsella*) and red algae. Integration of algal zonation, distribution of the other biota, and recurrence of distinct assemblages, enable recognition of seven depth-related benthic assemblages. Together with the physical properties of the facies, the benthic assemblages were used to define seven bathymetric zones, from upper to lower ramp: (1) algal assemblage (upper ramp); (2) crinoid-ramose bryozoan assemblage (mid-ramp); and (3) productid brachiopod assemblage, (4) colonial rugose coral-microbial encruster assemblage, (5) crinoid-fenestellid assemblage, (6) sponge-fenestellid, and (7) sponge assemblage (lower ramp). The vertical zonation of the mud-rich mounds and associated facies differ from that reported from the classical Upper Toumaisian-Lower Visean waulsortian moundbearing successions. </ABSTRACT>

51085 <TITLE>Discussion of Carboniferous stratigraphy and depositional environments in the Ahnet Mouydir area (Algerian Sahara) by Wendt et al. (Facies 55, 3: 443-472).</TITLE>

51086 <SOURCE>Facies 56, 3: 471-476.</SOURCE>

51087 <ABSTRACT>The attribution of a Bashkirian age to the Berga Limestone and the proposed Late Visean-Serpukhovian hiatus is not supported by the data and discussion presented herein. This also sheds some doubts on the existence of a lower Bashkirian transgression in entire North Africa. Wendt et al. (2009) have questioned the stratigraphic extension of some commonly used groups and organisms, but all data except the three samples containing *D. noduliferus* of Wendt et al. (2009) point to a Visean-Serpukhovian age. However, the Reggane-Ahnet data in combination to the Spanish data indicate that the first entry of *D. noduliferus* was possibly during the uppermost (?) Serpukhovian. and thus it is of limited use for defining the base of the Pennsylvanian. This may help to elucidate the confusion at this stratigraphic level, north of the Hoggar as well as on a global perspective. [original conclusions]</ABSTRACT>

51150 <TITLE>Upper Permian inozoid, demosponge, and hexactinellid sponges from Djebel Tebaga, Tunisia.</TITLE>
51151 <SOURCE>The University of Kansas Paleontological Contributions, New Series 7: 130 pp., 81 pls, 37 figs, 11 tables.</SOURCE>
51152 <ABSTRACT>Fossil sponge faunas from Upper Permian reefs and inter-reef rocks in the Djebel Tebaga area of southern Tunisia include the most varied and abundant Late Paleozoic inozoid fauna known. The inozoid sponge part of that assemblage, plus minor demosponge and hexactinellid sponges, are described from the numerous localities and collections. The Djebel Tebaga area of southern Tunisia includes the only outcrop of marine Upper Permian strata in the entire African continent and was in the western part of the classic Tethyan belt. The sponges described here were collected, in large part, weathered out from exposures of sandy carbonates, marls, and bioclastic limestones and are commonly associated with moderately large bioherms of which the sponges were the most important reef builders. [...] Seventy species are described of which fifty-four are new. Also included in the description are new examples of the demosponge Heliospongia finksi Termier and Termier, 1977a, and a fragmental brachiospongid hexactinellid. * Possible relationships of the Inozoida with the Paleozoic Heteractinida and Sphinctozoa are discussed. The latter are possible stem-groups from which the Inozoida may have developed during the Carboniferous. * The Inozoida were encrusters, frame builders, and bafflers for some of the bioherms in Djebel Tebaga. They produced moderately complicated community sequences, even on a small, hand-sample scale. Such sequences of encrustation, diagenesis, and preservation are described. Many hand samples show at least five generations of encrustation of sphinctozoans, inozoans, sclerosponges and algae. [excerpts from extensive summary]</ABSTRACT>

51165 <ABSTRACT>Inozoid sponges of Upper Permian reefs and inter-reef rocks in the Djebel Tebaga, southern Tunisia, have been investigated with regard to their taxonomy, skeletal microstructure, systematic position, and their relationship to other sponge groups. Based on Permian material from Djebel Tebaga, the new superorder Aspiculata and the new order Inozoida were proposed by Rigby & Senowbari-Daryan (1996) for inozoid sponges without spicules but with a rigid skeleton composed of aragonite or calcite. More than 70 species of inozoid sponges were described from Djebel Tebaga, most of them are new. Most probably the inozoid sponges were derived from the heteractinids during Upper Paleozoic time.</ABSTRACT>

51191 <ABSTRACT>Corallian outcrops of the Dogger in the Betioky area (Madagascar) have been previously interpreted as barrier reefs or atolls involved in a large carbonate platform. This statement appeared exceptional for these times. A field study demonstrates that, in fact, there are only sparse solitary or colonial corals, whose growth occurred with some difficulty. They developed in meadows strongly marked by terrigenous inputs, in a subsiding context, and during brief episodes favourable to the genesis of ooids.</ABSTRACT>

51254 <TITLE>Early Cretaceous coral faunas from East Africa (Tanzania, Kenya; Late Valanginian-Aptian) and revision of the Dietrich collection (Berlin, Germany).</TITLE>
51255 <SOURCE>Palaeontographica 285, 1/3: 23-75, 5 pls.</SOURCE>
51256 <ABSTRACT>The extensive vertebrate excavations of the Late Jurassic to Early Cretaceous around the Tendaguru hill in Tanzania in the early 20th century also yielded significant invertebrate faunas. The corals were first described by Dietrich (1926) and his work conformed to a remarkably high standard for his time. Since then, progress in examination methods and other criteria of coral classification has made a modern revision necessary. In addition, the stratigraphy of the coral bearing sediments has greatly improved over the past ten years, allowing a better palaeobiogeographic analysis. The present paper gives an introduction to the research history, discusses the various denominations of the lithostratigraphical units exposed in the

Tendaguru area, and explains the progress of the stratigraphy of these units. Using both the original material described by Dietrich, as well as collection material that he did not describe, the corals of the Cretaceous are described and illustrated using new thin sections. Several corals from the Early Cretaceous of Kenya are also included. The Jurassic corals from the Tendaguru area have not been examined. In total, 15 species from the Late Valanginian to Early Aptian unit and 31 species from the Late Aptian are described. Two genera described by Dietrich that were largely forgotten and many species established by him that were not precisely interpreted in later literature are revised here. *Camptodocis* replaces *Actinारेopsis* Roniewicz, 1968, and *Metaulastrea* corresponds to the concept of *Amphiaulastrea* Geyer, 1955, which is considered a junior synonym of *Pleurostylina* and should no longer be used. Together, these revisions place the Cretaceous corals of the Tendaguru area in a modern taxonomic and palaeobiogeographic context. [original summary]

51269 <ABSTRACT>Schizorhabdus libycus Zittel 1877 is a valid taxon, although the species obviously was characterized both incompletely and incorrectly. The skeleton of the cylindrical sponge is composed of large megacloones which are indicative of affinities to the lithistid suborder Megamorina Zittel 1878. New material, collected in the Sudr Formation (Maastrichtian) offers interesting information on the internal organization, the original appearance and the biotope of this sponge.</ABSTRACT>

- 51373 <ABSTRACT>The primary objective of this study is to document the development of corals and coral reefs during the early Paleogene in south-western Egypt. Corals have been known from this geological period since the expedition of Gerhard Rohlfs at the end of the last century. The interest in early Paleogene corals is also caused by the Cretaceous / Paleogene boundary event which drastically affected reef building organisms. After a recovery period of several million years, scleractinian corals began to take over the dominant role of reef constructors, a situation which has continued until today. In addition, the sedimentology and paleoecology of the limestones of the Paleocene Abu Tartar Carbonate Platform were studied. An attempt has been made to reconstruct the depositional history of this carbonate platform. The Abu Tartar Plateau is located west of El-Kharga (Kharga Oasis). It is covered by Early to Late Paleocene limestones.</ABSTRACT>

- 51386 <ABSTRACT>The primary objectives of this Ph.D. Thesis are to document

the development of corals and coral reefs during the early Paleogene in southwestern Egypt. Secondly, the sedimentology and paleoecology of the limestones of the Paleocene Abu Tartur Carbonate Platform were studied. An attempt has been made to reconstruct the depositional history of this carbonate platform. Two study areas were chosen: (1) the Abu Tartur Plateau west of El-Kharga (Kharga Oasis), which is covered by Early to Late Paleocene limestones and (2) the area of Farafra Oasis. Here, corals were found in Early Eocene layers. [...] Five coral species of the Early Eocene are described for the first time from Egypt, one species (*Goniopora farafraensis*) is new. [extracted from extensive summary]

51411 <SOURCE>Geol. Libya 4: 1401-1420.</SOURCE>
51412 <ABSTRACT>Carbonate buildups formed mostly of scleractinian corals were found in the Oligocene sediments of the Sirt basin north of Al Hufrah oil fields. The buildups form a widespread complex of patch-reefs. Another coral fauna comes from the vicinity of Ar Raqubah oil field, where the corals form an almost continuous horizon; reef bodies are not developed. The main reef builders found in the Oligocene of the Sirt basin are *Stylophora parvistella* Chevalier, *S. thirsiformis* (Michelotti), *Madracis decaphylla* Matheron sensu Chevalier, *Astraeopora decaphylla* Reuss, *Monticulastraea* ex gr. *daedalea* (Reuss), *Athecastraea maradahensis* sp.nov., *Actinacis rollei* Reuss, and *Agathiphyllia gregaria* (Catullo).</ABSTRACT>

51423 <TITLE>Facies analysis and biostratigraphy of the Auradu Limestone Formation in the Berbera-Sheikh area, northwestern Somalia.</TITLE>
51424 <SOURCE>Geologica Romana 29: 213-235.</SOURCE>
51425 <ABSTRACT>The main stratigraphic and sedimentological features of the

Auradu Limestone Formation [Tertiary / Paleogene] in NW Somalia, close to its type area, are outlined. The present study of the depositional and diagenetic characteristics, associated with the investigation of the fossil assemblages and their biostratigraphy and paleoecology, allows to focus on some significant features useful for a better definition of the paleoenvironmental setting and the stratigraphic evolution of the formation in its westernmost outcrop area. Biostratigraphic evidence gathered from the larger foraminiferal assemblages [and coral assemblages] allows a correlation of the lower Paleogene faunal associations of Somalia with the existing peri-Mediterranean biozonations, thus extending their validity to the Horn of Africa, with implications for the dating of neighbouring formations of the Arabic peninsula. </ABSTRACT>

51436 <TITLE>Early Miocene corals and associated sediments of the northwestern Gulf of Suez, Egypt.</TITLE>

51437 <SOURCE>Courier Forschungsinstitut Senckenberg 239: 57-81.</SOURCE>

51438 <ABSTRACT>Early Miocene corals from the northwestern Gulf of Suez area (Eastern Desert, Egypt) grew on a shallow epicontinental shelf flooded by the Burdigalian transgression. Acropora layers and isolated massive *Tarbellastraea* colonies associated with abundant coralline red algae (rhodolith and marl facies) and green algae (*Halimeda*) lived in a very shallow, lagoonal-like environment. Some small patch reefs were formed. The lack of a suitable substratum and the high sedimentation rate are considered the main reasons for the relatively low diversity (24 species/16 genera) of the Burdigalian coral fauna from this region. Global climatic cooling during this time favoured the development of temperate water carbonates and hindered the formation of more extensive coral reef structures. The described corals most probably were the predecessors of Middle Miocene coral faunas from the Red Sea coast which built large fringing reefs during the Langhian when the sea advanced from the Mediterranean Tethys to the Red Sea. This is shown by the presence of several identical or similar species (e.g., *Tarbellastraea reussiana*, *Favites neglecta*) described from these Langhian reefs. Generally, the described corals show a Mediterranean Tethyan affinity and are comparable to coral faunas from the Aquitaine Basin, central Iran, and Turkey.</ABSTRACT>

51450 <SOURCE>Neues Jahrbuch für Geologie und Paläontologie, Abhandlungen 225, 3: 337-371.</SOURCE>

51451 <ABSTRACT>The Pleistocene coral reefs at Gebel Zeit and Ras Gemsha (western side of the Gulf of Suez) form terraces of different elevations above the present sea level. The identified 30 species of

bryozoans, corals and molluscs are of strongly Indo-Pacific affinity. Many coral specimens show no alteration of their primary microstructure, but a few are affected by early meteoric diagenesis. The differences in Sr, Ca and Mg among coral families and their relation to diagenetic alterations are documented. The reconstructed depositional environments reach from upper reef slope to back-reef and water-depths from 1 to 50 meters.</ABSTRACT>

51489 <SOURCE>N. Jb. Geol. Palaont. Mb. 1999/4: 213-226.</SOURCE>
51490 <ABSTRACT>The reef limestones, of Langhian (Middle Miocene) age; were formed during regressive-transgressive episodes. They were subdivided into four main depositional facies: 1) fore-reef, made up of bioclastic marly limestone with broken skeletons and debris, 2) reef-core, constructed of a framework exclusively of branched colonies of Porites sp. coated by micrite submarine cements, 3) back-reef, consisted of friable limestone, rich in shell hash with floded Heterostegina praecostata and, 4) beach and nearshore, made up of fossiliferous cross-bedded pebbly sandstone. The complete leaching and alteration of the original aragonitic scleractinian corals microstructure, and the cements into low Mg-calcite mosaic by fresh water in the subaerial

- environment, is the main diagenetic process which affected the reef. Micrite is the most important constituent in the reef-core sediments (40-70 %) and all over the sequence in general. </ABSTRACT>

51593 <SOURCE>Coral Research Bulletin 04: 1-38.</SOURCE>
51594 <ABSTRACT>From ten localities in Egypt (Sinai and Western Desert; Albian to Paleocene) and seven localities in Greece (Boeotia and Macedonia; Aptian to Campanian) 75 species in 52 genera of both Scleractinian and Octocorallia are described. Because of the partially poor preservation of the material and the problems of coral systematics in general, half of the species were only determined generically. For this reason it is difficult to consider the relationships to other

- Cretaceous coral faunas. Only eight species from the Cretaceous in Egypt and 14 species from the Cretaceous in Greece are known from other localities outside these regions.</ABSTRACT>

- 51607 <ABSTRACT>Corals are extremely rare in Silurian to Middle Devonian rocks of central and South America and in southern Africa and none are reported from Antarctica, the areas that constituted the Malvinokaffric Realm. Most workers have interpreted the realm as one characterized by cold water; this is in accordance with its high latitude during the Silurian-Devonian and is the most likely explanation of the dearth of corals. It is also noted that the known Malvinokaffric marine shelly faunas are found in shales and siltstones whereas the rich coral faunas of the other realms occur in limestones and calcareous shales. However, in the other realms corals do also occur in shales and siltstones and the inhospitality of the Malvinokaffric sedimentary facies is not an adequate explanation for the scarcity of corals.</ABSTRACT>

51658 <SOURCE>Beringeria, Special Issue 2 [Morocco '95: The Lower-Middle Cambrian Standard of Gondwana]: 121-145.</SOURCE>
51659 <ABSTRACT>Archaeocyaths are present in the Lower Cambrian of Morocco from the "Calcaires Supérieurs" to the "Grés terminaux", [Amuslek and Issafene Formations according to Geyer (1989)]. They were studied from Anti-Atlas, Western High Atlas (Ounein) and Jebilet localities. During the Issendalenian and the beginning of Banian, archaeocyath faunas were homogenous without paleogeographic variations. Only one locality belongs to the Upper Banian. Five biostratigraphic zones may be recognized: Issendalenian (ex-Amuslekian) 1) Erismacoscinyathus fasciola-Retecoscinus minutus Zone 2) Erismacoscinus marocanus Zone (Hupe's zones I-III); Banian (ex-Issafenian): 1) Polystillicidocyathus-Halysicyathus Zone (Hupe IV-V) 2) Paranacyathus-Porocyathellus Zone (Hupe ?VI) 3) Jebiletosciscinus Zone (Hupe's ?VII). Generic assignments have been revised and new concepts for species reduce their number. Key sections and revised list of Moroccan species is established. Paleogeography is outlined for Morocco and Southwestern Europe.</ABSTRACT>

51736 <SOURCE>Zentralblatt für Geologie und Paläontologie Teil I (7-9): 1177-1188.</SOURCE>
51737 <ABSTRACT>Paleobiogeographic distribution of rugose corals essentially depends on ocean current systems. sea level fluctuations can cause migration between formerly isolated realms. The facies analysis of Middle Devonian sequences of the eastern Anti-Atlas (Morocco) reveals at least three T-R-cycles. Linked with the aggradational stacking, shallow marine, coral bearing reefal carbonates appear upon a carbonate ramp. Several immigration-pulses of Eastern American faunal elements into the Moroccan coral faunas are related to these transgressive events. Migration routes apparently are via Western Africa into Central Europe.</ABSTRACT>

51775 <SOURCE>Bulletin de l'Institut royal des Sciences naturelles de Belgique, Sciences de la Terre 75: 67-85.</SOURCE>
51776 <ABSTRACT>Several levels with Phillipsastrea have been sampled in the Upper Givetian of the Tafilalt and the Ma'der in Morocco and have been dated by conodonts. *P. weyeri* Coen-Aubert, 2002, *P. tafilaltensis* Coen-Aubert, 2002 and *Acanthophyllum simplex* (Walther, 1929) are present in all the outcrops investigated. They are associated in the Ma'der with *Neotemnophyllum breve* n.sp., *Phillipsastrea hollardi* Coen-Aubert, 2002, *Siphonophrentis laskowae* Wrzolek, 2002 and *S. crassa* n.sp.; the first species is restricted to the Upper Polygnathus varcus Zone whereas the three others occur also in the Upper Klapperina disparilis Zone. In the Tafilalt, the accompanying fauna in the Upper Klapperina disparilis and Lower Mesotaxis falsiovalis Zones is characterized by *Thamnophyllum amessouicum* n.sp., *Neoacinophyllum bultyncki* n.sp., *Siphonophrentis wangi* n.sp. and *Neotemnophyllum* sp. The latter three taxa suggest an influence of the western Yunnan in China. However, the remaining fauna shows affinities with that from the Upper Givetian of western Europe and Poland.</ABSTRACT>

51787 <TITLE>Discovery of thermophilic corals in an ancient hydrothermal vent community, Devonian, Morocco.</TITLE>
51788 <SOURCE>Acta Geologica Polonica 55, 1: 1-7.</SOURCE>
51789 <ABSTRACT>Living corals are remarkably broad in their thermal and bathymetric ranges. But corals that could tolerate abnormally high temperatures (higher than 40°C) are unknown both in the living communities and in the fossil record. Here we report the discovery of small thermophilic rugose corals in the Devonian vent community of southeastern Morocco. These organisms were adapted to conditions prevailing within chimney conduits of a hydrothermal system that developed on the roof of a submarine volcanic high. The coral larvae followed a calice-in-calice settlement and growth strategy to survive the contact with thermal fluids. This adaptation was not related to taxonomy and characteristic of all coral taxa present in the vents. Monospecific coral population was identified in several Emsian vents whereas the coral fauna of the single Givetian vent was more diverse and included four species. The entry of different rugose coral species into the hot vents resulted from atrophic relation to ostracods flourishing in the chimneys.</ABSTRACT>

51800 <TITLE>Vent and mound rugose coral associations from the Middle Devonian of Hamar Laghdad (Anti-Atlas, Morocco).</TITLE>
51801 <SOURCE>Geobios 39, 2: 155-170.</SOURCE>
51802 <ABSTRACT>Peculiar associations of small, solitary, deep-water rugose corals are described from the Middle Devonian buildups situated in the easternmost part of Hamar Laghdad area of southern Morocco. The most of them are monospecific and consist of simplified taxon *Amplexus florescens* but one is polyspecific and composed of specimens belonging to four different species representing three families. These rugosan associations form isolated nest-like aggregations where numerous densely packed specimens are arranged mostly in life position. The polyspecific and two monospecific associations are interpreted as growing in close proximity to venting fields. They reveal a unique calice-in-calice recolonization pattern expressed by successive settlement of juvenile specimens in the calice of dead individuals. This pattern was presumably a consequence of selective survival of coral larvae settling in extreme vent habitats. Although, the calice-in-calice pattern is common in both, mono- and polyspecific associations, there are differences expressed in the character of larval attachments and various types of the calice fillings. The trophic interaction between corals and ostracods is discussed (Fossil Cnidaria *Amplexus florescens*, not displaying calice-in-calice pattern of growth have been found within the mound where polyspecific association occurs. These are interpreted as growing away from venting fields. Comparisons of *Amplexus*-type coral faunas with the other North African and European corals allow the classification of these ampleximorph rugosan taxa as characteristic biotic components of the Middle Devonian mound environments influenced by venting activity. Two new genera and species, *Weyeria prima* and *Vesiculolasma erfoudi*, are introduced.</ABSTRACT>

51813 <TITLE>The Middle Devonian *Amplexus* coral reef of Ouhlane (Morocco) - New data on the geology and rugose coral fauna.</TITLE>
51814 <SOURCE>Geologica et Palaeontologica 33: 93-115.</SOURCE>
51815 <ABSTRACT>From the Middle Devonian locality *Amplexus* Ouhlane in the E Anti-Atlas of Morocco a rich reefal community is known. leMaitre (1947) was the first to publish a detailed paper about those fossil faunas (tabulate and rugose corals, stromatoporoids). This outcrop is reinvestigated, a columnar section is established and the coral bearing horizons are resampled. The stratigraphic division is refined, moreover, conodont biozonation of the section reveals a Late Eifelian/Early Givetian age. A facies model explains the occurrence of biogenic carbonates with hermatypic organisms. 17 taxa of rugose corals are described, 9 of them being new records for the locality. All described corals derive from the Lower Givetian timorensis-Zone.</ABSTRACT>

51840 <SOURCE>Coral Research Bulletin 7: 021-037. [Dieter weyer's 65th birthday commemorative volume; S. Schröder, H. Löser & K. Oekentorp (eds)]</SOURCE>
51841 <ABSTRACT>Phillipsastrea weyeri n.sp., P. tafilaltensis n.sp. and P. hollardi n.sp. have been collected in various outcrops of the Tafilalt and the Ma'ader which were dated by conodonts. P. hollardi has only been observed in the Ma'ader and characterizes mostly the Upper Polygnathus varcus Zone. It still occurs sparsely higher in the Givetian where it is associated with P. weyeri and P. tafilaltensis. These two species are also very abundant in the Tafilalt. They are locally accompanied by Kuangsiastrea pengellyi (Milne-Edwards & Haime, 1852) and more frequently by Acanthophyllum simplex (Walther, 1929). The fauna with A. simplex, Phillipsastrea tafilaltensis and P. weyeri seems to be highly characteristic of the Upper Givetian from the Tafilalt and the Ma'ader where it mainly occurs in the Klapperina disparilis and Lower Mesotaxis falsiovalis Zone. For comparison, the types of the Spanish species Phillipsastrea torreana (Milne-Edwards & Haime, 1851) and Argutastrea? pradoana (Haime, 1855) are described and figured.</ABSTRACT>

- 51854 <ABSTRACT>The new species *Czarnockia maroccana* is described from cephalopod limestones of the middle/upper Clymenia genozone (level with *Goniclymenia*) in the Tafilalt district of the Anti Atlas region. The small collection of seven syntypes demonstrates a surprising intraspecific variation visible only after intensive serial sectioning of all subtabular and calicular parts of the skeleton. This is the first record of the rare genus from a second area outside the type occurrence in the Wocklumeria genozone of the Polish Holy Cross Mountains. As a member of the phyletic line *Neaxon* > *Petraia* > *Famennelasma* > *Czarnockia*, the taxon should be found cosmopolitically in the psychrospheric *Cyathaxonia* facies of Upper Famennian times.</ABSTRACT>

- 51866 <SOURCE>Abhandlungen der Geologischen Bundesanstalt 54: 385-434.</SOURCE>
- 51867 <ABSTRACT>A probably deep, or moderately deep, photic zone coral fauna of early Givetian age is examined from Jbel Ou Driss. The genera *Zonophyllum*, *Lekanophyllum*, *Siphonophrentis*, *Heliophyllum* and *Spinophyllum* are reviewed and the new species *Zonophyllum maderense*, *Z. pegoconus*, *Lekanophyllum hollardi* and *Stringophyllum coenaubertae* are erected. Otsuka coefficients have been calculated to determine similarities between the genus composition of the Rugosa of the Ma'der basin and those of 15 other regions. Very high OC values are obtained from comparisons with the northern Spain - Pyrenees - Vendee and northern Vosges - Saar - Moravia regions. All these regions were likely situated on the Gondwana side of the Rhenic paleo-ocean. A lesser, but nevertheless high OC value between the Ma'der basin and the Rhenohercynian zone indicates that the Rhenic paleo-ocean was narrow. Comparison with the Appalachian belt gives a considerably lower OC value, and no more than 17% of the Ma'der basin Rugosa had an Eastern Americas Realm ancestry. In Givetian time, coral migration from the EAR had ceased or was greatly reduced, and transport of coral larvae was likely in a southwest direction through the narrow Rhenic paleo-ocean. Similarities decrease eastwards from the Ma'der basin along northern Gondwana to eastern Australia. The Baoshan-Luxi microplate was likely attached or close to Gondwana in Givetian time, at a longitude between the northern Pakistan part of the Indian shield and western Australia. The OC value between the Ma'der basin and the Altay-Sayan collage suggests that the allochthons carrying Givetian Rugosa were not accreted to the Angaran shield in Givetian time, and were likely situated at < 40° latitude.</ABSTRACT>

- 51878 <TITLE>Emsian deep-water Rugosa assemblages of Hamar Laghdad (Devonian, Anti-Atlas, Morocco).</TITLE>
- 51879 <SOURCE>Palaeontographica A284, 1-3: 17-68.</SOURCE>
- 51880 <ABSTRACT>Four types of assemblages composed of small, mostly undissected, deep-water Rugosa corals, are described from argillaceous sediments of the Amerboh Group (upper Emsian) in the area of Hamar Laghdad (eastern Anti-Atlas, Morocco). During that time the sea-bottom of studied area was extremely diversified due to prior formation of numerous, up to 20-50 in high, closely spaced mud mounds. The formation of mud mounds was caused by earlier hydrothermal activity, which ended temporarily by the end of inersus conodont Zone time. Since that time elevated mud mounds and especially depressed spaces between the mounds were continuously buried by argillaceous sediments of the Amerboh Group. The process of burial has been finished by the end of the Emsian. These extremely diversified bottom morphologies created exclusive environments where exceptional assemblages of deep-water Rugosa corals developed. Four assemblages of Rugosa corals are distinguished from each other not only in species content and richness, but also in different types of life strategies in response to various environmental conditions. The richest assemblage (A) comprising of 15 species belonging to 10 genera, settled directly on the already lithified slopes of mud mounds. Assemblage (B) occurring in the same time, in depressed areas between the mounds, is composed of nine species belonging to seven genera. Subsequent assemblages, (C) on the slopes, and (D) distanced from the mud mounds, developed within soft marly argillaceous deposits are less diversified and are composed of three species belonging to three genera and two species belonging to two genera respectively. These data show that the slopes of mud mounds acted as isolated oases M4064 with exclusively favourable environmental conditions for corals, and were surrounded by deep-water environments, unfavourable even for a relatively tolerant Laccophyllid fauna. Four new genera: Erfoudia n.gen., Marocaxon n.gen., Berberia n.gen., Pentacyathus n.gen. and 16 new species: Enterolasma pachythea n.sp., Sutherlandinia anna n.sp., Boolelasma magnum n.sp., Syringaxon exiguus n.sp., Syringaxon firmipes n.sp., Schindewolfia concors n.sp., Schindewolfia solida n.sp., Schindewolfia tenera n.sp., Catactotoechus instabilis n.sp., Erfoudia eisenmanni n.sp., Marocaxon subcylindricus n.sp., Marocaxon laticalix n.sp., Berberia kesskessi n.sp., Pentacyathus arduus n.sp., Pentacyathus tenuis n.sp., Pentacyathus variabilis n.sp. are described.</ABSTRACT>

- 51891 <TITLE>Monospecific rugosan assemblage from the Emsian hydrothermal vents of Morocco.</TITLE>
- 51892 <SOURCE>Acta Palaeontologica Polonica 49, 1: 75-84.</SOURCE>
- 51893 <ABSTRACT>Unique monospecific assemblages of small, solitary, undissected rugose corals are described from the Devonian deep-sea hydrothermal venting systems of the Hamar Laghdad (Anti-Atlas, Morocco). Assemblages of numerous rugosans (coral meadows) have been found around the outlets of venting channels irregularly forked within the Emsian mud mounds. Majority of rugose corals, which settled around vents, reveal a bizarre pattern of growth called here calice-in-calice. The phenomenon of calice-in-calice growth is related to selective survival of coral larvae i.e. it is postulated that the larvae, which settle within the calices of extinct

- individuals were more successful in their development. They probably use empty calices as shelters against the physical (hot or poisoning fluids) or biological (predators) factors. The presence of numerous carapaces of ostracods within the calices of extinct rugosans suggests a strong trophic relation between corals and ostracods, which lived around hydrothermal vents. New genus and species Hamarophyllum belkai is proposed. [original abstract]

51918 <SOURCE>Terra Nostra 2003, 5: 120-121</SOURCE>
51919 <ABSTRACT>Das Givetium und Frasnium war weltweit durch die maximale Ausbreitung von "Riffen" (Biostrome und Bioherme) verschiedener Gröeenordnung und mit unterschiedlichem ökologischem Aufbau charakterisiert. Bislang existieren im Devon nur beschränkte Daten zum Verbreitungsmuster spezifischer Riff-Faziestypen in Zeit und Raum. In diesem Zusammenhang ist ein Vergleich von Riffstrukturen weit getrennter Paläobreiten von besonderem Interesse, um Einflüsse von Paläoklima, Fazies und Plattentektonik auf Riffbauer und -bewohner zu ermitteln. Als erstes Fallbeispiel wurde ein koloniales Rugosen-Biostrom im NW-Maider des östlichen Anti-Atlas (Süd-Marokko) analysiert. Das Profil Taboumakhlouf-Ost ist schon seit langem miß verständlich unter de Bezeichnung "Höhe 760" bekannt (z.B. Coen-Aubert 2002), wurde allerdings bisher nicht paläoökologisch untersucht. Während vom N-Maider bis zum S-Tafilalt Korallen-Stromatoporen-Kalke aus dem frühen und mittlerem Givetium bekannt sind, ist dies das gröete in-situ Biostrom aus dem oberen Givetium des gesamten Anti-Atlas. Paläogeographisch handelt es sich um den Übergangsbereich vom Maider-Becken zu einer westlich liegenden Maider-Plattform. [first fragment of extensive (!) summary, or rather full note]</ABSTRACT>

</TITLE>
51931 <SOURCE>Revue de Paléontologie 23, 1: 181-208.</SOURCE>
51932 <ABSTRACT>A revision of Crenulipora difformis Le Maitre, 1956, type species of the genus, is presented and its attribution to a new subfamily of Favositids is proposed. The revision includes the examination of type specimens and numerous topotypes. The geographical and stratigraphical data areas follows: Morocco, Hamar Laghdad, top of the Kess-Kess Formation and basis of Amerboh, Upper Emsian. A revised diagnosis of the genus is given and the type species described herein in detail; its variations are extremely important and unusual in Tabulata. The main features of C.difformis are: more or less flat branches, calices bearing from 12 (usual) to only a few rows of spines showing a bilateral or axial symmetry, operculum frequent, wall sinuous in transverse sections, without peripheral thickening, spiny, tabulae numerous or not, very often "forked"; some vertical, pores of P1 and P2 type. Microlamellar microstructure. An accurate biometric analysis allows to recognize two opposite forms, one called "weak" and the other "strong" with between a group of "composite" specimens, but no new taxonomic units have been defined. The genus is recorded in Ougarta (Algeria), Armorican Massif (France) and probably in the Cantabrian Mountains (Spain).</ABSTRACT>

51943 <TITLE>Coexistence de lamelles et de microlamelles dans le sclerenchyme de "Ligulodictyum" Plusquellec 1973 (Tabulata, Devonien du Nord-Gondwana).</TITLE>
51944 <SOURCE>Courier Forschungsinstitut Senckenberg 164: 329-337. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 1]</SOURCE>
51945 <ABSTRACT>The pleurodictymorph genus Ligulodictyum Plusquellec 1973, from the late Gedinnian - Early Siegenian of the Armorican massive shows an entirely fibrous microstructure. Specimens -with a very similar morphology - from the Gedinnian of Mauritania (Pleurodictyum mauretanicum Le Maitre 1959) Morocco and Spain and from the Siegenian and Upper Emsian of Morocco show trabeculae often embedded in abundant stereoplasm. The microstructure of the stereoplasm, studied by ultra-thin sections with polished sides (LFP), exhibits two types of biocrystals: 1) standard lamellae in the proximal part of the basal plate, and 2) microlamellae with different size and shape in the middle and distal parts. This change of lamellar to microlamellar microstructures is a new finding. In some specimens - especially from Asturias - intercalations of fibrous layers in the microlamellar stereoplasm are described. The discovery of stereoplasm in the mauretanicum group probably will require the splitting of the genus Ligulodictyum. The change of lamellar to microlamellar microstructures proves that genera which solely differ by their microstructure, e.g. Michelinia and Turnacipora, may represent evolutionary stages of the same lineage and belong to the same family.</ABSTRACT>

51970 <SOURCE>Geologica et Palaeontologica 35: 53-61.</SOURCE>
51971 <ABSTRACT>Four families of tabulate corals are abundant in the Hmar Lakhdad Formation: auloporids, dendroporids and striatoporids are very frequent in the micritic mounds (named "kess-kess"), and favositids are rather common in the argillaceous limestones overlying the mounds. Statistical analysis of tabulate coral distribution shows an evident lateral variation. The western part of the mound range is characterized by a facies with Bainbridgia, the central part by a facies with tubular auloporids and ornate dendroporids, and the eastern part by a facies with tubular auloporids. Striatoporids and auloporids, fairly abundant in the western part, are present in all the kess-kess. Each facies corresponds with a part of the range limited by two normal faults. Tabulate coral distribution was probably controlled by synsedimentary tectonics, affecting the three blocks of Hmar Lakhdad. Building corals are absent and only bacterian structures (microstromatolites) can be observed in all kess-kess. So the mound cementation was probably controlled by bacterian activity. 51997 <ABSTRACT>The paper describes the three tabulate coral species Caliapora robusta (Pradáčová, 1938), Pachyfavosites tumulosus Janet, 1965 and Thamnopora major (Radugin, 1938), the rugose coral Phillipsastrea ex gr. irregularis (Webster & Fenton in Fenton & Fenton, 1924) and the chaetetid Rhabdopora crinalis (Schlüter, 1880). The specimens are described for the first time from Givetian and probably Frasnian strata of Semara area (Morocco, former Spanish Sahara). The material is stored in the Museo Geominero in Madrid. The tabulate corals and the chaetetid demonstrate close biogeographic relationships to Central and Eastern Europe as well as to Western Siberia. The fauna does not show any special influence of the Eastern Americas Realm. [original abstract]</ABSTRACT>

52021 <TITLE>Early Devonian Kess-Kess carbonate mud mounds of the eastern Anti-Atlas (Morocco), and their relation to submarine hydrothermal venting.</TITLE>
52022 <SOURCE>Journ. Sed. Res., Section A: Sedimentary Petrology and Processes 68/3: 368-377.</SOURCE>
52023 <ABSTRACT>Spectacular conical Early Devonian carbonate buildups up to 55 m high that crop out in the eastern Anti-Atlas of southern Morocco are microbially mediated carbonate mud mounds that were surfaced by soft-bottom communities dominated by small tabulate corals. They formed on the Hamar Laghdad elevation, which was created by a submarine volcanic eruption, and were associated with a network of synsedimentary radial and tangential faults that originated by uplift of the intrusive laccolithic body underlying the Kess-Kess Formation. These faults served as conduits for the migration of hydrothermal fluids to the sea floor. Most mounds developed over cross-points of radial and tangential faults. Vents were episodically active until the Famennian, but extensive vent carbonate production occurred only during the Emsian. Preliminary geochemical results document that mud-mound carbonates and calcite cements in neptunian dikes precipitated from brines comprising a mixture of hydrothermal fluids and seawater. In addition, carbon isotope compositions ($\delta^{13}\text{C}$ as low as -18‰PDB) suggest a contribution from thermogenic methane derived presumably from underlying basaltic intrusives. Aerobic bacterial oxidation of methane is favored as the main process driving carbonate precipitation in, and rapid lithification of, the mounds.</ABSTRACT>

52034 <TITLE>Signatures of Hydrocarbon Venting in a Middle Devonian Carbonate Mound (Bollard Mound) at the Hamar Laghdad (Anti-Atlas, Morocco).</TITLE>
52035 <SOURCE>Facies 40, 1: 281-296.</SOURCE>
52036 <ABSTRACT>The Middle Devonian Hollard Mud Mound is situated in the eastern Hamar Laghdad, which is a small mountain range in the Tafilalet in SE Morocco. In contrast to the well known Lower Devonian Kess-Kess mounds, the Hollard Mound is of Middle Devonian age. The facies in the core of this mud mound differs from that of the other parts of the mound, and exhibits signatures of ancient hydrocarbon venting. The carbonate phases of the core facies are derived from the oxidation of vent fluids and consist of clotted micrite, a cryptocrystalline carbonate associated with spheres of uncertain origin, and a calcitic rim cement (rim cement B). These vent carbonates show $\delta^{13}\text{C}$ values in the range of -11 to -20 PDB indicating that some of their carbon is derived from isotopically light hydrocarbons. Fossiliferous micrite has been affected by hydrocarbon venting in the proximity of the vent site, which is indicated by intermediate $\delta^{13}\text{C}$ values between vent carbonates and not affected sediments. Bivalves occur in dense populations within the core facies. They form autochthonous shell accumulations and are almost exclusively articulated. It is likely that these bivalves were dependent on chemosynthesis similar to their counterparts at modern vents. The vent deposits also exhibit an unusual prasinophyte assemblage, which might have been linked to the specific

- nutrient availability at the vent site. The ancient vent site is characterized by an enhanced carbonate precipitation and rapid lithification. The latter is corroborated by the three-dimensional preservation of phytoplankton (prasinophytes and acritarchs) and the occurrence of stromatolite pores. An early phase of carbonate corrosion predating the formation of vent carbonates affected the fossiliferous micrite of the core facies and is thought to be related to a phase of H₂S-rich venting.

52060 <TITLE>Microstructure of Siphonodendron (Lithostrotionidae).</TITLE>
52061 <SOURCE>Palaeontographica Americana 54: 489-500 [Oliver w.A.Jr et al. (eds): Recent advances in the paleobiology and geology of the Cnidaria: Proceedings of the 4th International Symposium on Fossil Cnidaria].</SOURCE>
52062 <ABSTRACT>The microstructure of two species of Siphonodendron is described by the method of ultra-thin sections: S. martini (M.-Edw. & H.) and S. sp. cf. S. dutroii Armstrong, from the Lower Carboniferous of Northern Africa. They represent two types of microstructure observed among species of Siphonodendron. The first, prevailing in the early viséan, is partly lamellar; the second, widespread in the late viséan and Serpukhovian, is completely fibrous. In both cases, an internal periodic structure in the wall, which has a correlation with the external growth-ridges, is described.</ABSTRACT>

52087 <SOURCE>Coloquios de Paleontología 57: 23-35.</SOURCE>
52088 <ABSTRACT>A new genus of rugose coral, Tizraia, has been recorded in the Tizra and Akerchi formations of the Adarouch area (Brigantian, Central Meseta, Morocco). The new genus is characterized by incomplete, mesa-shaped tabulae, absence of axial structure and presence of well developed lonsdaleoid dissepiments, as well as parricidal increase. It evolved from Diphyphyllum by the development of lonsdaleoid dissepiments. Only the type species, Tizraia berkhlii gen. nov. et sp.nov. is included with certainty in the new genus, but an additional species represented by one single specimen is tentatively described under this generic name. Tizraia has also been recorded in the Djerada Basin (Eastern Morocco) and may be present in Ireland. It has high biostratigraphic value as an Upper Brigantian (Upper Viséan) index taxon.</ABSTRACT>

52099 <TITLE>Rugose corals from the upper Visean (Carboniferous) of the Jerada Massif (NE Morocco): taxonomy, biostratigraphy, facies and palaeobiogeography.</TITLE>
52100 <SOURCE>Paläontologische Zeitschrift 84, 3: 323-344.</SOURCE>
52101 <ABSTRACT>The Visean succession of the Jerada Massif contains a relatively diverse rugose coral fauna, which comprises 12 genera. Only two of these (Siphonodendron and Lithostrotion) are reported to include more than one species. Most taxa show distinctive facies dependencies. Small solitary corals are found in shaly environments of the Oued Es-Sassi Formation. On the northern flank a coral patch reef formed on an oolitic shoal in the Koudiat Es-Senn Formation. Its core mainly consists of Lithostrotion vorticale colonies, whereas in its surroundings literally hundreds of specimens of Siphonophyllia samsonensis occur. Associated with these dominant taxa occur colonial and further large solitary taxa (Palaeosmia, Dibunophyllum). Tizraia and Pareynia are restricted to microbial-dominated buildup facies. Their presence might be strongly controlled by the development of this buildup type, because further occurrences in Algeria, Morocco, and Belgium are all in the same facies. The coral fauna at Jerada is a typical Late Visean assemblage for the Western European Province. The Eastern Moroccan Meseta may be an important pathway within the province

- for the connection between the Central Saharan basins and NW Europe. The biostratigraphic ages of the coral fauna partly contradict ages based on carbonate microfossils: the coral ages are slightly older and typical Brigantian coral taxa are absent.</ABSTRACT>

52112 <TITLE>Corals from the Upper Viséan of the southern Azrou-Khenifra Basin (Carboniferous, Central Moroccan Meseta).</TITLE>
52113 <SOURCE>Palaeoworld 19, 3-4: 294-305.</SOURCE>
52114 <ABSTRACT>This is the first taxonomic treatment of coral faunas from upper Viséan shallow-water limestones of the southern Azrou-Khenifra Basin (eastern central Morocco). Corals recovered during reconnaissance work represent 8 genera and 11 species of rugose corals, 1 heterocoral species, and 3 tabulate coral taxa. The fauna is tentatively attributed to the late Asbian. Siphonodendron scaleberense is described from Northern Africa for the first time. Facies differentiations clearly control the coral distribution in the stratotype of the Bou-Rifi Formation near Sidi-Lamine. In the Tabainout Ridge, the massive build-up facies is almost devoid of corals except for specialised forms such as ?Sutherlandia. Bioclastic and oncolitic limestone facies below and above the build-up facies contain coral faunas, which differ in their compositions. The fauna of the Azrou-Khenifra Basin is part of the west European-North African faunal province.</ABSTRACT>

52127 <ABSTRACT>Fourteen species of rugose corals belonging to the family Alophyllidae from Adarouch (Central Morocco) are described. One species is new, Clisiophyllum macrocolumellatum said & Rodriguez; six species perhaps correspond to undescribed forms, but the scarcity of material or its poor preservation impede confirm it and we maintain them in open nomenclature. Seven species are previously known and broadly distributed in the Palaeotethys during the Visean and Serpukhovian. [original abstract]</ABSTRACT>

52139 <SOURCE>Geological Journal 43, 4: 463-485.</SOURCE>
52140 <ABSTRACT>Three Upper Viséan to Serpukhovian limestone formations from the Adarouch region (central Morocco), North Africa, have been dated precisely using foraminiferans and calcareous algae. The lower and middle part of the oldest formation, the Tizra Formation (Fm), is assigned to the latest Asbian (upper Cf6γ Subzone), and its upper part to the Early Brigantian (lower Cf6δ Subzone). The topmost beds of this formation are assigned to the Late Brigantian (upper Cf6δ Subzone). The lower part of the succeeding Mouarhaz Fm is also assigned to the Late Brigantian (upper Cf6δ Subzone). 52151 <TITLE>Microbial-sponge and microbial-metazoan buildups in the Late Viséan basin-fill sequence of the Jerada Massif (Carboniferous, NE Morocco).</TITLE>
52152 <SOURCE>Geological Journal 43, 2-3 [M. Aretz, H.-G. Herbig et I. Somerville (eds): From Platform to Basin, Proceedings of the Carboniferous Conference, Cologne 2006]: 307-336.</SOURCE>
52153 <ABSTRACT>Three distinctive Late Viséan buildup intervals are differentiated on the southern limb of the Jerada Synclinorium. The oldest buildups (BI-1) are preserved as olistoliths in the Oued El Koriche Formation (Fm). They were located on a southern platform prior to reworking. The younger Koudiat Es-Senn Fm contains two autochthonous buildup intervals (BI-2 to BI-3). BI-1 and BI-2 buildups are large microbial-sponge buildups, BI-3 are small microbial-metazoan buildups in the capping bed succession above BI-2. All buildups are characterized by a rigid non-skeletal microbial framework. Growth of the largest BI-2 buildups started in aphotic to dysphotic conditions in a water depth significantly less than 100m and continued into agitated shallow-water. Smaller BI-2 buildups and all BI-3 buildups are encased in grainy shallow-water carbonates. In contrast to a mostly homogeneous microbial-sponge facies below, the uppermost part of the BI-2 buildups and all BI-3 buildups consist of heterogeneous boundstones with differing frame builders. BI-1 to BI-3 buildups represent different stages within a Viséan basin-fill sequence. Carbonate sedimentation ended with the deposition of peritidal oncolitic floatstones below the unconformably overlying Namurian shales. The Jerada buildups have many features commonly associated with reefs. Comparison with contemporaneous buildups shows considerable similarities to buildups from Algeria, the Eastern Moroccan Anti-Atlas and the British Isles. [original abstract]</ABSTRACT>

- 52164 <TITLE>Microfacies of Carboniferous Limestone Clasts from the Rif Paleozoic (Morocco): A Contribution to the Paleogeography of the Western Mediterranean Carboniferous Paleotethys.</TITLE>
- 52165 <SOURCE>Facies 19: 271-300.</SOURCE>
- 52166 <ABSTRACT>Post-lower Serpukhovian conglomerates with abundant limestone clasts are intercalated within the Carboniferous flysch succession of the Ghomarides (internal zone of the Rif, northern Morocco). They are restricted to two ghomaridic nappes (Beni Hozmar, Akaili; Fig. 1). No limestone-bearing conglomerates are known from the third nappe (Kuhdiat Tizian). 83.4% of the limestone clasts derived from shallow-shelf environments and adjoining proximal slope environments of late Visean (V3b γ) to early Serpukhovian (Namurian E1-E2) age. Microfacies types of the inner shelf lagoon and of restricted shelf environments dominate. They indicate a complicated mosaic facies pattern (Fig. 2). 16.6% of the limestone clasts derived from distal slope environments and deep, open marine environments. They are of unknown age except for one Upper Devonian pebble from around the transition doII α / doII β . All are supposedly of late Middle Devonian and Late Devonian age. Their sedimentology as well as the age and the microfacies of the limestone clasts indicate that the conglomerates of the Ghomarides are homologous to the Marbella Formation of the Malaguides (Betic Cordillera, southern Spain). The conglomerate of Binifaillet (Minorca, Balearic Islands) is also similar. The source area of the conglomerates was the not any more existent Betico-Rifean Block south of the Malaguide-Ghomaride flysch trough. Owing to their facies development in Devonian and Carboniferous times, the nappes of the Ghomarides and the Malaguides can be arranged in a successively more distal position towards the source: nappe of Beni Hozmar - nappe of Kuhdiat Tizian - nappe of Akaili + Malaguides (Fig. 4). Minorca, which received its flysch sediments from the north, seems to be influenced only episodically by conglomerate inputs from the south. [fragment of extensive summary]</ABSTRACT>

- 52217 <SOURCE>Comptes Rendues de Geosciences 339, 1: 65-74.</SOURCE>
- 52218 <ABSTRACT>A quantitative study of the Upper Jurassic coral associations of Cape Ghir (Atlantic High Atlas, Morocco) revealed highly diverse coral assemblages characterizing three reef environments, each of them dominated by one of the following genera: Dimorpharea, Microsolena, and Styliina. A fourth assemblage is characterized by nerinean gastropods and stromatoporoids. Combined GPS surveys, 3D representation, and facies distribution studies permitted to understand the geometry of this coral reef within a particular tectonic setting. The reef became installed on top of a tilted block of Jurassic age subsequently folded into an east-west-trending anticline near the village of Tighert, exhibiting a 5 to 10° northward dip of its northern flank near the lighthouse of Cape Ghir. We suggest that the different fossil assemblages encountered in the field belong to one and the same fossil reef tract (within a unique facies model). The previously reported hypothesis of two successive reef horizons representing different biochrons is abandoned.</ABSTRACT>

52255 <TITLE>Ellipsoidaeraea hemisphaerica n.sp. (Scleractinia) from the Middle Jurassic of the central High Atlas (Morocco).</TITLE>
52256 <SOURCE>Paläontologische Zeitschrift 63, 1/2: 6-14.</SOURCE>
52257 <ABSTRACT>Ellipsoidaeraea hemisphaerica n.sp. is a solitary cupulate scleractinian (Archaeofungiina) occurring in lower Middle Jurassic, probably Bajocian strata at the southern rim of the central High Atlas north of Errachidia. The strata are dated by the lituolid foraminifer Timidonelia sarda Bassoulet, Chabrier & Fourcade 1976. Ellipsoidaeraea hemisphaerica n.sp. belongs to a rare genus known up to now only from Toarcian strata of western Algeria and northern Morocco. It is distinguished from the other species of that genus by its proportions. At the type locality, the coral occurs in a lagoonal setting in a coral-sponge / spongiomorphid biostrome and in overlying oolitic limestones.</ABSTRACT>

52283 <ABSTRACT>Ce gisement appartient à l'important district stratoïde plombo-zincifère de la région Sud d'Oujda (40km), Maroc. Le gisement de Touissit est interstratifié dans une série dolomitique aaléno-bajocienne, transgressive sur un paléorelief primaire. Cette série est assimilée à un complexe récifal biostromal à base de boues organiques d'origine vraisemblablement algale.</ABSTRACT>

52307 <TITLE>Geology, facies model and coral associations of the Late Jurassic reef complex at cape Ghir (Atlantic High Atlas, Morocco).</TITLE>
52308 <SOURCE>Comptes Rendus Geosciences 339, 1: 65-74.</SOURCE>
52309 <ABSTRACT>A quantitative study of the Upper Jurassic coral associations of Cape Ghir (Atlantic High Atlas, Morocco) revealed highly diverse coral assemblages characterizing three reef environments, each of them dominated by one of the following genera: *Dimorpharaea*, *Microsolena*, and *Stylina*. A fourth assemblage is characterized by nerinean gastropods and stromatoporoids. Combined GPS surveys, 3D

representation, and facies distribution studies permitted to understand the geometry of this coral reef within a particular tectonic setting. The reef became installed on top of a tilted block of Jurassic age subsequently folded into an east-west-trending anticline near the village of Tighert, exhibiting a 5 to 10° northward dip of its northern flank near the lighthouse of Cape Ghir. We suggest that the different fossil assemblages encountered in the field belong to one and the same fossil reef tract (within a unique facies model). The previously reported hypothesis of two successive reef horizons representing different biochrons is abandoned.</ABSTRACT>

52334 <SOURCE>Notes Serv. Géol. Maroc Rabat 1973, 34, 254: 151-156.</SOURCE>

52335 <ABSTRACT>Des minéralisations plombo-zincifères sont connues dans les calcaires subrécifaux sinémuriens autour du socle paléozoïque de Mougueur, dans le Haut Atlas oriental. * Parmi ces minéralisations, il existe des amas de smithsonite à proximité, soit de paléokarsts minéralisés en plomb, soit de cassures stériles. * Ces amas sont constitués en majeure partie par de la smithsonite à faciès rubanné. L'étude minéralogique a montré qu'il existait une smithsonite microcristalline déposée dans un premier stade. Des phénomènes de recristallisation ont ensuite provoqué la formation de smithsonite cristalline, d'hydrozincite et d'hémimorphite. L'hypothèse d'une origine primaire et non supergène de la smithsonite microcristalline est avancée.</ABSTRACT>

- 52387 <ABSTRACT>The reef outcrop of Aghram Amallal (South-East of Fes) belongs to the reef formations of the south side of the South Rifan Corridor. It is presented like a horizontally allongated lense (approximately 60m lenght; 3 to 6m thickness). The bioconstruction is almost exclusively assured by the Tarbellastraea genera. The developed colonial morphologies are varied and their spatiotemporal distribution has allowed to establish morphological zonations. The study of different distinguished morphological zonations, the investigation of the accompanying fauna and flora as well as the analysis of the inter and intracolony sediment let appear a rythmicity of the bioconstruction and the sedimentation. This rythmicity is summoned by two "regressive" sequences that are separated by a positive fluctuation of the sea level. The environmental conditions seem to characterize a "back reef" set, and permit to assimilate the studied reef to a "Patch" that would integrate itself to an important marine platform. This later would develop in front of Eiderj faults.</ABSTRACT>

- 52400 <ABSTRACT>The reef outcrops of Bumeriem (north east of Tazouta) belong to the later Miocene reef formations of the South Rifan Trench. They are represented in the form of more or less elongated lenses, and display a vertical repartition on three successive levels. The reef constructions are essentially built by Porites and Tarbellastraea; Palaeoplesiastraea is much less abundant. The developed colonial morphologies, whether they are massive or branched, are very much varied. The spatio-temporal distribution of these different types of colonies has allowed to establish morphological zonations into these reef outcrops. The study of the different distinguished morphological zonations, the analysis of the intercolony sediment and the examination of the accompanying fauna and flora allow to make a certain number of paleoecological deductions. Generally, the environmental conditions seem to characterize a "back reef" environment frequently situated near the "reef crest". The analysis of the vertical succession of the different sets let appear the clearly rhythmic character of the reef construction and of the sediment. This kind of rhythm is summoned by four "regressive" sequences, having each a few meters and all tend to be sandy. The reappearance, at the end of each of these sequences, of the reef conditions would display a positive fluctuation of sea level.</ABSTRACT>

- 52464 <SOURCE>Errachidia meeting, abstract-book; SDS-FGCP 421: 18-20 [Feist R., Talent J. & Bernard O. (eds)].</SOURCE>
- 52465 <ABSTRACT>The tabulate coral faunas of the Moniello-Santa Lucia Formations (upper Emsian-lower Eifelian, Cantabrian Mountains, NW Spain) and the "recif coralligene de Ouhahane" (Tafilalt, Morocco, assigned by le Maitre 1947, to the Eifelian) are compared in a quest for increased understanding of relationships among the various Devonian outcrops in Morocco, and between provinces of the Maghrebo-European realm. The Devonian of the Asturian-Leonese Domain, in the Cantabrian Mountains (NW Spain) is characterized by alternation of detrital and carbonate units, principally with benthic fauna, deposited on a shallow marine platform. Reef episodes of differing importance were developed in some of the carbonate successions. The first of these, upper Emsian in age, is not very important but some genera of tabulate corals (especially Crenulopora and Schlueterichonus) simply paleobiogeographic affinity of this region with north Africa (Fernandez-Martinez & Tourneur, 1995). Gondwana biogeographic patterns. [first part and conclusion of extensive summary]</ABSTRACT>

- 52478 <ABSTRACT>Restudy of Mesofavosites schoupei Potthast & Oekentorp 1988 (Emsian-Eifelian boundary in SE Morocco) and of Pachyfavosites pseudoseptatus Oekentorp 1975 (Emsian of Asturias/N Spain) shows that M. schoupei has to be assigned to Striatoporella Rukhin 1938 because of the typical growth form, the peripheral thickenings of the walls and the development of spines, P. pseudoseptatus has been assigned to Pachyfavosites on the basis of its strikingly thick walls. Diagenetic processes may result in secondary microstructures, for example the arrangement of carbonate fibers. Therefore, wall thickness is useless as a diagnostic feature. In this view, P. pseudoseptatus corresponds very well with other representatives of the genus Riphaeolites.</ABSTRACT>

- 52490 <SOURCE>Revue de Paleobiologie 13, 2: 411-425. [in French, with English abstract]</SOURCE>
- 52491 <ABSTRACT>Several Lower Devonian localities of Morocco (Middle Atlas

and coastal Meseta) yielded for the first time a hyolithid (Pterygotheca sp.), an orthothecid (Orthotheca sp. A), an epizoan tabulate coral *Hyostragulum ometanum* n.sp. and a beyrichiacean ostracode (*Gibba kandarensis* n.sp.) together with rare bivalves, cephalopod shells, abundant brachiopods and dacryoconarids. Only the hyolithids, the new tabulate coral and the new ostracode species are described herein. Specific commensal relationships between the hyolithid *Pterygotheca* sp. and the epizoan tabulate coral *Hyostragulum ometanum* n.sp. are demonstrated and compared with similar cases from Bohemia and the Armorica Massif (France). From a palaeobiogeographical point of view, the genus *Hyostragulum* appears as a typical north-Gondwanan genus. The genus *Orthotheca* occurs in both Morocco (*Orthotheca* sp. A) and southern Spain (*Orthotheca* sp. B) like the dimorphic beyrichiacean ostracode *Gibba kandarensis* n.sp. These new data confirm the close faunal affinities previously described between North Africa and southwestern Europe during the Lower Devonian. A lower Emsian age is proposed for the fossiliferous beds of Spain and Morocco.

52503 <SOURCE>Palaeontographica A227, 1-3: 1-86.</SOURCE>

52504 <ABSTRACT>The revision of the holotype and topotypes of *Dendropora* (= *Trachypora* ?) *gigantea* Le Maitre 1952, brings new data on the structure, the increase (lateral increase with apical corner pore) and the microstructure of this tabulate coral. The new genus *Saouraepora* - type species *D. gigantea* - is erected for branching corallum with strongly thickened peripheral zone where corallites are perpendicular to the surface, tabulae complete, incomplete and convex, rounded calices with granular intercalicinal platform, wall composed of upwards divergent lamellae, median dark lamina only in axial zone and inner peripheral zone of branch. Several species in open nomenclature and a new species - *S. armoricana* - are described from Lower and Middle Devonian; *Holacanthopora irregularis* Le Maitre 1957 is assigned to *Saouraepora*. The genus is represented in the Carboniferous by *Pachypora oklahomensis* Snider 1915. The variability of the genus is important, and brief review is given; its affinities with *Praemichelinia* are undoubtedly established and possible relationship with *P. homofavosa* are suggested; this interesting ramose species is described in appendix. Between branching coralla the microstructure of the wall prevents confusion with *Parastriatopora* (microlamellar) and evolves from it. Biographic data show that *Saouraepora* evolves in the North-Gondwana shelf during Lower and Middle Devonian and migrates to North-America during Upper Devonian or Lower Carboniferous. In this area the genus is located East of the Transcontinental arch.</ABSTRACT>

52515 <TITLE>Fossil corals from the Midway Atoll.</TITLE>
52516 <SOURCE>US Geol. Surv. prof. Pap. 680-G: 1-7; Washington.</SOURCE>
52517 <ABSTRACT>Fossil corals were recovered from the cores and cuttings of the two drill holes made in Midway atoll in 1956. Reef-building scleractinian corals were relatively continuous from near the surface to a depth of 1,143 ft. Above 494 ft, six species representing five genera were recognized, all identical with the living Hawaiian reef fauna; the age range was Pliocene to Holocene. At and below 494 ft was a poorly preserved surface reef fauna of Miocene age, represented by 10 genera and 13 species; this fauna was unlike that of similar age found in the drill holes at Bikini and Enewetak (formerly Eniwetok). 52528 <TITLE>A new Recent Sclerosponge from Ngargol, Palau Islands and its fossil representatives.</TITLE>
52529 <SOURCE>Bulletin Tohoku Univ. Sci. Dept., ser. 2 (geol.), 46, 1: 1-9.</SOURCE>
52530 <ABSTRACT>The new genus and species Tabulospongia horiguchii is described. It has a calcitic skeleton like that of a ceriod tabulate coral. Siliceous megascleres and microscleres are also part of the skeleton. The surface is marked by stellate grooves of the excurrent system. Acanthochaetetes wellsi Hartman and Goreau is removed from the genus Acanthochaetetes because, unlike the fossil forms, it contains spicules and is placed in the new genus. Mori believes that the presence of polyps in stromatoporoids is indicated by the presence of oolites within the skeleton of a Parallelostroma typicum from Gotland. The argument used is that a filter feeder could not survive in an environment of this sort "because it lacks sufficient ability to remove the obstacles from the living tissue of the skeleton. The fact that the stromatoporoid could survive in the oolites environment may prove that it had polyps with tentacles like other coelenterates because only the tentacles, possibly with nematocysts could remove ooids falling down continuously on the skeleton by wave action". He concludes that the stromatoporoids may be hydrozoans or a phylum intermediate between the Porifera and the Coelenterata.</ABSTRACT>

52569 <ABSTRACT>Globular bodies with vermicularly-sculptured surfaces and cellular internal structure, identified as the hydrozoan Heterastridium conglobatum Reuss, are found in late Triassic rocks of New Caledonia in a Monotis shellbed on Ile Hugon. Less well-preserved specimens, identified as H. cf. conglobatum and H. sp., occur in rocks of the Richmond Group in Nelson and the Taringatura Group in Southland, New Zealand. These occurrences seem to demonstrate the presence of the Suessi zone in New Caledonia and New Zealand Upper Norian sequences.</ABSTRACT>

52620 <SOURCE>G.E.G. Westermann (ed.): The Jurassic of the Circum-Pacific. Part V: Biogeography: 324-327; New York (Cambridge University Press).</SOURCE>
52621 <ABSTRACT>Circum-Pacific Jurassic corals were poorly known until recently. Only two monographs on Japan existed, by Yabe and Sugiyama (1935) on the stromatoporoids and by Eguchi (1951) on the Scleractinia. Rare and insignificant coral occurrences were reported from Indonesia by Tobler (1923) and van Bemmelen (1949). * In the past decade, numerous Jurassic corals have been collected in Canada (T. P. Poulton), western Mexico (T. E. Stump), northern Chile (P. Prinz), the Philippines, western Thailand, and Sarawak (H. Fontaine), Sakhalin and Koryakia (E. V. Krasnov), and Sumatra and Japan (L. Beauvais). Studies of these faunas have contributed to the dating of the source rocks (Lias and Dogger for Canada, Dogger for northern Chile, Dogger and Malm for western Mexico, Sumatra, Sarawak, Japan, and Sakhalin) and to paleogeography (Beauvais and Stump 1976; Krasnov 1983; Beauvais, Bernet-Rolland, and Maurin 1985, 1987).</ABSTRACT>

52646 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 245, 3-4: 462-482.</SOURCE>
52647 <ABSTRACT>The global spatiotemporal distribution of the Cretaceous carbonate platform biota, which is characterized by tropical; Mesogean (= Cretaceous Tethys) taxa, is an important aspect of Earth's paleobiogeography. All available records of this biota in the Northwest Pacific (Japan and Sakhalin Island) are summarized in order to elucidate its stratigraphic distribution patterns and faunal changes, with special attention given to the biota of the Late Aptian-Early Albian. This carbonate platform biota flourished from the Berriasian to Early Albian interval in the Northwest Pacific, indicating that the Northwest Pacific clearly belonged to the Tethyan biotic realm at that time. A step-wise demise of the carbonate platform biota transpired in the latest Aptian to middle Albian interval. Mesogean key taxa (rudists and dasycladacean algae), some Mesogean indicators (hermatypic corals and stromatoporoids) and nerineacean gastropods disappeared at the Late Aptian to Early Albian transition. Following this event, other Mesogean indicators (orbitolinid foraminifers and calcareous red algae) and coated grains disappeared at the Early to middle Albian transition. There is no record of carbonate platform biota in the Northwest Pacific during the long interval between the Middle Albian and Paleocene. The step-wise demise of the carbonate platform biota in the latest Aptian-middle Albian interval strongly implies a vicariance event, which separated the North Pacific from the Tethyan biotic realm and established the North Pacific biotic province.</ABSTRACT>

52658 <TITLE>Facies of sunken Early Cretaceous atoll reefs and their capping Late Albian drowning succession (Northwestern Pacific).</TITLE>
52659 <SOURCE>Facies 27: 153-174.</SOURCE>
52660 <ABSTRACT>Since first described in detail by Hamilton (1956), the causes and timing of the drowning of several hundred guyots in the northwestern Pacific is a puzzling question. Thus, the northwestern Pacific is one of the key areas in deciphering the demise of flat-topped platforms throughout the Earth's history. Based on older palaeontological data and the newly found shallow-water benthic foraminifera, the atoll reefs probably had a major period of vertical aggradation during the Barremian and the Aptian into the Late Albian depending on the stage of atoll development (type of guyot). New sedimentologic and stratigraphic data suggest a strong fall in sea level, leading to karstification and the formation of lowstand fringing reefs, prior to an even rapid rise of greater amplitude in the Late Albian Rotalipora appenninica zone ultimately causing drowning. After

climate relaxation, a sea level rise led to the final formation of small barrier reefs, rimming the top of many guyots in the Japanese Group, the Wake Group and the Mid Pacific Mountains. They can be interpreted as structures indicating final shallow-water carbonate production on top of the atoll during drowning. The facies of the syn- and post-drowning sediments on the guyot tops are strikingly similar even when vast distances apart. This and the biostratigraphic data suggest a synchronous drowning of many seamounts investigated up to now. Biotic composition and facies of the final Albian reefs are very similar to Albian caprinid-dominated reefs in the Caribbean region, indicating comparable environmental controls. In the case of the northwestern Pacific guyots, the simultaneous demise of reefs could be due to a short-term cooling event in the Late Albian, connected with a strong regressive-transgressive cycle with an amplitude of about 180m. This event is also known from the Tethys and the Atlantic. Climatic disturbances triggering short-term cooling and including a high amplitude regressive-transgressive sea level cycle, might be responsible not only for the Late Albian event, but also perhaps for other reef drownings throughout the Earth's history.

52671 <TITLE>Cretaceous history of Pacific Basin guyot reefs: a reappraisal based on geothermal endo-upwelling.</TITLE>

52672 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 112: 239-260.</SOURCE>

52673 <ABSTRACT>The mid-Cretaceous histories (origin, growth, death) of algal rudist stromatoporoid reef communities located on many Pacific Basin guyots are complex and controversial. These shallow water, tropical communities originated on volcanic edifices extruded during the Barremian - Albian [interval], grew upward during edifice subsidence / transgression throughout the Aptian, Albian and Cenomanian and several of them died almost synchronously near the Cenomanian / Turonian boundary. During their periods of origin and growth, we postulate that the reef ecosystems received dissolved oxygen by wave surge and nutrients by geothermal endo-upwelling. By this process oceanic waters of intermediate depth (approx. 500-1500m) were: (a) drawn into the weathered and fractured volcanic summit and lower part of the older reef and driven upward through the porous framework by the remnant geothermal gradient of the volcanic foundation and (b) emerged at the reef surface to support the high metabolism of the living community. * The death of most of the reefs near the Cenomanian Turonian boundary approximately coincides with the most intense oceanic anoxic event (OAE) in Pacific Ocean history. During this OAE the chemistry of the endo-upwelled fluids arriving at the reef surface changed from nutrient / oxygen-rich to dysoxic-anoxic toxic, and killed the community. Additionally, the combination of foundation subsidence and global transgression reduced aeration of interstitial reef waters by wave turbulence. The post-mortem history of the guyot summits consisted of: (a) drowning to prevent revival of the reef communities, (b) deposition of Turonian-Cenozoic fossiliferous pelagic -sediments in the former atoll lagoons and dead reef debris and (c) minor erosion (submarine; karstification?) of the dead reef frameworks.</ABSTRACT>

52684 <TITLE>Siliceous Sponges of the Takatika Grit (Cretaceous-Paleogene), Chatham Islands, South Pacific.</TITLE>
52685 <SOURCE>Journal of Paleontology 83, 5: 811-819.</SOURCE>
52686 <ABSTRACT>Siliceous sponges are rare in the Cretaceous-Paleogene record, with only a handful of published accounts from the Southern Hemisphere. Various preserved siliceous sponges, both Hexactinellida and Demospongiae, have been recovered from the Takatika Grit (Campanian-Danian), Chatham Islands, New Zealand. Hexactinellid sponges are represented by the Euretidae *Eoretichone australis* n.gen. and sp., *Pararete* sp., and Euretid gen. and sp. indet., *Auloplax?* sp. (Dactylocalycidae) and *Tretodictyiid* gen. and sp. indet., as well as by loose hexactines and fragments of dictyonal skeletons. Demosponges are represented only by loose spicules typical of Astrophorida, and perhaps lithistids. These fossils represent the first account of sponges of this age from the New Zealand region of the southwest Pacific. [original abstract]</ABSTRACT>

52710 <TITLE>The Cenozoic hermatypic corals in the eastern Pacific: History of research.</TITLE>
52711 <SOURCE>Earth-Science Reviews 72, 1-2: 67-87.</SOURCE>
52712 <ABSTRACT>Studies of hermatypic corals in the eastern Pacific have mainly focused on Recent species, and relatively few of these works have studied fossil corals. The purpose of the present contribution is to provide a comprehensive synthesis on Cenozoic hermatypic coral studies that will serve: a) to identify gaps in our understanding about the Cenozoic evolution of eastern Pacific hermatypic fauna, and b) to be used as a baseline for future work in the region. Our knowledge regarding the eastern Pacific fossil coral fauna has increased gradually since 1864. A total of 151 coral species including synonyms have been recorded in the region. The species richness increases from Paleocene to Oligocene followed by a loss of species towards the Pleistocene, though to some extent biodiversity estimates are affected

by sampling intensity. Fossil bearing units are spatially restricted to Washington-Seattle, south and central California, Gulf of California and Chiapas, and there is a lack of outcrops in western Mexico and Central America. In general, fossil coral studies have been sporadic, incidental in nature, and restricted to species descriptions, faunal lists and geographic affinities. The relative lack and nature of the hermatypic fossil studies in the region have directly affected our understanding about the origin of the modern eastern Pacific coral fauna and its evolutionary history. Studies regarding to taxonomy and systematics, and detailed spatio-temporal community dynamics, are essential for understanding the evolution of the fauna. </ABSTRACT>

52736 <TITLE>Radial calcite in Lower Miocene strata, subsurface Enewetak Atoll.</TITLE>

52737 <SOURCE>Journal of Sedimentary Petrology 56, 6: 743-762.</SOURCE>

52738 <ABSTRACT>Petrographic and stable isotopic data are consistent with precipitation of radial calcite in its present form directly from seawater. Precipitation of radial calcite after aragonite dissolution indicates precipitation distinctly after deposition, probably in a burial environment. Dissolution of aragonite by deep marine water is suggested by: 1) abundant marine cement associated with aragonite dissolution; 2) a lack of meteoric cements associated with aragonite dissolution; and 3) no evidence of subaerial exposure in Lower Miocene strata between 400 and 819 m. Modern Pacific Ocean water is undersaturated with respect to aragonite at depths where aragonite dissolution is observed (375-850 m). Tidal fluctuations and temperature profiles indicate that Lower Miocene strata containing radial cementation are interpreted as having occurred in seawater (undersaturated with respect to aragonite) circulating through the atoll. Variations in magnesium concentration in Enewetak radial calcite may be the result of original heterogeneity or differential loss of magnesium during later diagenesis in seawater. The first alternative is preferred. Precipitation of radial calcite at different rates (at different degrees of saturation) could cause variable magnesium concentrations. More deeply buried radial calcite

may have precipitated more slowly in deeper, less supersaturated water, resulting in lower magnesium concentrations. Likewise, slower rates of precipitation may have resulted in organic infestations and lower magnesium concentrations in inclusions-rich bands. Enewetak radiaxial calcites suggest that two factors might be critical to development of radiaxial fabric: 1) precipitation at fluctuating rates, and 2) formation in waters undersaturated with respect to aragonite. [SECOND PART OF EXTENSIVE SUMMARY] </ABSTRACT>

52777 <ABSTRACT>Like many coral specialists [8230;] J.E.N. Veron thought Australia's Great Barrier Reef was impervious to climate change. 34; Owned by a prosperous country and accorded the protection it deserves, it would surely not go the way of the Amazon rain forest or the parklands of Africa, but would endure forever. That is what I thought once, but I think it no longer. 34; This book is Veron's 39; silent spring for the world's 039; coral reefs. * Veron presents the geological history of the reef, the biology of coral reef ecosystems, and a primer on what we know about climate change. He concludes that

the Great Barrier Reef and, indeed, most coral reefs will be dead from mass bleaching and irreversible acidification within the coming century unless greenhouse gas emissions are curbed. If we don't have the political will to confront the plight of the world's reefs, he argues, current processes already in motion will become unstoppable, bringing on a mass extinction the world has not seen for 65 million years.

52815 <SOURCE>Cahiers ORSTOM, sér. Géologie 5, 1: 3-24.</SOURCE>
52816 <ABSTRACT>Les mouvements verticaux mio-plio-quaternaires de la région Nouvelle Calédonie-Loyauté sont analysés du point de vue de leurs amplitudes et de leurs vitesses. Les phénomènes à l'origine de ces mouvements sont répertoriés et des modèles proposés. Un bombement de la

lithosphère de la plaque australienne avant son plongeaiement sous la plaque océanique Pacifique, au niveau de la fosse des Nouvelles Hébrides, semble être responsable de la surrection au Quaternaire des atolls coralliens surélevés formant les îles Loyauté. Il y a concordance entre les faits géologiques et géomorphologiques observés sur le terrain et les mouvements verticaux calculés en fonction du déplacement de la plaque australienne sur le bombement théorique établi à partir des paramètres connus de la lithosphère de la région. La présence probable d'un bombement de lithosphère avant son plongement est un trait structural qui semble devoir être rencontré avant toutes les zones de subduction.

52840 <TITLE>Impact of two sequential Pacific hurricanes on sub-rubble cryptic corals: the possible role of cryptic organisms in maintenance of coral reef communities.</TITLE>
52841 <SOURCE>Journal of Paleontology 61, 4: 663-675.</SOURCE>
52842 <ABSTRACT>The hermatypic scleractinian cryptic coral biota living under mobile rubble in the reef flat and back reef zones of a Fijian fringing reef was surveyed in detail in August of 1984; only 138 days later the reef was struck by the first of two sequential hurricanes (57 days apart). The sample areas were re-studied in August 1985, thereby providing the first detailed census of pre- and post-hurricane cryptic reef coral populations, and allowing an assessment of hurricane impact on these populations. The 61 cryptic species (60 corals and Millepora) show 88 percent commonality with the intertidal and shallow subtidal reef surface coral population (68 species), and therefore are a good representation of the surface biota. A major effect of the hurricanes was a reduction of almost 50 percent in the number of boulders sheltering cryptic coral. However, among boulders that retained coral through the storms, there was only a five percent reduction in the mean number of corals per boulder, signifying that damage to the surviving population was minor. The composition of the surviving cryptic coral population is essentially unchanged from its pre-hurricane state (there are differences in absolute abundances), and the relative importance of the species does not show marked change in most cases. Coral morphologies show little change in their absolute and relative percent abundances after the hurricanes. In contrast to what is normally seen in reef surface habitats, therefore, coral colony form did not appear to be an important determinant in survivability for those living under

boulders; primary selection by the storms seems to have been on boulder form rather than cryptic coral form. Cryptic sub-rubble populations may function as a preserve for elements of the pre-hurricane reef surface community. For example, delicately-branching forms that are commonly devastated in reef surface habitats during hurricanes may, in some cases, be preserved in great numbers under boulders or in other cryptic habitats. This provides a recruitment pool that can greatly accelerate their recovery and re-establishment on the post-hurricane reef surface, and dampen the potentially severe community dislocations arising from intense competition for space in instantaneous new reef substrate.

52853 <TITLE>Paleoecologic implications of modern coral and bryozoan communities from southern Leyte, Philippines.</TITLE>

52854 <SOURCE>Mitteilungen des Geologisch-Palaeontologischen Institutes der Universitaet Hamburg 71: 405-431.</SOURCE>

52855 <ABSTRACT>As part of a broader study encompassing the paleologic significance of Recent Bryozoa in different Philippine ecosystems, we have observed an association of corals and bryozoans in Southern Leyte in the central part of the archipelago. This association is non-reefal since strong currents combined with migrating sand waves form an abrasive environment. Moreover, typhoons are frequently encountered in the study area. Since framebuilding is widely suppressed, the hermatypic coral association shows a lowered diversity and is dominated by pioneering, high energy resistant species. However, the bryozoans exhibit high diversity with a dominance of spot form zoaria and sheets formed by species which have a low competitive ability. The abrasion results in the total lack of zoaria of the runner-type. Encrusting bryozoan species turned out to react most sensitive to certain abiotic parameters which affect the biological interactions. They apparently can be better utilized in paleologic studies than erect species. The species *Parasmittina soulesi* (Bryozoa, Ascophora) is newly described.

52866 <TITLE>Stoichiometric modeling of carbon diagenesis within a coral reef framework.</TITLE>

52867 <SOURCE>Geochimica et Cosmochimica Acta 54: 2439-2449.</SOURCE>

52868 <ABSTRACT>Water sampled from the interior framework of Checker Reef, Oahu, Hawaii, indicates that the aerobic and anaerobic oxidation of organic matter dominates diagenesis within the reef framework. Reef interstitial water chemistry shows clear deviations from surface seawater: oxygen is depleted while dissolved inorganic carbon, H₂, inorganic nutrients, sulfide, and methane concentrations are elevated. Dissolved calcium is also elevated in most interstitial waters, indicating net dissolution of calcium carbonates. A mass-balance model

- used to determine the extent to which major biogeochemical reactions occur reveals that sulfate reduction is the predominant anaerobic process.</ABSTRACT>

53114 <SOURCE>Lithology and Mineral Resources 39, 2: 135-144.</SOURCE>
53115 <ABSTRACT>Duration of the functioning of elements of the lateral paragenetic reef-evaporite systems in Cambrian and Late Jurassic has been calculated. Discrepancy between total durations of the vertical growth of barrier reefs and evaporite formation varies by a factor of 3-50. Neither barrier reefs were growing up nor salt was deposited in halogenic basins for enormous time spans. Specific features of the reef-evaporite system should be taken into account in the estimation of ore potential (in particular, presence of sulfides of Pb, Zn, and other metals) in barrier-reef massifs. 53152 <TITLE>Biomineralization of calcified skeletons in three Pacific coralline demosponges - an approach to the evolution of basal skeletons.</TITLE>
53153 <SOURCE>Courier Forschungsinstitut Senckenberg 201: 371-383.</SOURCE>
53154 <ABSTRACT>Biomineralization of calcareous basal skeletons in coralline sponges is a strongly phylogenetically convergent character. However, the basic mineralization process is ancestral and exhibits similarities with mineralization processes seen in bacterial biofilms and organomineralization via controlled taphonomy. The main biocalcification events in the phylogenetically distinct taxa Vaceletia sp., Astrosclera willeyana, and Spirastrella (Acanthochaetetes) wellsi are discussed. Vaceletia, a demosponge with a thalamid basal skeleton, exhibits the most ancestral way to build a calcareous skeleton via controlled taphonomy. Archaeocyathids exhibit the same skeleton-forming mode as seen in Vaceletia. The stromatoporoid Astrosclera willeyana

forms intracellularly egg-shaped aragonitic aster in a first step which grow together via an epitactical process. This mode of calcification is realized in many late Permian and Triassic coralline sponges with different phylogenetic origins. The chaetetid *S. (Acanthochaetetes) wellsi*, phylogenetically the most evolved coralline sponge taxon, forms its unique calcitic skeleton in extracellular acidic organic mucilages in the presence of collagen, In all cases the mineralization is controlled by acidic matrix proteins.</ABSTRACT>

53165 <TITLE>Basal skeletal formation, role and preservation of intracrystalline organic matrices, and isotopic record in the coralline sponge *Astrosclera willeyana* Lister 1900.</TITLE>

53166 <SOURCE>Boletín de la Real Sociedad Española de Historia Natural, Sección Geológica 91, 1/4: 355-374.</SOURCE>

53167 <ABSTRACT>A specimen of the coralline demosponge *Astrosclera willeyana* Lister with a ¹⁴C-age of approximately 400 years was collected in a small cave at Ribbon Reef No. 10 in the Northern Great Barrier Reef. Composition and transformations of organic matrices, intimately linked to the Sr-aragonitic biominerals of the calcified skeleton, were examined by biochemical analyses. The matrices participate in the biomineralization process as long as the spherulites are growing and even during extracellular growth stages. Chromatographic analyses and biochemical characterization (molecular weight, amino acid, and monosaccharide composition) of the organic matrix from different growth layers of the skeleton show a stable composition of the insoluble organic matrix (IOM), but changing composition of the soluble organic matrix (SOM). The SOM in young skeletal parts exhibits high concentrations of aspartic and glutamic acid, which strongly decrease in the older parts of the skeleton. 53295 <TITLE>Association of a tube inhabiting Tanaidacean, Bifida scleractinicola gen. nov., sp.nov., with bathyal scleractinians off New Caledonia (Crustacea Tanaidacea - Cnidaria Scleractinia).</TITLE>
53296 <SOURCE>Mesogee 48: 189-199.</SOURCE>
53297 <ABSTRACT>Four species of solitary scleractinian corals were found to be the hosts of one species of tube inhabiting tanaidacean off southeastern New Caledonia (3 stations, depth 570-860 m). The tube is attached to the outer side of the coral skeleton, its distal end being near the calicular edge or bending over the edge into the calice. This position suggests that the tanaidacean needs to keep close to the polyp tissues for feeding. It also suggests immunity to the defense reactions of the cnidarian host. The coral surface beneath the tube is altered: superficially eroded or forming a very shallow groove, and of a chalky white aspect that contrasts with the normally lustrous and shiny surface. The erosion caused by the tanaidacean is thought to be chemical. The new tanaidacean - scleractinian association closely resembles that between the tubicolous polychaete Lumbrineris flabellicola and various scleractinian species. * The tanaidacean Bifida scleractinioides gen.nov., sp.nov., is placed in the family Anathruridae, subfamily Leptognathiinae, based on peraeopodal structure and armament. Within the subfamily Bifida gen.nov. is characterized by at least four cleft (bifid) terminal spines on the MX 1. Peraeopodal setation indicates a probable closer relationship to Pseudoparatanais.</ABSTRACT>

53375 <ABSTRACT>Etude de la répartition des Scléactiniaires dans les différentes zones récifales. Sur la pente externe du récif barrière, les coraux sont peu abondants et disparaissent complètement entre 30 et 40 mètres. La faune du lagon est beaucoup plus riche. Comparaisons avec les autres îles récifales des Tuamotu. * Les Scléactiniaires jouent un rôle essentiel dans le peuplement des récifs et du lagon quoique sur la pente extérieure du récif barrière, on observe un faible recouvrement du substratum par ces organismes. Dans cette publication, est donné un aperçu sur leur répartition dans les différentes zones récifales: récif barrière, récifs frangeants, pinacles et fond du lagon. L'étude systématique des espèces sera présentée dans un Mémoire sur les Scléactiniaires de Polynésie Française.</ABSTRACT>

53413 <SOURCE>Coral Reefs 03, 2: 87-90.</SOURCE>
53414 <ABSTRACT>Growth rhythms in the reef coral *Porites lobata* are revealed by X-radiography and stable carbon and oxygen isotopic analysis. High density increments were deposited during warm temperatures in summer and low density increments during winter. The seasonal temperature variations are reflected in the oxygen isotope ratios. The coral carbonate shows a constant depletion in ^{18}O of -2.7% relative to calcite in equilibrium with the ambient seawater. The mean annual growth rate of the specimen studied was 1.3 ± 0.3 cm/year. [original abstract]</ABSTRACT>

- 53478 <SOURCE>Postilla 167: 21 pp., 15 figs; Peabody Museum, Yale University.</SOURCE>
- 53479 <ABSTRACT>A new sclerosponge, Acanthochaetetes wellsi, with a calcitic skeleton made up of contiguous vertical tabulate calicles ornamented within by vertical rows of irregular clumps of spines is described from cryptic habitats on reefs in Western Pacific region. A lamellar microstructure characterizes the calicle walls and spines. Increase in number of calicles occurs as intramural offsets. An epitheca with growth lines surrounds the entire sponge. * Living tissue is restricted to the space above the outermost tabulae and a thin layer lying above the calcareous skeleton. Siliceous spicules of two kinds, tylostyles and modified spirasters, are distributed in the living tissue but are not incorporated into the calcitic skeleton. Star shaped groups of exhalant canals converge upon central oscules on the sponge surface and leave astrorhizal patterns impressed into the calcareous skeleton below. * A new order, the Tabulospongida, of the class Sclerospongiae is proposed to receive the new Pacific species together with its Jurassic and Cretaceous forebears. Despite suggestive similarities between acanthochaetetids and favositids, a phylogenetic relationship between these two groups is considered unlikely on the basis of present evidence. * Sampling site: reefs of Rongerik Atoll, Guam.</ABSTRACT>

53505 <ABSTRACT>Three new types of a Recent colonial sphinctozoan coralline sponge are presented. All types show close relationships to Vaceletia crypta, a non colonial form from Indo-Pacific reef caves. The first two types were discovered in shallow water reef caves of the Osprey Reef, which is located on the northern Queensland Plateau in the Coral Sea. The sponges are common in these caves. The third type of a colonial sphinctozoan was found only at three localities at the North Astrolabe Reef and Great Astrolabe Reef of the Fiji Islands. The third type shows similarities with a previously described deep water variation of Vaceletia from New Caledonia.</ABSTRACT>

53517 <SOURCE>Bulletin de la Societe geologique de France 166, 1: 77-84.</SOURCE>
53518 <ABSTRACT>On the northwestern part of Moorea Island, calcification rates for 8 benthic species (Halimeda opuntia var hederacea, H. opuntia var. opuntia, H. incrassata f. ovata, H. discoidea, Amphiroa fragilissima, Porolithon onkodes, Hydrolithon reinboldii and Padina tennisi) were estimated using the total alkalinity method during 24 hours cycles, spread in the course of a year. The daily calcification rate vary largely within the taxa. Halimeda play a major role in the carbonate budget and particularly in the sediment deposition. The hourly rates vary over a 24-hours-cycle with a decrease during the night period. Moreover, the calcification measurements spread in the

course of the year exhibit a strong seasonally in the carbonate production. Lastly, the annual inorganic carbon budget shown that these species play an essential role in the balance of the reef calcification rates.

53555 <TITLE>Automicrites in a modern marine microbialite. Formation model via organic matrices (Lizard Island, Great Barrier Reef, Australia).</TITLE>
53556 <SOURCE>Bulletin de l'Institut océanographique, Monaco, special volume 14, 2: 237-263.</SOURCE>
53557 <ABSTRACT>within shallow water caves of fringing reefs of Lizard Island (Great Barrier Reef) indurated microbialites were observed. These microbialites are formed under dark conditions and therefore no phototrophic organisms are present. The microbialites are composed of microcrystalline high-Mg calcites (12-15 mol% MgCO₃). They exhibit mean values of δ13C +3.5 and δ18O - 1 which are close to seawater equilibrium. Two main types of microbialites are observed, a thrombolitic one with relatively high net growth and a hardground type with reduced growth rates. They are associated with a filterfeeding sessile benthic community which is dominated by coralline sponges. The high-Mg calcitic micrite is mainly formed in place (automicrite = organominerals). The accumulation of fine-grained biodebris provides

only 15% of the total rock volume. Following types of automicrites are recognized: a. mineralized microbes, b. spherical peloids, c. micrite formed in microcavities, d. micrite formed within thrombolitic structures, e. micrite formed within hardgrounds, and f. micrite (micropeloidal) formed by decaying tissues (via ammonification). All studied automicrites exhibit high amounts of Asp- and Glurich macromolecules (soluble matrices) which are regarded as responsible for crystal nucleation. The observed modern automicrites and the related products are a key to understand the formation of widely distributed fossil microbial buildups ("mud mounds").</ABSTRACT>

53568 <TITLE>Modern cryptic microbialite / metazoan facies of the Lizard Island Section (Great Barrier Reef; Australia). Formation and concepts.</TITLE>

53569 <SOURCE>Facies 29: pp?</SOURCE>

53570 <ABSTRACT>From shallow water caves of fringing reefs related to continental islands of the Lizard Island Section thrombolitic micritic microbialites were observed. The microbialites exhibit always a light decreasing facies succession. The succession starts with a corallgal community and ends with light independent microbial biofilms and benthos (coralline sponges etc.). The sessile mineralized benthos community is constructed of crustose foraminifera, serpulids, thecidean brachiopods, bryozoans, and coralline sponges. The observed benthic community is very similar to those one observed in cryptic habitats of Aptian and Albian reefs of northern Spain. For longtime studies of the microbialite formation and growth rates of coralline sponges the specimens were stained in vivo, within their natural habitat with histochemical fluorochromes and nonfluorescent agents. Main results are a very slow growth of the microbialite and associated sponges (50-100µm/y). Only few calcifying microbes are participators during microbialite formation. Calcifying acidic organic macromolecules are mainly responsible for microbialite formation by cementing detrital material. Fe/Mn-bacterial biofilms are responsible for strong corrosion of the microbialite. Beside the corrosive activity of the Fe/Mn-bacterial biofilms boring sponges (Aka, Cliona) are the main destructors. Geochemically the observed microbialites are composed of mainly high-Mg calcites and exhibit high positive δ13C (+3 to +4) values.</ABSTRACT>

- 53595 <SOURCE>Journal of Paleontology 58, 3: 636-650.</SOURCE>
- 53596 <ABSTRACT>Several sclerosponge and related species occur sparingly within modern reefs of Enewetak (formerly Eniwetok) Atoll in the central Pacific Ocean. Ranging over 4-35m depths, the sclerosponges occupy both the outer reef wall and lagoonal coral knolls at Enewetak. The species encountered are described as seen in standard paleontologic preparations; these forms can thus be readily compared with various important fossil groups. The sclerosponge Acanthochaetetes wellsi is of finely tubular construction, the sclerosponge Astrosclera willeyana is densely labyrinthine, the celetia crypta consists of successively stacked hemispherical shells. - 53608 <SOURCE>Geoscience Canada 28, 2: 71-78.</SOURCE>
- 53609 <ABSTRACT>Globally unique hexactinellid (siliceous) sponge reefs, found in deep (200m), glacially scoured troughs of the western Canadian continental shelf, have been explored by a manned submersible. Submersible observation and geophysical data allow examination of the physical and biological processes that have shaped the sponge reefs, which began to form about 9 thousand years (k.y.) ago. The mounds (bioherms) and sheet-like accumulations (biostromes) cover a low-angle, non-depositional, iceberg-scoured seafloor, relict since the deglaciation of the region. Biohermal structures are up to 19 m in height, and are covered with hexactinosan sponges up to 1.5 m tall, creating a benthic habitat that discontinuously covers roughly 700 km². Similar to extinct siliceous sponge reefs, mud mounds, and reef mounds that were widespread during the Mesozoic, the modern reefs are like a "living fossil" and provide a unique modern analogue. Fishing activities, especially trawling or bottom dragging, have damaged the slow-growing reefs in some areas.</ABSTRACT>

53620 <TITLE>Discovery of a "Living Dinosaur": Globally Unique Modern Hexactinellid Sponge Reefs off British Columbia, Canada.</TITLE>
53621 <SOURCE>Facies 44, 1: 265-282.</SOURCE>
53622 <ABSTRACT>Globally unique hexactinellid sponge reefs occur on the continental shelf off British Columbia, Canada. They cover about 425 km² of seafloor on the continental shelf off British Columbia (Canada) in water depths between 165 and 240 metres and occur on a low-angle deep shelf, iceberg scoured seafloor, characterized by very low sedimentation rates and very stable environmental conditions. The sponge bioherms are up to 19 metres high with steep flanks, whereas the biostromes are 2-10 metres thick and many kilometres wide. They all consist of dense populations of only seven hexactinellid species. Three of them, all hexactinosan species (*Aphrocallistes vastus*, *Heterochone calyx*, *Farrea occa*) are the main frambuilders, composing a true rigid framework of sponge skeletons encased in a organic rich matrix of modern clay baffled by the sponges. Growth rates of hexactinosan sponges range in the order of 0-7 centimetres per year. The base of the oldest sponge reefs date from approximately 9000 years b.p. Different invertebrate and fish faunas occupy the reefs than occur on adjacent seafloor areas and some species appear to use the sponge reef complex structures as refugia where they can hide. Sidescan sonar data and direct observation by manned submersible clearly show that large areas of sponge reefs have been heavily damaged by seafloor trawling in the past decade. These unique extant siliceous sponge reefs can be used as a modern analogue for a better understanding and interpretation of fossil siliceous sponge reefs, known from many ages and many locations world wide.</ABSTRACT>

53633 <TITLE>*Cymbastela hooperi* sp.nov. (Halichondrida: Axinellidae) from the Great Barrier Reef, Australia.</TITLE>
53634 <SOURCE>Bulletin de l'Institut royal des sciences naturelles de Belgique, Biologie 66, suppl. 1996 [Willenz P. (ed.): Recent advances in sponge biodiversity inventory and documentation]: 103-108.</SOURCE>
53635 <ABSTRACT>*Cymbastela hooperi* sp.nov. is described from the Great Barrier Reef, Australia. This species belongs to the recently erected genus of stalked sponges, *Cymbastela Hooper* & Bergquist, 1992. The new species is the eighth member of this Australasian genus. *Cymbastela hooperi* sp.nov. is distinguished from other *Cymbastela* species, by its unique growth form (stalkless and flattened on substrate), its yellow to brown colour, its loose skeletal morphology, the often telescope spicule shape and its chemistry. The new species produces a large number of structurally related diterpene isonitrile derivatives which demonstrate significant in vitro antimalarial activity. One of these compounds, di-isocyano-adociane, is also found in *Amphimedon terpenensis* Fromont, 1993. In addition both species present similar skeletal characters and spicule size. Considering this, a new combination is proposed: *Cymbastela terpenensis* (from *Amphimedon*). [original abstract]</ABSTRACT>

53673 <SOURCE>Bolletino Mus. Inst. Biol. Univ. Genova 48-49 (1980-1): 87-141.</SOURCE>
53674 <ABSTRACT>[Thirty-six species are described, mostly with illustrations of specimens and spicules. Twenty-seven of these are new, and nine are little known. The following genera are represented (those marked * contain new species: Leucetta, Sycon, Cinachyra*, Cliona, Didiscus (unnamed), Acanthella*, Auletta*, Phakellia*, Batzella*, Dictyonella*, Arenochalina, Mycale*, Neofibularia, Kerasemna* gen. n., Echinoclathria*, Cladocroce*, Gellius* (possibly a Microxina), Gelliodes*, Amphimedon*, Callyspongia*, Siphonochalina*, Arenosclera* gen. n., Xesto-spongia*, Carteriospongia*, Ircinia*, Euryspongia*, Dendrilla, Pseudoceratina*. * The material was collected and made available to the author by staff of the Heron Island Research Station. Unfortunately, no proviso was apparently made for depositing the type material in a museum in Australia, as is customary with other groups of the Australian fauna. All type material is now deposited in the Museum of Natural History of Genoa, Italy, with register numbers given in the publication. It is hoped that such a regrettable mistake will not be

- repeated.]</ABSTRACT>

53776 <TITLE>Origin of atoll dolomites distinguished by geochemistry and
crystal chemistry: Kita-daito-jima, northern Philippine Sea.</TITLE>
53777 <SOURCE>Sedimentary Geology 183, 3-4: 181-202.</SOURCE>
53778 <ABSTRACT>Kita-daito-jima is a carbonate island located at the
northwestern region of the Philippine Sea (25°55.6'N, 131°16.9'-19.8'E). Dolomites extend from the island surface to a depth
of 100m below the ground surface (mbgs). Strontium isotope stratigraphy
indicates that subsurface units C1 (0-49.7 mbgs) and C2 (49.7-103.4

mbgs) were dolomitized at 5.5 Ma and 2.0 Ma, respectively, and that island-surface dolomites are products of dolomitization at 1.6-2.0 Ma. X-ray diffraction analysis indicates that the island-surface and borehole dolomites comprise variable mixtures of four and three dolomite crystal phases, respectively. Each of these phases is distinguished by a different Ca and Mg content. Three textural types can be recognized in the Kita-daito-jima dolomites, fabric-preserving crystalline nonmimetic (CNM), crystalline mimetic (CM), and fabric-preserving microsucrosic (MS). CNM dolomites contain more calcian phases, whereas MS dolomites commonly are richer in more stoichiometric phases. Backscattered electron images indicate that calcian dolomite phases were precipitated earlier than the more stoichiometric dolomite phases and that there is no significant hiatus between the phases, although they are diachronous. Both the island surface and borehole cores dolomites show linear relationships between whole-rock $\delta^{18}\text{O}$ composition and Mg contents and between whole-rock trace element concentrations (Sr and Na) and Mg contents. These covariances result from phase mixing, not stoichiometric effects. Deconvolution of whole-rock isotopic and elemental compositions based on the relative abundance of phases reveals that each phase has a distinct chemical and isotopic composition. Oxygen isotopic compositions of the island surface and borehole dolomites suggest that all dolomite phases formed in seawater and that dolomitization primarily occurred during glacio-eustatic sea-level lowstands and cooler ocean temperatures.

53854 <TITLE>The Cyclone winifred Storm Bed, Central Great Barrier Reef Shelf, Australia.</TITLE>
53855 <SOURCE>Journal of sedimentary Petrology 58, 5: 845-856.</SOURCE>
53856 <ABSTRACT>Shelf sediments were collected immediately before (8-20 January 1986), immediately after (9-10 February 1986) and one year after (27 February 1987) cyclone Winifred crossed the central Great Barrier Reef shelf on 1 February 1986. The storm produced a normally graded, mixed terrigenous-carbonate storm bed more than 11 cm thick, covering an area at least 1,200 km², and extending more than 30 km offshore to water depths greater than 40 m. The storm layer encompasses two lithologically distinct shelf-parallel facies belts. The nearshore (0-25 m depth) storm bed is 3-11 cm thick, thins offshore, and grades upward from medium sand to silty clay. Offshore (25-43 m depth) the storm bed thickens to more than 11 cm and consists of normally graded, well sorted, relict quartz and skeletal, gravelly sands capped by thin mud veneer. The cross-shelf distributions of grain size, mineralogy, carbonate content, and carbon isotope ratios were very similar before and after Winifred, suggesting the storm bed did not result from offshore-directed storm currents, rather, in situ resuspension and settling of the shelf sand with shoreward transport of mud. In contrast

to storm sedimentation models which predict thinning and fining offshore, winifred created a layer that becomes thicker and coarser grained in deeper water in response to cross-shelf substrate changes. After one year the winifred storm layer was well preserved nearshore (<20 m water depth), but completely bioturbated offshore (>30 m water depth) below fairweather wave base. Preservation may not be a matter of insulating the layer from physical reworking below fairweather wave base but of burying it where rates of sediment accumulation outpace bioturbation. The effects of storms similar in size to winifred may be well concealed in ancient shelf sequences subject to rapid biological remixing of storm layers.</ABSTRACT>

53881 <SOURCE>Journal of sedimentary Petrology 59, 6: 1036-1051.</SOURCE>
53882 <ABSTRACT>Sediments in the 5-25 m deep lagoon of Davies Reefs, a typical mid-shelf reef in the Central Great Barrier Reef, are described, based on data gleaned from 19 soft sediment cores (75 mm diameter, up to 7.5 m penetration), 22 surface sediment samples and air lift surveys. The Holocene sediment pile, which averages 5-10 m thickness, is entirely skeletal in origin and has a very poorly sorted, coral gravel-rich base which grades up into poorly sorted muddy sands with infaunal molluscan gravel. These muddy sands (mainly derived from the reef rim as opposed to being produced in situ on the lagoon floor) have been intensely bioturbated by callianassid shrimps, leaving the infaunal molluscan gravel patently distributed and the bivalves disarticulated and preferentially oriented subhorizontally, concave-up. There are no vestiges of primary depositional sedimentary structures such as bedding or cross-bedding. Radiocarbon dating suggests that significant accumulation of muddy-sand in the center of the lagoon did not begin until about 2,500-3,000 yr BP; and that sediment accumulation rates have increased through time from an average of 1.4 mm / yr between 2,400 and 640 yr BP, to 3.4 mm / yr over the past 640 years. Interpreting these data, the coral gravel-rich base to the sediment pile represents a period of prolific coral growth across the top of Davies Reef Platform following flooding by the Holocene transgression but before the outer reef rim caught up with sea level to form a lagoon. When the rim did reach sea-level (about 3,000-4,000 yr BR?), it started to shed large quantities of mud and sand grade sediment into

the center of the reef platform and this, combined with decreased water circulation, led to the demise of coral growth in the newly formed lagoon. As the area of reef rim at sea level increased, so too did the supply of sediment to the lagoon, which explains the observed increase in sediment accumulation rate through time. Using previously published data to aid speculation into the future development of the lagoon, a shallowing-upwards model for reef lagoon sedimentation is developed. In this model, a complete sequence consists of a fining-upwards base (reflecting the gradation from coral gravel up into bioturbated muddy sands) and a coarsening-upwards top (reflecting a gradation from bioturbated muddy sands up into a zone of shallow subtidal coral rubble and patch reefs, then inter- and supratidal windward storm shingle ramparts and leeward sand cays).</ABSTRACT>

53893 <TITLE>Low-cost artificial reef program in the Philippines: an evaluation in the management of a tropical coastal ecosystem.</TITLE>

53894 <SOURCE>Beiträge zur Paläontologie 20: 1-6.</SOURCE>

53895 <ABSTRACT>This paper evaluates a 15-year program on low-cost artificial reefs (LCAR) in the Philippines resulting in an eco-economic analysis of reefs. The most common and popular materials used in the construction of artificial reefs are discarded tires and bamboos. Concrete cement is rarely used due to the high cost of its materials. Available data reveals that there is a low biological productivity in bamboo and tire artificial reefs with an average of 0.154kgm-3wk-1 and 0.010kgm-3wk-1, respectively, compared with the natural reefs having 0.256kgm-3wk-1. Likewise, findings show that fishermen earn a lower income of PHP 6.16kgm-3wk-1 from using bamboo reefs and PHP 0.40kgm-3wk-1 from tire reefs in comparison with the earnings from natural reefs which is PHP 10.24kgm-3wk-1. Preliminary researches on the ecology of artificial reefs (i.e., bamboo and tires) showed that the substrates of such reefs are not conducive to reef organism encrustation, and as rubber tires decay they produce toxic chemicals adding more problems to the ecosystem. Recommendations for the tropical coastal ecosystem management are presented.</ABSTRACT>

53906 <TITLE>Late Quaternary evolution of coral reefs on a cool-water carbonate margin; the Abrolhos Carbonate Platforms, southwest Australia.</TITLE>

53907 <SOURCE>Mar. Geol. 110: 203-212.</SOURCE>

53908 <ABSTRACT>Late Quaternary coral reefs have developed on the southwestern Australian margin, which has otherwise been characterized by cool-water carbonates since the Eocene. The Houtman Abrolhos coral reefs are at the limits of existence, extending, with the assistance of the Leeuwin Current, a poleward-flowing, warm water stream, into a

region dominated by more temperate communities. Coring in the Easter Group reefs, supported by high precision dating, by both U/Th TIMS and 14C methods, has shown vigorous coral growth, with reefs over 26m thick in the Holocene and over 15m thick in the Last Interglacial. Each of the three Abrolhos platforms consists of a central platform composed of Last Interglacial reefs, about which windward and leeward Holocene reefs developed asymmetrically. Reef, peritidal and eolian facies comprise the emergent Last Interglacial limestones which are extensively calcretized, with reef facies up to 5m above MSL. The Last Interglacial highstand lasted for at least 10ka from 130 to 120ka, and possibly 15ka, from 132 to 117ka. Holocene reef facies are also emergent by 0.5m, and are overlain by peritidal and storm ridge facies in an upward-shallowing sequence. Windward (10m thick) and leeward (26m thick) Holocene reefs in the Easter Group show contrasting lithofacies. The wave-exposed windward reefs consist of a slow-growing association of coralline algal bindstones and coral framestones, whereas fast-growing coral framestones dominate the more protected leeward reefs. The leeward reefs commenced growth 10,000 years ago and grew to the present sea level by 6500 years ago, generating Holocene constructional topography consisting of [blue-hole](#) terrain in the leeward parts of the platforms.

 53919 <TITLE>Geological reconstruction of Fangataufa atoll (South Pacific).</TITLE>
 53920 <SOURCE>Mar. Geol. 110: 377-391.</SOURCE>
 53921 <ABSTRACT>Several boreholes drilled by the Commissariat à l'Énergie Atomique have reached and passed through the volcanic bedrock of Fangataufa atoll. The sampled volcanic rocks under the coral ring were produced during both aerial and submarine activity, whereas rocks drilled under the lagoon were erupted during submarine volcanism only. The bathymetric data show that the atoll has a [starfish](#) shape. The rift zones are elongated in N-S, N70-80 and N120 directions; these three main directions are also the directions of structural discontinuities in the lithosphere. Reconstruction of the atoll's topography before erosion using a slope angle of about 16° shows that the maximum height reached by the volcano was about 1300m above sea level. For comparison, the maximum height of Mehetia island (southeast of Tahiti) is approximately 435m. The successive construction stages are: (1) initiation of volcanism along the rift zones and construction of a central volcano; (2) production of brecciated lavas; (3) emergent volcanism; and (4) central and aerial activity. The present day position of the aerial volcanic rocks under the coral reef and the submarine products under the lagoon is discussed with reference to two hypotheses. The first is based on sea level changes and the second on a tectonic origin (collapse of the atoll's flanks). Using recent geochronological data, the submarine construction of the atoll related to the hot-spot activity lasted about 1.1Ma. The accumulation rate was approximately 0.7 cm/yr (1.5 x 10⁻³km³/yr) and the aerial volcanic activity lasted about 2Ma (1.5 x 10⁻³km³/yr).</ABSTRACT>

53933 <SOURCE>Goettinger Arbeiten zur Geologie und Palaeontologie, Special Volume 2 [Reitner J., Neuwiller F. & Gunke l F. (eds): Global and Regional Controls on Biogenic Sedimentation I. Reef Evolution]: pp ???</SOURCE>
53934 <ABSTRACT>The post-glacial sealevel rose to ca. 3m above the present in the northern Great Barrier Reef ca. 6,000 yrs BP. It oscillated with at least one younger highstand ca. 3,500 yrs BP, and two intermittent lowstands. The present level was reached only a few hundred years ago. The younger sealevel highstand has left marine encrustations on the exposed granite of the Lizard Island Group, coral colonies on the shore platforms around Lizard Island, and shingle terraces and storm beaches on Nymph Island and in the Turtle Group of Low wooded Isles. This sealevel history is consistent with the one derived from Rottne st Island, western Australia. In contrast, the Caribbean experienced a single-phased sealevel rise without highstands above present datum. The marked contrast in overall structure and zonation between the Pacific and the Atlantic barrier reefs may be attributed to these different sealevel histories.</ABSTRACT>

53958 <TITLE>High energy coralg al-stromatolite frameworks from Holocene reefs (Tahiti, French Polynesia).</TITLE>
53959 <SOURCE>Sedimentology 41, 4: 655-676.</SOURCE>
53960 <ABSTRACT>Drill cores from Holocene reefs on Tahiti (French Polynesia) reveal a framework composed of massive branching acroporids encrusted by coralline algae associated with sessile vermetid gastropods and arborescent foraminifers. Laminated micritic crusts form coatings over coral branches or, more commonly, over related encrusting organisms throughout the cored reef sections; these crusts appear as a major structural and volumetric component of the reef framework. The microbial nature of these micritic crusts is inferred from their typical organic growth forms and geometry, the occurrence of microbial remains and stable isotope measurements. The reef communities accumulated at depths less than 5m below mean sea level in a high

energy environment throughout vertical growth from 7140 ± 170 yr BP to the present. The nature of the involved benthic communities, stable isotope data and high calcification rates of microbially encrusted corals strongly suggest that local environmental conditions have been optimal for reef development for the last 7000 years. The causes of the predominance of microbial communities over actual encrusters (red algae, foraminifers) remain problematic and could be related to short term fluctuations in ecological parameters. Microbial micritic crusts seemingly played a prominent role in protecting the coralgal colonies from bioeroders and grazers and, possibly, in strengthening the framework, due to rapid lithification. The record of similar microbial crusts in other Quaternary reef tracts suggests that microbial communities may have played a more prominent role in Quaternary reefs than presently recognized.</ABSTRACT>

53971 <TITLE>Bioerosion rates on coral reefs: interactions between macroborers, microborers and grazers (Moorea, French Polynesia).</TITLE>

53972 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 113: 189-198.</SOURCE>

53973 <ABSTRACT>A two-year experimental study of bioerosion at Moorea Island, French Polynesia, clearly demonstrated the importance of microborers in the initial stages of the establishment of infaunal boring communities. Rates of erosion by micro- and macroborers and by grazers were estimated from measurements of carbonate removal from experimental substrates, using Image Analysis. The studied substrates have been exposed for 2, 6, 12 and 24 months. After 2 months of exposure, the only borers present in the substrates were cyanobacteria and one chlorophyte (Phaeophila sp.) and their bioerosion rate was estimated at 0.6kg CaCO₃ m⁻² yr⁻¹. In the course of the 2 years of exposure, recruitment of macroborers occurred and their estimated rates of erosion increased during this period from 2.15 to 90g CaCO₃ m⁻² yr⁻¹. Carbonate removal by grazers was the dominant agent of erosion, responsible for 89% of the total bioerosion: 2.6kg CaCO₃ m⁻² yr⁻¹, as recorded in substrates exposed for 2 years. The measurable rates of bioerosion by microborers apparently decreased with the time of exposure from 0.6 to 0.2kg m⁻² yr⁻¹, but these values are underestimations which need to be corrected by including the intensity of microboring in substrate layers removed by grazing. Bioerosion is dependent on numerous environmental factors such as depth, light availability, and nutrient supply. A good knowledge of bioerosional processes in modern environments could highlight bioerosion significance in the fossil record.</ABSTRACT>

- 53984 <TITLE>La bioerosion dans le cycle des carbonates: essais de quantification des processus en Polynesie francaise.</TITLE>
- 53985 <SOURCE>Bulletin de la Societe geologique de France 166, 1: 85-94.</SOURCE>
- 53986 <ABSTRACT>The contribution to bioerosion of the major boring and grazing species on coral reefs was estimated on French Polynesia by three methods: (1) experimental models using dead coral samples exposed for 5 years. Bioerosion was mainly due to microboring organisms during the first two months, and to macroborers after 6 months of experiment. Grazing was the dominant process since one year and accounted for 66% of the total bioerosion which reached 2.6kg CaCO₃ m⁻²y⁻¹ after two years of exposure: (2) bioerosion rates of grazers. The quantity of carbonate eroded from the reef framework by echinids and scarid fishes was determined through the study of gut contents production. On Moorea barrier reef flat, bioerosion was estimated to 4.5kg CaCO₃ m⁻²y⁻¹ for echinids and to 1.7kg CaCO₃ m⁻²y⁻¹ for scarids; (3) influence of reef communities upon carbonate budget. On the reef studied calcification processes dominated over dissolution processes (2kg CaCO₃ m⁻²y⁻¹. In laboratory experiments, the living corals depleted the carbonate content of seawater (3.7g CaCO₃ m⁻²y⁻¹) which is in turn highly restored by the activity of boring organisms and grazers. These results demonstrated the great importance of bioeroders and grazers in determining the calcium carbonate budget of coral reefs.</ABSTRACT>

54193 <SOURCE>Cahiers ORSTOM, sér. Géologie 6, 1: 41-61.</SOURCE>
54194 <ABSTRACT>Les sédiments actuels de la Baie de Saint-Vincent sont le résultat d'une part de sables et vases détritiques siliceuses d'origine terrigène, d'autre part de sables parfois vaseux détritiques calcaires d'origine corallienne. La cartographie des faciès met en évidence leurs origines. Cette sédimentation est continue depuis la transgression Flandrienne mise en évidence dans les carottages par le contact argile lagunaire et vase marine. Des éléments chimiques tels NiO, Fe2O3 ou en traces comme le Bore, le Strontium, caractérisent certains faciès.</ABSTRACT>

54232 <SOURCE>[Bull.?] Acad. Roy. des Sci. d'Outre-Mer, Cl. Sci. nat. et méd., N.S. 19, 1: 102 pp., 37 figs, 12 tabl.</SOURCE>
54233 <ABSTRACT>Le présent travail constitue une étude descriptive et synthétique de l'écologie marine littorale dans l'Archipel des Galapagos. * Les facteurs du milieu dépendent de la géomorphologie et de la nature du substrat, cependant la plupart d'entre eux sont influencés par l'océan environnant. * Dans une première partie du travail, la géomorphologie de l'archipel, la météorologie et l'hydrologie sont décrites. Une étude saisonnière de l'hydrologie à Bahia Academia (Santa Cruz) est abordée. * Dans le domaine littoral, le faciès rocheux domine. Les substrats meubles sont peu nombreux, peu étendus et dispersés dans tout l'archipel. On trouve, également quelques biotopes particuliers: les coraux, les mangroves et les réseaux souterrains d'eaux saumâtres. Une description de la zonation intertidale en faciès rocheux est faite à Bahia Academia. Le schéma général de cette zonation est représentatif de l'ensemble des côtes rocheuses de l'archipel.</ABSTRACT>

54376 <ABSTRACT>Using the method of underwater transects the construction of relief, distribution of facies and principal hermatypes, and reef dwellers on the littoral of Pentecost, Paama and Lopevi Islands, New Hebridian archipelago is studied. * On the base of disconformities between underwater levels a conclusion is drawn about irregularity of oscillatory movement of earth crust blocks during Cenozoic in this area. The initial stages of colonization of fresh lava tongues by corals and calcareous algae were studied.</ABSTRACT>

54402 <ABSTRACT>La diagenèse ou les transformations subies par un sédiment carbonate de faible profondeur sont proportionnelles au temps écoulé depuis la formation de ce carbonate puis sont dépôt. Le problème majeur de la diagenèse est donc la datation non seulement du sédiment concerné, mais aussi des transformations qui l'ont affecté d' une part après sa formation, et d'autre part, après son dépôt. * Nous envisagerons donc quels sont ces problèmes de datations avec les méthodes directes et les méthodes indirectes à la lumière des dernières découvertes, tant du point de vue de tectonique globale que du point de vue des paléoniveaux marins et du paléoenvironnement. 54414 <SOURCE>Géologie et paléocéologie des récifs [J. Geister & R. Herb (eds)]: 29.1-29.12.</SOURCE>
54415 <ABSTRACT>L'océan Pacifique a été, à la fin du XIXème siècle et au début du XXème siècle l'enjeu de rivalités économiques très grandes et le champ clos de courses maritimes entre les puissances riveraines ou européennes. En effet, de petites îles, d'un diamètre de quelques kilomètres seulement, se révélèrent, en général à la suite de découvertes dues au hasard, être recouvertes de phosphates dont l'exploitation s'avérait chaque fois très facile, par suite de l'absence de terrains de couverture. * Les phosphates océaniques constituent une sorte d'exception dans les dépôts de phosphates mondiaux et cela pour plusieurs raisons. Ils sont d'abord opposés systématiquement aux autres dépôts phosphatés par suite de leur origine dite "de guano". Du point de vue gisement, d'après 3 gisements observés, le minerai de phosphate se trouve piégé dans un karst, souvent complexe et profond. Ce karst est en général creusé dans une roche dolomitique. Du point de vue particules, au contraire, ils apparaissent formés de particules sédimentaires identiques aux autres particules phosphatées visibles dans les autres gisements (par exemple tunisien, marocain), oolithes, pisolithes, pelotes focales et bioclastes phosphatisés. - 54557 <SOURCE>Géologie et paléocéologie des récifs [J. Geister & R. Herb (eds)]: 28.1-28.28.</SOURCE>
- 54558 <ABSTRACT>Les études océanographiques, menées depuis plus d'un siècle, ont montré que les sédiments marins carbonates actuels se répartissent schématiquement en deux groupes; les boues à globigérines recouvrent les plaines abyssales tandis que les plates-formes sous-marines ou les plateaux continentaux intertropicaux entre les isobathes 0 et 200m, voient l'élaboration et l'accumulation de sédiments, à granulométrie variable, des lutites aux rudites, mais dont la minéralogie est à dominante aragonitique. * D'autre part, les roches carbonatées sédimentaires anciennes, quelle que soit leur origine paléogéographique et paléobathymétrique, se présentent sous deux faciès minéralogiques apparemment monotones et constants, calcaires ou dolomies. On appelle donc diagenèse le passage, d'une part, du sédiment meuble à la roche consolidée, et, d'autre part, l'ensemble des phénomènes et des mécanismes physiques, chimiques, minéralogiques ou biologiques qui fait passer un sédiment meuble, aragonitique, dans le cas des faciès intertropicaux peu profonds, à une roche cohérente, massive, calcaire ou dolomitique. - 54584 <ABSTRACT>A total of 206 species of azooxanthellate Scleractinia are listed from Philippine-Indonesian region, 176 of which are reported as new records. The newly reported specimens originate primarily from the Musorstom 1-3 and Karubar expeditions, but also include specimens collected by the "Albatross", Danish Expedition to the Kei Islands, Snellius 2 Expedition, "Galathea", Mortensen's Java-South Africa Expedition, "Hakuho Maru", "Siboga", Corindon 2, and Estase 2 expeditions as well as some others. In all, approximately 15,600 specimens from some 640 stations are reported, the new records including the description of 26 new species and 3 new genera. Also, 4 new combinations and 1 new name are proposed (Caryophyllia crosnieri for C. elongata Cairns 1993, non Duncan 1873). [first fragment of extensive summary]</ABSTRACT>

54595 <TITLE>Associations of coral and boring bivalves: Lizard Island (Great Barrier Reef, Australia) versus Safaga (N Red Sea).</TITLE>
54596 <SOURCE>Beiträge zur Paläontologie 20: 31-39.</SOURCE>
54597 <ABSTRACT>Associations of coral and boring bivalves from Lizard Island (Great Barrier Reef, Australia) are reviewed and compared with those from Safaga, northern Red Sea. Although certain coral and Lithophaga species are present in both areas, the respective associations differ regionally distinctively in *L. laevigata* and *L. simplex*. Hosts for *L. laevigata* at Lizard include *Astreopora*, *Coscinaraea*, *Cyphastrea*, *Goniopora*, *Montipora*, *Porites*, and *Psammocora*, at Safaga, *Favia*, *Leptastrea*, *Porites*, and *P. (Synaraea)*, rarely *Cyphastrea* and *Montipora* in co-occurrence with *L. purpurea*. Hosts of *L. simplex*, at Lizard include *Acanthastrea*, *Astreopora*, *Echinopora*, *Favia*, *Goniastrea*, *Lobophyllia*, and *Symphyllia*, at Safaga *Astreopora*, *Goniastrea*, and *Pavona*. At Lizard, *L. lima*, found in single or few specimens per coral colony, occurs alone or together with *L. laevigata* (in *Porites*), or *L. simplex* (in *Acanthastrea*, *Astreopora*, and *Favia*). Most bivalve species have a variety of hosts, a few seem to be restricted to a single coral genus. Different genera of bivalves may be found in the same host specimen, e.g., *Pedum* and *Lithophaga* in *Montipora* (at Safaga, Red Sea) and *Porites* (at Lizard, GBR). At Lizard, *Pedum* was found only in *Porites*, including *P. (Synaraea)*, while it occupies at least 12 host genera in the northern Red Sea, particularly *Montipora*. In contrast to coral rock, where several different boring bivalves can occur next to each other, rarely more than one *Lithophaga* species is found per host colony, although it happens in both areas. On the other hand, the same coral species may be inhabited by one species of *Lithophaga* in one area and (mainly) by another in the other area. In *Lithophaga*, more associations are established at Lizard than at Safaga, while in *Pedum* it is the other way round. Altogether, more different associations can be noted than equal ones. Generally, coral-bivalve associations are regionally stable and do not overlap. Thus, host determination should yield the bivalve identity, too.</ABSTRACT>

54608 <TITLE>Modern Reef Development and Cenozoic Evolution of an Oceanic Island / Reef Complex: Isla de Providencia (Western Caribbean Sea, Columbia).</TITLE>
54609 <SOURCE>Facies 27: 1-70.</SOURCE>
54610 <ABSTRACT>Providencia Island in the SW Caribbean is 4,5 to 8,5km across (including Sta. Catalina Island). In contrast to nearby San Andres, which is an elevated Tertiary atoll, Providencia is formed by an extinct Miocene volcano. This lies far off the Middle American mainland, and therefore its geological history is somewhat unique among other western Caribbean islands. The submarine basement of Providencia

rises with steep to vertical slopes from an ocean of approximately 2,000m depth. This island itself is rugged with peaks reaching up to more than 360m above present sea-level. It is surrounded by a wide carbonate insular shelf protected towards the NE and SE by the second largest barrier reef (after that of Belize) of the Caribbean Sea. The entire reef complex forms a carbonate shelf, which consists of a 32km long windward bank-barrier reef with lagoonal environments in its lee, dotted with patch reefs and minor fringing reefs. [...] The contemporary shelf morphology is the product of a complex history of sea-level oscillations accompanied by terracing at different levels, renewed reef growth and erosion. Of this history, at present, only a few evolutionary stages may be recognized. Volcanic activity did not contribute to the geomorphologic evolution of the island and shelf in post-Miocene time. The shelf was last exposed to subaerial weathering during the sea-level lowering that accompanied the late Wisconsinian glaciation. It appears that since reflooding in the early Holocene some 5,000 years ago, renewed reef growth and sedimentation have only partly concealed or modified the pre-existing shelf topography. [first and last fragment of extensive summary] </ABSTRACT>

 54622 <SOURCE>Stuttgarter Beitr. Naturkunde B 15; 203 pp., 11 pls, 29 figs.</SOURCE>
 54623 <ABSTRACT>San Andres, a small high standing limestone, situated near the western margin of the Caribbean Sea is formed by uplifted reef rock of Tertiary (San Andres Formation) and Pleistocene age (San Luis Formation) as well as by Holocene terrestrial and beach deposits (Bay Formation). It is surrounded by a recent reef complex. * The recent reef complex consists of barrier, fringing and patch reefs. Most reefs show rich coral growth with a clearly discernible coral zonation. Off the west coast, the shelf is formed by two submarine terraces at 4 and 20m of depth. A detailed description of the whole reef complex is given and the process of reef development and erosion are analyzed. * The zonal distributions of benthic environments within the reef complex have been analyzed and interpreted leading to a more general scheme of zonation and classification of Recent Western Caribbean reef complexes. Three facies areas may be defined according to the type of substrate and the related bottom communities. [first part of extensive summary] </ABSTRACT>

54647 <TITLE>Zur Okologie und Wuchsform der Saeulenkoralle Dendrogyra cylindrus Ehrenberg - Beobachtungen in den Riffen der Insel San Andrea (Karibisches Meer, Kolumbien).</TITLE>
54648 <SOURCE>Mitt. Inst. Colombo-Aleman Invest. Cient. 6: 77-87; Santa Marta.</SOURCE>
54649 <ABSTRACT>Submarine observations around San Andres Island indicate that quiet backreef and leeward reef waters from 1 to 20m deep, are the most favorable habitat for the pillar coral Dendrogyra cylindrus. It thrives even at the submarine terraces along the calm west coast of the Island, where abrasive action by coral fragments is heavy during occasional storm surges. Besides a few minor incrusting and hemispherical species, Dendrogyra seems to be the only major scleractinian to resist abrasion and break-down without permanent damage in this environment. Dendrogyra initiates colony growth with a broad incrustation followed by upgrowth of pillars. Unstable basement may cause tumbling of the whole coral and subsequent pillar growth at approximately right angles to old columns. This process may be repeated, resulting in the formation of a third generation of pillars.</ABSTRACT>

54661 <SOURCE>FC&P 15, 1.2: 51</SOURCE>
54662 <ABSTRACT>The systematic descriptions of the corals are accompanied by excellent photographs that show the coral species both as skeletons and in their original habitat. The remarkably good reproduction quality of the coloured submarine pictures is especially noteworthy. Wherever possible, the authors add exact location maps and topographical as well as ecological profiles of the reefs described. The book has become an easily accessible introduction to reef ecology and coral systematics, an inventory and guide book to the Recent reefs of Colombia. Undoubtedly, it will form the basis for any future reef protection measures in Colombia. [final fragment of a review]</ABSTRACT>

54714 <ABSTRACT>The windward reef complex NE and E of San Andres Island is briefly described in terms of submarine topography, sediments and the distribution of corals and other benthonic organisms. The breaker zone of the San Andres barrier and other exposed western Caribbean reefs characteristically exhibits a profuse growth consisting almost exclusively of Millepora. In this respect they are different from most other described west Indian reef localities, where Acropora palmata is the dominating species in this part of the reef. The replacement of Acropora palmata by Millepora is interpreted as an adaptation of the reef crest community to high energy environments due to long swell prevailing at the western end of the Caribbean Sea. A few short reef sections exposed to the maximum degree of wave energy show conspicuous algal ridges.</ABSTRACT>

54765 <SOURCE>Mitt. Ges. Geol. Bergbaustud. Oesterr. 37: 97-118. [in German, with English summary]</SOURCE>
54766 <ABSTRACT>After the extinction near the Permian-Triassic boundary scleractinian corals first appear in Anisian reefs. They are the only new order in the Triassic reef associations. Until now 313 species belonging to 90 genera are known from the Triassic. During the Triassic the scleractinians show a continuous diversification, along there was an extinction of nearly 90% of the species near the Carnian-Norian boundary. The highest number of taxa occurs in the Norian. In the Rhaetian the number of taxa diminishes. Until the end of the Triassic all scleractinians became extinct. To examine morphological trends the Triassic scleractinian corals have been subdivided into three types of growth forms: solitary, dendroid and cerioid. From the Anisian to the Rhaetian the number of the solitary types diminishes, whereas the amount of the cerioid taxa increases. The portion of the dendroid taxa is nearly constant during the Triassic. The shifts in the composition of the growth forms are explained by general trends in the evolution of the scleractinians, and by changes in the availability of nutrients near the Carnian-Norian boundary. From the Anisian to the Carnian corals play a subordinate role in Triassic reefs. Only in some small and favourable places they could contribute to the reef fauna. Since the Norian scleractinians are one of the most important groups of reef organisms. Dendroid taxa like Retiophyllia contribute most to the mass of reef organisms. The higher abundance of corals in Norian and Rhaetian reefs is explained by several factors: the more common occurrence of grazing organisms (snails, echinoderms) which probably prey on algae, thus providing free space for corals to settle; the symbiosis of the corals with zooxanthellae facilitating the conquest of the light zone and providing better conditions in nutrient poor environments.</ABSTRACT>

54777 <TITLE>Uniform habit spectrum vs. taxonomic discrepancy between two

- succeeding Triassic coral faunas: A proof of the intra-Norian faunal turnover.</TITLE>
- 54778 <SOURCE>Palaeoworld 19, 3-4: 410-413.</SOURCE>
- 54779 <ABSTRACT>Triassic coral fauna from the Tethys Ocean contains, besides colonial cerioid, meandroid and thamnasterioid corals, a high percentage of solitary and pseudocolonial, phaceloid corals with exclusively epithecal walls, about one-fifth of the genera with micromorphology of septa having pennules or menianes. These features are significant indications of moderate depth environments of low energy level and reduced illumination. Despite a uniform spectrum of growth forms, microstructural criteria allow discriminating a middle Anisian-early Norian (A2-N1) fauna from the middle/late Norian-Rhaetian (N2/3-R) one. Taxonomy of the two faunas shows meaningful differences: of four families that dominated in A2-N1 fauna, Volzeiidae, Conophylliidae, and Tropiastraeidae are absent from the N2/3-R fauna and Margarophylliidae are present in a considerably reduced volume. As a consequence of reduction of the earlier corals, particular morphologies were eliminated. In the N2/3-R fauna, five families are abundant: the solitary and phaceloid Reimaniphyllidae and Stylophyllidae, along with colonial Cuifastraeidae, Pamirosehididae and Astreaeomorphidae, all known as rare and rudimentary elements in the earlier fauna. This change in faunal content in the Tethys during the Norian was controlled by environmental factor(s) hardly identifiable by simple observation, as this is not connected with any obvious facies or change in coral growth form. - 54790 <TITLE>Noriphyllia, a new Tethyan Late Triassic coral genus (Scleractinia).</TITLE>
- 54791 <SOURCE>Paläontologische Zeitschrift 83, 4: 467-478.</SOURCE>
- 54792 <ABSTRACT>Noriphyllia gen. n. is a distinctive coral representing the Coryphyllidae, a group of Late Triassic scleractinian corals. Coral faunas of this age are poorly known. The new coral is distinguished from related corals belonging to the reimaniphyllids by key features of septal microstructure as discerned in thin sections. This microstructure consists of a straight/wavy midseptal zone and lateral septal stereome organized into thin fascicles of fibres, producing a fine and sharp micromorphology of the septal sides. The solitary genus Noriphyllia gen. n. contains two Early Norian species: N. anatoliensis sp. n. chosen as the type species and N. dachsteinae sp. n., and a Carnian species referred to as N. monotutoensis sp. n. The new genus is widely distributed in the Late Triassic, Early Norian reef facies of the Tethys region (Northern Calcareous Alps, Austria; Taurus Mountains, Turkey) and it also occurs in the Carnian of Timor. Noriphyllia gen. n. is unique and details of its microstructural features add new understanding to the composition of both Late Carnian and Early Norian corals. [original abstract]</ABSTRACT>

54803 <TITLE>Late Triassic reefs from the Northwest and South Tethys: distribution, setting, and biotic composition.</TITLE>
54804 <SOURCE>Facies 51, 1-4: 442-453.</SOURCE>
54805 <ABSTRACT>The paleolatitudinal distribution patterns during Ladinian and Carnian time are characterized by an increasing expansion of reefs from the northern to the southern hemisphere. The optimum of reef diversity and frequency in the Norian is associated with the development of extended attached or isolated carbonate platforms. Norian-Rhaetian sponge and coral reefs of the Northern Calcareous Alps developed (1) as reef belt composed of patch reefs in platform-edge positions facing the open marine northwestern Tethys basins and (2) as patch reefs in intraplatform basins as well as in ramp positions. Carnian and Norian-Rhaetian sponge and coral reefs of the Arabian Peninsula are formed (1) as reef complexes at the margins of carbonate platforms on the tops of volcanic seamounts in the southern Tethyan ocean, as small biostromes on these isolated platforms, and (2) as transgressive reef complexes on the attached platform of the Gondwanan margin. The Norian Gosaukamm reefal breccia of the NW Tethys is a counterpart of Jabal Wasa reefal limestone of the Gondwana margin with similarities in geological setting and biotic composition. Rhaetian coral biostromes of low diversity known from the Austrian Koessen basin resemble to the time equivalent Ala biostromes of the isolated Kaur platform in the southern Neo-Tethys by forming a discontinuous layer in shallow intraplatform basin setting.</ABSTRACT>

54829 <TITLE>Oxygen isotopes and climatic control of Oxfordian coral reefs (Jurassic, Tethys).</TITLE>
54830 <SOURCE>Palaios 25, 11: 721-729.</SOURCE>
54831 <ABSTRACT>Stable isotope studies were carried out on shells of reef-dwelling brachiopods and oysters to evaluate the impact of climate changes on coral communities during the Oxfordian (Late Jurassic) in western Europe and northwestern Africa. Low to medium diversities observed in coral associations in the pioneering and terminal reef phases correlate well with average seawater paleotemperatures of 20.3 °C. The reef climax coincides with optimum environmental conditions, reflected by a high coral diversity and an average seawater

- temperature between 22 and 30 °C. The results of this study show that water temperatures set the physiological limits for the distribution of corals and coral reefs in Oxfordian time.</ABSTRACT>

- 54843 <SOURCE>Sedimentary Geology 166, 3-4: 311-334.</SOURCE>
- 54844 <ABSTRACT>Assessing the palaeobathymetry of pelagic deposits is rather speculative, as proof through lithology or fossils significant for depth estimates is sparse. This is unfortunate as the bathymetric history of pelagic successions allows to conceive the evolution of continental margins and oceanic basins. Discoveries in coral biology bring an unexpected impact on basin analysis. Evidence strongly suggests that pennular corals, fossil and modern, constitute a zooxanthellate group with an outstanding specialization in colonizing deeper parts of the marine photic zone. This adaptation includes light amplification by autofluorescent pigmented cells, and particular feeding, witnessed by peculiar gastric ducts and skeletal features. Such corals occur in the Umbria-Marche and Sabina Apennines on top of Late Jurassic submarine highs and at basin margins. Values of palaeodepth relative to pelagic deposits are provided by corals and other environmental data. Because depth reconstruction involves classical Tethyan facies, such as Ammonitico Rosso, Aptychus limestone and radiolarian cherts, we must note that these results do not meet with actualistic models relying on carbonate dissolution for estimating depth. Deposits viewed as bathyal to abyssal could also have accumulated within, or just below, the photic zone. Thus, a new insight opens on Mesozoic bathymetries, regarding vast areas (Middle East to Caribbean) and on subjects ranging from platform drowning to regional extension styles.</ABSTRACT>

- 54856 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 222, 1-2: 10-32.</SOURCE>
- 54857 <ABSTRACT>The paleobiogeographical distribution of Oxfordian ammonites and coral reefs in northern and Central Europe, the Mediterranean area, North and East Africa, and the Middle East and Central Asia is compared with the distribution in time and space of the most important lithofacies. Interest in the Oxfordian is focused on changes in facies and in biogeographical patterns that can be interpreted as the results of climatic events. Paleotemperature trends inferred from oxygen isotopes and paleoclimatic simulations are tested against fossil

and facies data. A Late Callovian–Early Oxfordian crisis in carbonate production is indicated by the widespread absence of Lower Oxfordian reefal formations. There is a gap (hiatus) in deposition on epicontinental platforms, with Middle Oxfordian deposits resting paraconformably on Upper Callovian, while shales accumulated in adjacent intracratonic basins. Simultaneously, in Mediterranean Tethys, radiolarites accumulated in deep troughs while Rosso Ammonitico facies formed on pelagic swells. However, deposition on swells was also discontinuous with numerous gaps (hiatuses) and sequences that are much reduced in thickness. Middle Callovian deposits are generally overlain by Middle Oxfordian limestones. The dearth of carbonates is consistent with a cooling event lasting about 1 My. By the middle Oxfordian a warming, leading to a greenhouse type conditions, is suggested on the basis of both biogeographical (mostly coral reef distribution) and geochemical data. Carbonates spread onto an extensive European platform while radiolarites reached a maximum development in the Mediterranean Tethys. Two distinct latitudinal belts, with seemingly different accumulation regimes, are therefore inferred. Similar latitudinal belts were also present in the late Oxfordian, when carbonates were widespread. The distribution of reefal facies in the late Oxfordian–early Kimmeridgian fits relatively well with GCMs simulations that imply low rainfall in the Tethyan Mediterranean area and slightly higher precipitation in central and northern Europe. Local salinity variations, reflecting more arid or humid conditions, may bias the paleotemperature signal inferred from $\delta^{18}O$ values. Biogeographical and facies distributions, combined with $\delta^{18}O$ values, unravel the ambiguity and support a Late Callovian–Early Oxfordian cooling followed by warming in the later Oxfordian.

54883 <ABSTRACT>A new taxon of a coralline sponge is described from a Lower Cretaceous–Urgonian component of the Coniacian a Basiskonglomerat a; of the Gosau facies near Oberwossen (Chiemgau, Southern Germany).

The sclerosponge exhibits bundles of subradially arranged tylostyles in the outer layer of the basal skeleton (ectosome). Microscleres are missing. The arrangement of the tylostyles is characteristic for the demosponge taxon Hadromerida (pars). Missing the microscleres is close relationship to the taxon Suberites/polymastia is very probable. The calcareous basal skeleton exhibits a stromatopotpid architecture.

54894 <TITLE>The incertae sedis Carpathoporella Dragastan, 1995, from the Lower Cretaceous of Albania: skeletal elements (sclerites, internodes / branches, holdfasts) of colonial octocorals.</TITLE>

54895 <SOURCE>Facies 55, 4: 553-573.</SOURCE>

54896 <ABSTRACT>The incertae sedis Carpathoporella Dragastan, 1995, reported from the Lower Cretaceous of the Western Tethyan domain, is usually interpreted as remains of calcareous algae (Dasycladales or Characeae). New thin-section material from the Aptian of Albania sheds light not only on its biogenic nature but also the morphological variability of this taxon. In fact, Carpathoporella represents the debris of colonial, bushy, most likely gorgonid octocorals with tuberculated spheroids that maybe fused at least near the basal root-like holdfast. Colony branching originates from longitudinally grooved calcareous branches or internodes. Possible relationships to other Upper Cretaceous to Palaeogene genera are discussed and a revised critical inventory of Cretaceous octocorals is presented. Due to the evidenced morphological features, Carpathoporella could either represent an ancestral isidid octocoral of the order Alcyonacea such as Moltkia Steenstrup or, due to the likely primary aragonitic skeletal mineralogy, a representative of Epiphaxum Lonsdale of the order Helioporacea. Due to morphological analogies, the new combination Carpathoporella elliotti is proposed. In any case, the Lower Cretaceous record from Tethyan peri-reefal shallow-water carbonates is highlighted since numerous skeletal findings of fossil gorgonid Octocorallia were so far only known from Upper Cretaceous and younger strata of outer shelf environments of the boreal realm. The origin of deep-water Upper Cretaceous octocorals from Lower Cretaceous shallow-water taxa such as Carpathoporella is proposed as a possible further example of onshore/offshore evolutionary pattern. 54907 <TITLE>Structure, repartition et signification paleogeographique d'Aspidiscus, hexacoralliaire cenomanien de la Tethys [structure, distribution and paleogeographic significance of Aspidiscus, a Cenomanian scleractinian coral of the Tethys].</TITLE>

54908 <SOURCE>Bulletin de la Societe geologique de France 1987, 8, III, 5: 921-934.</SOURCE>

54909 <ABSTRACT>Aspidiscus is a coral of a particularly attractive form,

easily recognizable by field geologists. Therefore the numerous citations in the literature and the frequency in many collections favour the setting of a distribution map for the species of this Cenomanian genus. Apart from a single non-confirmed mention from Uruguay, all the specimens collected to date come from around the Mediterranean with an exceptional abundance in North Africa. Lesser concentrations are known from the Middle East, Spain, France and Greece. In North Africa the localities which yielded *Aspidiscus* are aligned from eastern Algeria via Tunisia to Tripolitania in a narrow belt (less than 100 km) over 1000 km. This belt, directed NW-SE, cuts obliquely the structural lines. The various outcrops along this strip seem to gather in groups (7 to 8) recalling the pattern suggested, by Freund (1961) for the distribution of ammonites in the Middle East during the Lower Turonian - that of parallel troughs (with ammonites) separated by ridges and directed NE-SW. The recognition of faulted-tilting blocks; announced by Bureau (1983, 1984, 1986) may also be attempted in explaining the layout of the *Aspidiscus* localities in North Africa, which coincides rather well with satellite photogeological alignments (Biju-Duval et al. 1976). The enigmatic mention of this coral in Uruguay raises the question of sea links - Atlantic or Trans-Saharan (Collignon and Lefranc 1974) - between North Africa and South America during the Cenomanian. </ABSTRACT>

54933 <TITLE>The Miocene coral reefs and reef corals of the SW Gulf of Suez and NW Red Sea: distribution, diversity and regional environmental controls.</TITLE>

54934 <SOURCE>Sedimentation and tectonics in rift basins, Red Sea - Gulf of Aden [B.H. Purser & D.W.J Bosence (eds)]: 296-319; Chapman and Hall.</SOURCE>

54935 <ABSTRACT>Coral reefs developed within the Gulf of Suez - northern Red Sea region during a relatively brief time interval which corresponds to the Middle Miocene maximum of worldwide marine transgression associated with a global warm climate. The mixed carbonate - siliciclastic sequences including reefs belong to the marine Miocene syn-rift unit (Group B or Upper Rudeis - Kareem Formations) and possibly extend from Langhian to early Serravallian. * Various sites where coral reefs occur are presented with description of reef geometries and their relationships to local structural framework together with diversity of coral fauna and associated organisms. Studied reef locations extend along the Egyptian coast of the Gulf of Suez and northwestern Red Sea

from north of Hurghada to the Abu Ghusun - Ras Honkorab area. [...] Mediterranean reef corals and coral reefs became definitively extinct within the Gulf of Suez - northern Red Sea region at the latest during the Serravallian, as a result from the increasing restriction of marine water inducing the evaporite sedimentation. This regional restriction is interpreted as directly related to the gradual closure of the Suez Isthmus likely due to both eustatic and tectonic movements and finally leading to the isolation of the Gulf of Suez - Red Sea from the main basin of the Mediterranean i.e. much earlier than the extinction of the reef corals within the Mediterranean at the end of the Miocene. 54973 <SOURCE>Facies 18: 219-230.</SOURCE>
54974 <ABSTRACT>Three major cycles of fossil coral reef development have been recognized on the Jordanian coast of the Gulf of Aqaba. Eustatic changes in sea level, coastal erosional processes and faulting has led to the formation of seven distinct terraces. It seems that the eustatic sea level changes governing the development of these reefs correspond to glacial and interglacial episodes of the late Pleistocene.</ABSTRACT>

54985 <TITLE>Facies, Fossil Record, and Age of Pleistocene Reefs from the Red Sea (Saudi Arabia).</TITLE>
54986 <SOURCE>Facies 22: 1-46.</SOURCE>
54987 <ABSTRACT>Facies patterns within the Pleistocene reef terraces along the Red Sea coast exhibit lateral changes over short distances. These changes reflect either transitions within the depositional environment or they are related to minor or major sea level fluctuations. On the basis of quantitative distribution of biota in the field as well as in thin section it is possible to establish and map these lateral patterns. Important biota are framebuilders and secondary reef encrusters (foraminifers, coralline algae). Frequency distributions of sessile foraminifera and scleractinians are strikingly similar to those of the recent environment within diagenetically unaltered terraces. The main reef terraces occur in different elevated levels above the present sea level. Morphological steps are caused by onlap during different sea levels, by tectonics, or by erosion during transgression. Although several morphological steps exist which obscure the terrace stratigraphy, only three reef units can be distinguished. Each unit exhibits a lateral facies development, which begins at the shore, covering the whole lagoonal facies and ends at the upper reef slope. Besides this lateral facies pattern vertical patterns occur as well, showing a transgressive sequence in the youngest (lower) and oldest (upper) unit and a regressive one in the middle unit. In top quality outcrops, like wadi sections, it is possible to differentiate within the youngest reef unit between three onlapping reef cycles. Such cycles, however, can not be seen in the middle and oldest formations. The three reef cycles within the youngest unit and the three units as well, exhibit different degrees of diagenetic alterations, which are strongly reflected by a gradual reduction in the number of biota. This reduction may be best described as a process of $\#34$; sieving $\#34$; . where these differences in diagenesis are recorded, they correspond to the age of the reef units. U/Th datations of the investigated terraces reveal an age for the youngest unit between 86.000 and 118.000 years B.P. During this time three major sea level high stands have occurred, which explain the existence of three reef cycles. The age of the middle formation is around 205.000 years, while the age of the oldest formation can only be assumed to fit in the time span between 290.000 and 340.000 years B.P. All these data correspond to other published datations along the Red Sea coast.</ABSTRACT>

55000 <ABSTRACT>Les côtes du Golfe d $\#039$;Aden de la Mer Rouge au Golfe de Tadjoura présentent des dépôts calcaires coralliens pleistocenes. Ces formations, de faciès variés, permettent de définir une unité chronostratigraphique datée à environ 125000 ans largement étendue qui

constitue un repère précis de la stratigraphie du Pleistocene. Les affleurements en position topographique élevée présentent des traces de lessivage et de recristallisation responsables de la transformation en calcite de l'aragonite des coraux. Pour cette raison, ils ne peuvent être datés et ne peuvent pas toujours être rattachés avec certitude au même cycle. Ils pourraient comprendre des niveaux plus anciens. Le repère daté permet de chiffrer les déformations subies par la bande littorale du golfe depuis 125000 ans. Les déformations dépassent 20 ou 50m (peut-être 100m pour un repère non daté). Elles se traduisent par des failles de 8m de rejet mesurable et un mouvement d'ensemble positif qui atteint son maximum le long du méridien d'Obock. Vers le SO et le N, les déformations s'atténuent et la surface du niveau marin de 125000 ans se rapproche progressivement du niveau actuel de la mer. </ABSTRACT>

55025 <SOURCE>Palaeontographica Americana 54: 254-260 [Oliver w.A.Jr et al. (eds): Recent advances in the paleobiology and geology of the Cnidaria: Proceedings of the 4th International Symposium on Fossil Cnidaria].</SOURCE>
55026 <ABSTRACT>Uplifted coral reefs on the eastern Red Sea coast and the Gulf of Aqaba compared to their modern analogues reveal faunal differences due to diagenesis. Whereas all biota show more or less the same amount of diagenetic reduction in numbers, aragonitic mollusks are more reduced in number. Although the skeletons of many organisms and also marine cements, consist of aragonite, their reaction to diagenesis in the vadose environment differs. The diagenetic alteration of aragonite cements into calcite occurs earlier than that of aragonitic coral skeletons. The diagenesis of aragonitic mollusks begins only after the complete replacement by calcite of aragonite in corals and cements. In this stage the diagenetic environment can be already so well advanced that leaching predominates with little concomitant calcite precipitation. This leads to a major loss of aragonite mollusks. This diagenetic sequence can be related to the differing influence of organic matrices formed during aragonite precipitation; to the density of the crystal fabric; and also to the degree of undersaturation of the meteoric water with respect to CaCO₃.</ABSTRACT>

55128 <TITLE>Sea level and coral atolls: Late Holocene emergence in the Indian Ocean.</TITLE>
55129 <SOURCE>Geology 18: 62-66.</SOURCE>
55130 <ABSTRACT>The Cocos (Keeling) Islands in the eastern Indian Ocean were visited by Charles Darwin, who described geomorphological evidence that he considered supported his subsidence theory of coral-reef development. However, several other accounts of the reef islands have questioned Darwin's interpretation, and have suggested that a conglomerate platform that underlies most of the reef islands may indicate recent emergence of the atoll. Radiocarbon ages of corals from this conglomerate platform, reported here, indicate that it formed in the late Holocene. Fossil in situ microatolls above present upper coral growth limits, the levation of associated beachrock, and the morphological similarity of the conglomerate platform to the present

reef-flat deposits indicate a late Holocene sea level above the present relative to the atoll. The atoll has undergone at least 0,5 m of emergence since about 3000 yr B.P. This represents the first radiometrically dated evidence of Holocene emergence from islands in the eastern or central Indian Ocean.</ABSTRACT>

55141 <TITLE>Is damage susceptibility linked to coral community structure? A case study from South Africa.</TITLE>

55142 <SOURCE>Beiträge zur Paläontologie 20: 65-73.</SOURCE>

55143 <ABSTRACT>Africa's southernmost coral communities are situated in northern Natal, South Africa (27°50' S), within the Maputaland and St. Lucia Marine Reserves. Growing concern about the possible impact of recreational activities on the health of the coral ecosystem prompted the present study on the structure and health of the reefs. Coral community studies by means of line transects identified three basic coral community types, which correlated with the geomorphology of the sandstone outcrops on which corals grew. 1) Fossil dunes were dominated by alcyonacea in depths between 8 and 24m. 2) Flat outcrops between 18 and 24m depth were dominated by scleractinia (mainly Acropora). Within these community types, a further small-scale differentiation into sub-communities inside and outside of gullies occurred. 3) Deep hard substrata between 25 and 34 m depth were dominated by sponges, ascidians and sea-fans. Quantitative damage assessment was used to correlate community structure to damage susceptibility. The flat-outcrop Acropora community was considered most fragile, while the other community types (dominated by leathery alcyonaceans or by sponges) were considered more robust. Such quantitative assessments can be of value to the development of zoning schemes for marine reserves.</ABSTRACT>

55154 <TITLE>Long-term fluctuations of coral communities at Aqaba and on Sanganeb-Atoll (northern and central Red Sea) over more than a decade.</TITLE>

55155 <SOURCE>Beiträge zur Paläontologie 20: 89-97.</SOURCE>

55156 <ABSTRACT>Quantitative analyses of coral communities had been carried out on test squares in a fore reef area of a fringing reef near Aqaba (northern Red Sea) and on inner and outer reef slopes on Sanganeb-Atoll (central Red Sea) in 1976 (Mergner & Schuhmacher 1981) and 1980 respectively (Mergner & Schuhmacher 1985). Further investigations at Aqaba in 1989 and on Sanganeb in 1991 yielded information on the growth and mortality of individual colonies as well as data on long-term fluctuations of community parameters. Near Aqaba, data of the test square U-7 (5 x 5m in size) at a depth of some 10m showed that significant changes occurred in the composition of the coral reef community between 1976 and 1989: xeniid soft coral colonies

completely disappeared during this time, in total, 112 species of Cnidaria including 88 Scleractinia were found in the test square in 1976 and 1989. The diversity ($H1 = 3.23$ in 1989- $H1 = 3.42$ in 1976, based on Cnidaria-coverage) compared to the highest in the world. On Sanganeb-Atoll coral communities of four test squares (TQ-FV) of 5 x 5m were analyzed. The data of 1991 for four TQs comprised a total of 3034 colonies of 130 species of stony corals, soft corals and hydrocorals, among them 86 species of Scleractinia. A mean diversity of $H1 = 2.80$ in 1991 and $H1 = 2.58$ in 1980 (based on Cnidaria-coverage) was recorded. The comparison of the qualitative analyses of the Sanganeb TQs in 1980 and 1991 proved the constancy of the coral communities. The analysis of the TQs near Aqaba and on Sanganeb-Atoll, however, showed significant differences when compared latitudinally. On Sanganeb-Atoll the data suggest that the stable abiotic conditions support a relative constancy of the coral communities in the reef areas studied, whereas near Aqaba considerable alterations become evident over a decade. Higher fluctuations of abiotic conditions (light, temperature) near the boundary of the geographical reef belt as well as grazing by sea urchins may account for retarded regeneration after occasional disturbances.</ABSTRACT>

55167 <TITLE>Distribution and Environmental Control of Coral Assemblages in Northern Safaga Bay (Red Sea, Egypt).</TITLE>
55168 <SOURCE>Facies 36, 1: 141-162.</SOURCE>
55169 <ABSTRACT>Coral assemblages in northern Safaga Bay, Red Sea, Egypt, are qualitatively described. Nine distinct assemblages were found, which correspond to quantitatively defined community types previously described from the area off Hurghada, northern Red Sea. Their distribution within northern Safaga Bay was mapped. Strong gradient and/or steep relief assemblages were: Acropora assemblage on windward (exposed) reefs, Porites assemblage on leeward (sheltered) reefs, Porites assemblage on leeward (sheltered) reefs, Millepora assemblage on current exposed reefs, Stylophora assemblage on reef flats. Low gradient and/or low relief assemblages were: Acropora dominated coral patches in areas of good circulation to a depth of 15m, Stylophora/Acropora coral patch assemblages in shallow sheltered environments, faviid carpet in low relief areas between 10 and 25m which with increasing turbidity turns into a depauperate faviid carpet, Porites carpet in low relief areas between 5 and 15m with clearest water, Sarcophyton carpet in low relief areas with high suspension load, platy scleractinian assemblage in deeper water (>25m) with low light intensity. The distribution of coral assemblages depends basically on 1) topography 2) hydrodynamics 3) light and 4) suspension load.</ABSTRACT>

- 55180 <TITLE>Coral frameworks revisited - reefs and coral carpets in the northern Red Sea.</TITLE>
- 55181 <SOURCE>Coral Reefs 18: 241-253.</SOURCE>
- 55182 <ABSTRACT>Coral communities were investigated in the northern Red Sea, the Gulfs of Suez and Aqaba, for their framework building potential. Five types of coral frameworks were differentiated: Acropora reef framework, Porites reef framework, Porites carpet, faviid carpet, and Stylophora carpet. Two non-framework community types were found: Stylophora-Acropora community, and soft coral communities. Reef frameworks show a clear ecological zonation along depth and hydrodynamic exposure gradients, with clear indicator communities for each zone. By definition, coral carpets build a framework and lack a distinct zonation since they only grow in areas without pronounced gradients. In the northern Red Sea they show a gradual change with depth from Porites to faviid dominance. A Stylophora carpet is restricted to shallow water in the northern Gulf of Suez. Although growth rates of carpets may be somewhat smaller than those of reefs, the carbonate accumulation is considered to be higher in carpet areas due to their significantly higher areal extension. In addition, reef and carpet have different sediment retention characteristics - the carpet retains, the reef exports. The in situ fossilization potential of coral carpets is expected to be higher than that of reef frameworks.</ABSTRACT>

- 55194 <SOURCE>Facies 30: 1-14.</SOURCE>
- 55195 <ABSTRACT>From a study of two areas, Jesira and the Bajuni Archipelago, about 400 km apart, a general pattern can be established for the Recent facies, together with the morphological and taxonomic features of the corals. Present day coral development is characterized by true fringing reefs in the Bajuni Archipelago and by scattered patches and knolls in the Jesira area. The coral fauna, consisting of 27 genera and 63 species so far (including all uncertainties, but not sight records), is rather poor, though coral communities are locally well developed. These figures probably reflect incomplete study and sampling. Although comparison with other areas may therefore be premature, a preliminary biogeographical analysis suggests that this fauna is more closely related to that of the Red Sea than to East Africa and the Seychelles. This differs from other published biogeographical work on Indian Ocean coral faunas, but further study of the corals in this and neighboring areas of the Indian Ocean is needed in order to resolve this apparent anomaly.</ABSTRACT>

55350 <SOURCE>Zool. Jb. Syst. Bd. 100: 451-465.</SOURCE>
55351 <ABSTRACT>The " Seychelles Coral Reef Conservation Expedition" operated in the Seychelles from 25th July to 12th september 1971 and brought home from Baie Ternay, on the north-west of the island of Mahé, a coral collection which was handed over to the Hessian State Museum, Darmstadt. * The expedition divided the investigated bay into zones: 1, sand and algae; 2, marine angiosperms; 3, sand; 4, sand with isolated patch reefs containing live corals; 5, reef flat consisting mainly of dead coral fragments and algae; 6, reef slope with living corals, gradually increasing to 10m followed by a steeper slope to 25m depth;

- 7, sand with isolated corals sloping gently from 20m to 30m. * Corals were collected at four points: on a patch reef 1.5m deep, and on the reef slope at 10, 17 and 25m, using SCUBA. The coral composition of the different points is described and listed in a table. The difference in coral composition between Baie Ternay and other coral reefs at the east side of Mahé is discussed and it is suggested that the particularly sheltered position of Baie Ternay, open to NW and sheltered from the prevailing SE monsoon winds accounts for these differences. * In a systematic section the 29 collected coral species from 21 genera are listed, partly described and supplied with notes about geographical distribution. One species, *Caulastrea furcata*, is new for the Seychelles.

55389 <SOURCE>In Proceedings of the Second International Symposium on Coral Reefs (22nd June to 2nd July 1973, Brisbane); Published by The Great Barrier Reef Committee; vol. 2: 655-670.</SOURCE>
55390 <ABSTRACT>The present paper is supplementary to the paper submitted to the Symposium on Corals and Coral Reefs held at Mandapam, South India, in 1969, in which the basic ideas of a coral sociology, founded upon

the elements of phytosociology, were explained. In the present paper the more essential principles, somewhat modified, are repeated. The Rasdu Atoll in the Maldives is taken as an example to show how coral reefs can be examined with coral sociological methods. On eight sample quadrats of the inner reef flat, on ten of the outer reef flat and on six of the lagoon bottom, abundance-dominance and gregariousness of the corals occurring there were determined and listed in tables. The corals were arranged according to their frequency. Frequency diagrams and variation curves of the species numbers of the different stands were drawn, and reference is made to the differences in the composition of the sample quadrats. The reefs of Rasdu Atoll are compared with other reefs of the Maldives. * Basic viewpoints of classification of coral communities in terms of dominant, differential and characteristic species are explained. Provided that detailed and unequivocal keys of identification exist, particularly for the difficult coral genera, it should be possible to establish coral associations and characteristic species by co-operative effort. </ABSTRACT>

55453 <TITLE>Zur Diagenese aragonitischer Strukturen am Beispiel rezenter und
pleistozaner Korallenriffe des Roten Meeres. [in German, with English
summary]</TITLE>
55454 <SOURCE>Natur u. Mensch, Jmitt. 1982: 109-115.</SOURCE>
55455 <ABSTRACT>The diagenetic alteration of aragonite cements into calcite
happens earlier than that one of aragonitic coral skeletons within the
vadose environment. The diagenesis of aragonitic molluscs starts after
the complete replacement of aragonite by calcite in corals and cements.
This diagenetic sequence can be referred to the different influence of
organic substances during aragonite precipitation, to the density of
the crystal fabric, as well as to the degree of saturation of the
meteoric water with respect to CaCO₃ within the diagenetic environment.

55466 <TITLE>Film review: "Die Korallengarten von Shadwan" von H.
Fleissner & G. Fleissner.</TITLE>
55467 <SOURCE>FC&P 13, 2: 60.</SOURCE>
55468 <ABSTRACT>Der Film wurde in den Jahren 1964 bis 1967 im nordlichen
Roten Meer gedreht, und zwar im Bereich der Inseln der Strasse von
Cubal (hauptsachlich bei Shadwan) und an der agyptischen Festlandkuste
zwischen Hurghada und Koseir. Er besteht aus etwa 2 gleich langen
Teilen. Teil 1 behandelt die Organisation und Ausrustung der Expedition
zum Roten Meer und die Herstellung der fur die Aufnahmen wichtigen
Hilfsmittel. Teil 2 ist als Lehr- und Dokumentarfilm konzipiert und
gibt einen umfassenden uberblick uber biologische und geologische
Zusammenhange in rezenten Korallenriffen. * Die Szenerie und die
Handlung des Riff-Films wird ausschliesslich durch die Korallen und
die Mitglieder der Faunengemeinschaft der Riffe bestimmt. Ein breiter
Raum wird der Darstellung von Wechselbeziehungen zwischen den
Rifforganismen sowie von ihrem Verhalten eingeräumt. Daneben machen
technisch perfekte mikroskopische Nahszenen die Zooxanthellen und
Nesselkapseln der Riffkorallen sichtbar. Sehr spektakulare
Zeitlupen-Nahaufnahmen zeigen die Explosion einzelner Cniden. Als

Beispiel für die Ernährung der Korallen sieht der Zuschauer, wie die Polypen kleine Amphipoden fangen, und wie die Beute zum Mund der Polypen transportiert wird. Eine Zeitrafferszene demonstriert darüberhinaus anschaulich, wie die Polypen ihren Korallenstock selbst von Sedimentüberdeckung reinigen. * Der Film wurde speziell als Lehrfilm für Universitäten und Schulen sowie für das Fernsehen gedreht. Obschon die Feldarbeiten nun fast 20 Jahre zurückliegen, gibt er nach Ansicht des Rezensenten unter allen vergleichbaren, öffentlich ausleihbaren Riff-Filmen die abgerundetste Einführung in den Themenkreis des rezenten Korallenriffes. Deshalb bietet er gerade auch dem Riffpalaontologen und Paläoökologen, der keine Gelegenheit hat, in rezenten Riffen zu tauchen, notwendige Einblicke in das heutige Riffkosystem sowie Anschauungsmaterial für die wichtigsten geologischen Prozesse und damit wertvolle Anregungen für die Interpretation von fossilen Riffablagerungen. Auch für den Laien ist die Vorführung des Filmes wegen der ausserordentlich schonen und mit technischer Perfektion gedrehten Unterwasserszenen ein grosser Genuss.

55507 <ABSTRACT>Wasserproben aus dem Bereich der Phantom-Bank werden auf ihren Gehalt an Sauerstoff, Orthophosphat, Ammoniak, Nitraten, Nitriten, Kieselsäure, Chlorophyll und Phaeophythin, Fe, Cu, Mn und Zn sowie auf ihre Salinität hin untersucht. Das Wasser der Region wird insgesamt als mesotroph eingestuft. Zur relativ hohen Produktivität bei verhältnismäßig geringer Biomasse des Phytoplanktons scheint die hohe Wassertemperatur beizutragen. Weitere Untersuchungen betreffen die Durchleuchtung des Wassers in Abhängigkeit von der Wellenlänge des Lichtes und der Wassertiefe, sowie die Verteilung der Strahlungsenergie in Abhängigkeit von der Wassertiefe.</ABSTRACT>

55520 <ABSTRACT>Es wurden 150 Gastropodenarten und 70 Pelecypodenarten aufgesammelt. Die repräsentativsten 70 Gastropodenarten und 35 Pelecypodenarten werden unter Angabe ihrer Verteilung über 37 Sammelstationen in Reihenfolge ihrer Häufigkeit aufgelistet. Die Sammelstationen reichen bis in 10m Tiefe. Die quantitative Verbreitung der Gesamtfauna sowie diejenige von ausgewählten Arten im Bereich der Bank werden graphisch dargestellt und diskutiert. Ferner werden die Grossen- und Altersstruktur, die vielfach beobachtete Zertrümmerung der Schalen, sowie die unterschiedliche Verteilung der rechten und linken Klappen erörtert. Betrachtungen über die allgemeinen ökologischen Bedingungen auf der Bank sowie über den möglichen Einfluss des östlichen Timor-Stromes auf die Bildung der Molluskenvergesellschaftungen runden den Artikel ab.</ABSTRACT>

55533 <ABSTRACT>Die Phantom-Bank hat fast elliptischen Umriss und besteht aus einem System felsiger Wälle und sandiger Becken. Diese bilden eine Struktur, welche einem ringförmigen Riff mit zentraler Lagune sehr

ahnlich ist. Der Abfall von der Oberkante der Walle zum Boden der Becken beträgt 3-5m. Vergleiche von Tiefenmessungen über der Bank mit 65 Jahre alten Messungen ergaben eine seitherige Absenkung der Bank um 5-6 cm. * Auf der Phantom-Bank wurden folgende physiographische Zonen ausgeschieden und anhand der Korallenfauna charakterisiert: (1) Aussenabhang, bestehend aus Steilabhangen und senkrechten Felswänden. Umgibt die Bank allseits und ist in Tiefen zwischen 16 und 20m sowie 40 und 60m ausgebildet. Er wird grosstenteils besiedelt von dunnen, schildförmigen und seltener von verzweigten und massigen Kolonien. An Steilstufen wurde eine dichte Besiedlung durch Halimeda beobachtet, an den Steilhängen Gerolle, bestehend aus Halimeda-Sand. Im oberen Teil des Abhanges wurden gut ausgebildete Brandungsrinnen-Systeme festgestellt. Die Bedeckung durch Riffbildner erreicht in diesem Bereich bis zu 100% und besteht vor allem aus blattförmigen und astigen Kolonien von Acropora sowie astigen Porites, dickastigen Millepora und Heliopora. (2) Aussenrand der Bank im Uebergangsbereich zum Hang. Es ist 10 bis 20m breit, eben bis leicht geneigt, mit verstreuten bis zu 1m hohen Buckeln und grossen abgestorbenen Acropora-Kolonien. Auf den Konvexformen des Reliefs beobachtet man eine intensive Besiedlung durch Heliopora coerulea, Porites nigrescens, Acropora cytherea, A. palifera, grosse, massige Poritiden und Faviiden sowie Kalkalgen (v.a. Halimeda). (3) Durch Erosion überprägte Zone, mit einem Relief, das stark durch Ausbildung zahlreicher Buckel und Spitzen gegliedert ist. Letztere erreichen 2 bis 3m Höhe und erscheinen stark von der Erosion zerfressen. Sie werden in mehreren Etagen von Korallen besiedelt, insbesondere von Acropora, Heliopora, grossen, taibförmigen Kolonien von Porites, Favia und Leptoria. Grosse Blöcke aus Riffkalk bilden hier Pseudo-Fleckenriffe. (4) Zone der "blauen Lagunen". Sie umfasst die Depressionen vor allem im Ost- und Südostteil der Bank. Der Meeresboden ist hier weithin mit Kalksediment bedeckt, vor allem von Sand, über dem das Wasser blau erscheint. Korallenbesiedlung (Helioporen, Milleporen, Acroporen und weichkorallen) sowie vereinzelte Ansammlungen von Fungien sind ausschliesslich auf den Bereich von Erhebungen beschränkt. * Die beobachtete, physiographisch-ökologische Riffzonierung und der Artenreichtum der Korallen ist mit typischen indopazifischen Riffen vergleichbar. Die Acroporen sind auch hier Hauptriffbildner, treten in zahlreichen Wuchsformen auf und reichen bis in 10m Tiefe. Sie repräsentieren 1/3 des Artenbestandes.

55544 <TITLE>Korallobionten der Steinkorallen. [in Russisch]</TITLE>

55545 <SOURCE>Biologiya korallyovykh rifov. Issledovaniya na banke Fantom (Timorskoye morye). Sbornik nauchnykh trudov: 43-50; AN SSSR, Dalnevostochnyi Nauchnyi Tsentr, Vladivostok.</SOURCE>

55546 <ABSTRACT>Es werden Ergebnisse einer vergleichenden Untersuchung von Koralllobionten (Epibionten und Endobionten) verschiedener Korallengattungen dargestellt. Diese basiert auf der Analyse von 34 lebenden Kolonien strauchförmiger Korallen verschiedener Gattungen, welche in 12 bis 17 m Wassertiefe gesammelt wurden. In Tabellen wird die Häufigkeit und Zusammensetzung der auf den verschiedenen Korallengattungen angetroffenen Koralllobionten zusammengestellt. Diagramme geben Darstellungen von Diversität und Dominanz sowie von Artenzahl und Biomasse der Koralllobionten in Abhängigkeit von der Grösse der Wirtskolonien bei strauchförmigen Acroporen und Pocilloporen. Die Anzahl der Arten, die Häufigkeit und die Biomasse der

- Korallobionten erhöhen sich beträchtlich mit der Grössenzunahme der Wirtskoralle. Der Besiedlungsgrad von Pocillopora durch Epibionten übertrifft denjenigen von Acropora. In frühen Wachstumsstadien werden beide Korallengattungen durch dekapode Krebse besiedelt. Mit dem Wachstum der Kolonie treten bei den Pocilloporen Ophiuren und Asteroiden hinzu, während sich zwischen den Acroporen Fische einnisten. Die dekapoden Krebse erreichen auf strauchförmigen Wuchsformen von Korallen verschiedener Gattungen ihre grösste Häufigkeit. </ABSTRACT>

55559 <ABSTRACT>Untersucht wurden Gehalt und Verhältnis photosynthetischer Pigmente, Absorptions- und Anregungsspektren der Fluoreszenz sowie die Geschwindigkeit von Photosynthese und Atmung der symbiontischen Zooxanthellen verschiedener Korallenarten. Die untersuchten Korallen lebten in folgenden 3 ökologischen Nischen: in kräftig durchlichteten, sowie abgeschatteten Bereichen (Wassertiefe 15 bis 17m) und in 45m Wassertiefe. * Die Untersuchungen ergaben Einflüsse der Beleuchtung auf den Gehalt an photosynthetischen Pigmenten, auf das Chlorophyll, den biochemischen Energiefluss, die Atmung sowie auf die Photosynthese. Ferner zeigte sich, dass im abgeschatteten Bereich und in 45m Tiefe die Anpassung an die verringerte Beleuchtung auf gleiche Weise verwirklicht wird, und dass die Korallen hier das Licht geringerer Intensität besser ausnutzen. </ABSTRACT>

55583 <TITLE>Book review: Die Malediven. Paradies im Indischen Ozean; by I. Eibl-Eibesfeldt.</TITLE>
55584 <SOURCE>FC&P 13, 2: 64-65.</SOURCE>
55585 <ABSTRACT>In den knapp 20 Jahren seit Erscheinen von Eibl-Eibesfeldts erfolgreichem Buch "Im Reich der tausend Atolle" sind Flugreisen von Europa selbst zu entlegenen tropischen Küsten nicht nur möglich geworden, sondern sie werden auch in grosser Zahl zu erschwinglichen Preisen angeboten und durchgeführt, so dass heute tausende von tauchbegeisterten Naturfreunden zu tropischen Koralleninseln reisen. Sicher haben die Fernsehberichte von Hans Hass über die "Xarifa"-Expeditionen und Eibl-Eibesfeldts oben genanntes Buch mit der Schilderung der Riffuntersuchungen in den Malediven im Rahmen einer dieser Expeditionen zu einem nicht unwesentlichen Teil zu dieser Entwicklung beigetragen. Es ist deshalb verständlich, dass sich Verfasser und Verlag der Muhe unterzogen haben, das erfolgreiche "Atollbuch" überarbeitet und wissenschaftlich auf den neuesten Stand ergänzt für die heutige Generation von Riff-Besuchern wieder herauszubringen. 55598 <ABSTRACT>Das Buch ist sicher eine obligatorische Lektüre für jeden, der sich als Wissenschaftler oder als Tourist auf eine Tauchreise zu den Malediven vorbereitet. Es ist darüberhinaus ein hervorragendes und leicht zugängliches Einführungskolleg in die Biologie von Riff und Lagune, geschrieben von einem Autor, der schon vor über 30 Jahren als einer der ersten Wissenschaftler mit moderner Tauchausrüstung loszog, um das Leben der Riffe direkt am Ort unter Wasser zu studieren. Und es ist die packende Schilderung der verschiedenen Aspekte des rezenten Riffökosystems, das dieses Buch gerade auch für den Geologen und Paläontologen zu einer besonders lesenswerten Lektüre macht. 55610 <SOURCE>Bern [University ?] Ph.D. Thesis; 1993.</SOURCE>
55611 <ABSTRACT>An investigation of reef corals from Mauritius (Indian Ocean) was undertaken with 2 aims: studying underlying principles of sclerochronology and searching for the skeletal records of environmental stress factors affecting local reefs, which have recently

suffered heavy degradation. 129 skeletons of massive Porites, representing 2 species (*P. lutea*, *P. solida*), and 14 corals of other massive species were sampled from a variety of localities and depths, especially at the west coast. [introductory part of extensive summary]

55636 <SOURCE>Atoll Research Bulletin 334: 1-22.</SOURCE>

55637 <ABSTRACT>Coral collections were made along the Saudi Arabian coastline of the Red Sea, from Haql in the north (Gulf of Aqaba), to Jizan in the south, including nearshore and offshore collecting sites. Corals were taken from all depth-zones in the Jeddah area (max. depth 65m), but from shallow water only (max. depth 9m) at all the other sites. The present collection consists of 146 species of Scleractinia, the octocoral *Tubipora musica*, and among the hydrozoans 3 species of *Millepora*, and *Distichopora violacea*. 12 scleractinian species are new for the Red Sea: *Pocillopora* cf. *eydouxi*, *Acropora anthocercis*, *A. aspera*, *A. cerealis*, *A. divaricata*, *A. donei*, *A. echinata*, *A. monticulosa*, *Montipora peltiformis*, *M. turgescens*, *M. undata*, and *Porites australiensis*. Collections were made from 1981 through 1988.

55650 <ABSTRACT>A new species of toxic marine sponge, *Biemna laboutei* sp.nov., belonging to the order Poecilosclerida, family Desmacellidae,

- is described from the outer-reef slope of Nosy-Be, Madagascar. The species is the sixth known desmacellid to have toxic (dermatitis-producing) properties. It is compared with other desmacellids from the Indian Ocean region. [original abstract] </ABSTRACT>

- 55662 <SOURCE>Coral Reefs 05, 3: 151-154.</SOURCE>
- 55663 <ABSTRACT>The stylasterid Distichopora nitida was found during dives at four localities in the South Maalhosmadulu Atoll, Maldives, Central Indian Ocean. It occurs at the reef slope in a depth of 22-48m at the edge of grottoes. All features of the Maldivian coral coincide with Boschma's (1959) description of D. nitida from the Pacific Ocean. The most important characteristics and the distribution of D. nitida were compared with those of other shallow water representatives of the genus in the Indo-Pacific. A locality of D. nitida in the western Indian Ocean, thus far unpublished, is mentioned.</ABSTRACT>

55752 <TITLE>Significance of Different Traits of Soft-Coral Assemblages (Octocorallia, Alcyoniina) in benthic Reef Communities of the Red Sea.</TITLE>
55753 <SOURCE>Goettinger Arbeiten zur Geologie und Palaeontologie, Special Volume 2 [Reitner J., Neuwiller F. & Gunke] F. (eds): Global and Regional Controls on Biogenic Sedimentation I. Reef Evolution]: pp ???</SOURCE>
55754 <ABSTRACT>Different types of soft-coral assemblages in Red Sea benthic reef communities were investigated with regard to spatial distribution patterns, dynamics in abundance and persistence as well as hermatypic (or "anti-hermatypic") properties. The detailed patterns of 12 by species predominantly preferred depth ranges and fluctuations in abundance were mapped for the Xenidae, a group of rapid colonizers of denuded substrates. Further qualitative observations included the other alcyoniid and nephtheid genera Sarcophyton, Lobophytum, Sinularia, Litophyton and Dendronephthya. The results were used to define and describe "Xenia-aspects" for the predominant scleractinian species assemblages along the reef slope depth gradient of reefs near Aqaba (northern Red Sea) and at the Sanganeb-Atoll (central Red Sea). The hermatypic properties of two species of Sinularia are presented. The skeletal values for porosity, compressive and bending strength of S. leptoclados resemble those of common scleractinian taxa. These soft corals considerably contribute to the reef framework in lagoonside and windward slope habitats of the Sanganeb-Atoll. with regard to characteristics of colonizing behavior, competition and persistence, predominant soft-coral taxa capable of high areal occupation in Red Sea reefs are grouped into four types of assemblages, which demonstrate the wide spectrum of alcyonacean life history traits. It is suggested that these different types can describe variable soft-coral assemblages with regard to their functional significance in benthic reef communities.</ABSTRACT>

55792 <SOURCE>The Raffles bulletin of zoology 52, 1: 7-10.</SOURCE>
55793 <ABSTRACT>A new species of azooxanthellate solitary Scleractinia, Javania erhardti, is described from relatively shallow water in Indonesia. It differs from congeners in having six cycles of septa (192 septa), slightly concave septal axial edges, and a rudimentary columella. To aid in its identification, both a key to the 10 known Recent species in the genus and a distribution table of the 13 fossil and Recent species are given. Javania erhardti often contains commensal boring sponges in its base.</ABSTRACT>

55805 <SOURCE>Neues Jahrbuch für Geologie und Paläontologie, Monatshefte 2003, 11: 641-644.</SOURCE>
55806 <ABSTRACT>The analysis of trace elements of thirty-four specimens of scleractinian corals from the Red Sea Coast indicates an enrichment in Cu, Pb, Ni, Zn and Co in Recent skeletons in comparison with their Pleistocene counterparts which were deposited in a pristine environment unaffected by human activities. Differences in the distribution patterns of trace elements among the Recent specimens are attributed in general to differences in microstructure and microarchitecture of the examined species. The highest concentrations are generally found in skeletons with loose crystal packing and high intergranular porosity (suborder Fungiina and occasionally Astrocoeniina), whereas the lowest concentrations are mostly recorded in skeletons with tight crystal packing as well as lower reactive surface area and intercrystalline porosity. The high concentrations of trace elements in Recent skeletons of scleractinian corals may be attributed to the increase of landfills, domestic sewage, phosphate mining and tourism activities in the Hurghada area.</ABSTRACT>

55856 <TITLE>Diversity and Distributional Patterns of Reef Building Scleractinians in Recent Lagoonal Patch Reefs on the Coast of Kenya.</TITLE>
55857 <SOURCE>Facies 16: 1-10.</SOURCE>
55858 <ABSTRACT>Four patch reef areas were mapped in detail within the microatoll zone of the narrow fringing reef near Kilifi (Coast of Kenya). The biota of these four test areas were counted according to frame building scleractinians and reef dwellers, including calcareous algae. The species diversity of the scleractinians was evaluated using the Shannon Wiener Theory Index. This index is small in landward

patches, increasing towards the inner microatoll zone with a maximum almost at the beginning of the rear reef. Here, this index becomes zero, probably owing to decreasing water depths that limit vertical patch reef growth within the lagoonal environment. The interaction between the substrate preparation by coralline algae and reef destruction by sea urchins are additionally important factors influencing this species diversity pattern. </ABSTRACT>

55870 <SOURCE>Senckenbergiana marittima 21, 1/4: 77-86.</SOURCE>
55871 <ABSTRACT>The Red Sea and especially the Gulf of Aqaba are characterized by mixed siliciclastic and marine carbonatic shallow water sediments. Alluvial fans of varying dimensions deposited during ephemeral flash floods continue into the marine environment. They are partly settled by calcareous biota. Coralline algae are prominent pioneer encrusters, however, scleractinians with spherical growth patterns occur as well. Such coralliths enclose a core of one or several pebbles of crystalline rocks. Their almost regular growth banding in the outer part of the sphere is caused by bioturbation of scarid and balistid fishes.</ABSTRACT>

55909 <SOURCE>Facies 27: 105-112.</SOURCE>
55910 <ABSTRACT>The growth history of some recent Porites colonies of Mauritius Island (Indian Ocean) was dated by sclerochronological methods. Couples of high-density and low-density bands represent the annual growth rate of the corals and allow the growth pattern of every year in the corallum to be counted. The growth and structure of the skeletons of Porites solida and Porites lutea were investigated. Older parts of the aragonitic skeleton in these 10 to 20 year old corals show various secondary microstructures resulting from alterations and thickenings of the elements of the skeleton. The primary needle-like aragonite crystals are absent in older parts of the corallum and blocky aragonitic cements can occur. Pores and primary skeletal elements are overgrown by new microstructures. These microstructures are caused by secondary cementation and exhibit frontal zones (Stirnzonen), zigzag-like and pseudolamellar-structures. The lamellar structures can be compared with similar structures in the exoskeleton of some Rugosa. A very short early diagenesis within the recent corals is responsible for the thickening and alteration of skeletal elements. It occurs only 4 to 5 years after formation of the skeleton and tends to increase in importance in older parts of the corallum. Nevertheless, there is no proof for any alteration of aragonite to calcite.</ABSTRACT>

55921 <TITLE>New species and new records of recently described species of the coral genus Acropora (Scleractinia: Astrocoeniina: Acroporidae) from Indonesia.</TITLE>
55922 <SOURCE>Zoological Journal of the Linnean Society 120, 1: 27-50.</SOURCE>
55923 <ABSTRACT>Six new species of the coral genus Acropora are described from Indonesia. These include a species which is remarkable for tubercular coenosteal structures similar to those of the confamilial genus Montipora. The new species include three regional endemics (A. togianensis and A. batunai from central east Sulawesi and A. derawanensis from east Kalimantan), one species with broad distribution across the southern island chains (A. sukarnoi) and two species which occur throughout most of the Indonesian archipelago (A. indonesia and A. hoeksemai). A further two species described from western Australia and Papua New Guinea in 1994 (A. turaki and A. jacquelineae respectively) are recorded from Indonesia for the first time, as common members of an unusual assemblage type in the Togian Islands. The range of another species described from Lombok in 1994 (A. suharsonoi) is extended into Bali. With A. desalwii, A. lokani and A. indiana, this brings to 12 the number of Acropora species newly recorded as being endemic to the Indonesian archipelago or to Indonesia and one adjoining region (either the Indian Ocean or the western Pacific). 55934 <TITLE>Stable isotopes from recent and fossil Porites sp. in the Northern Red Sea.</TITLE>
55935 <SOURCE>Coral Research Bulletin 05: 161-169.</SOURCE>
55936 <ABSTRACT>The stable isotopic composition of scleractinian corals (PISOTOPESorites sp.), two recent and one fossil, from the Egyptian Red Sea coast was studied. The oxygen isotope record proves the assumption that recent sea surface temperatures are comparable to the time of last sea level highstand in Eemian (stage 5e, 125.000yBP). Deposition of high-density and low-density bands in respect to season shows the same patterns as today with high-density band deposition in winter (low water temperatures) and low-density band deposition in summer (high water teperatures). $\delta^{18}O$ is negatively correlated with $\delta^{18}C$ with a shift in phase of 1 to 2 month. Thus, acoupling of carbon isotopes to light intensity and oxygen isotopes to water temperature is suggested. To get an overview on seasonal patterns of stable isotope composition a sampling technique with a resolution of four samples per year is of sufficient precision.</ABSTRACT>

55948 <SOURCE>Zoologische Mededelingen 065, 16 [24.12.1991]: 221-245.</SOURCE>
55949 <ABSTRACT>Three Indonesian species of Heterocyathus and two of Heteropsammia are briefly diagnosed. Remarks are given in their synonymy, phenotypic variation, and ecology. All five species are found on soft substrata in the proximity of coral reefs and live in association with a sipunculan worm. This interspecific association is discussed with regard to whether it is mutualistic or parasitic.</ABSTRACT>

55961 <SOURCE>Marine Geology 118: 187-194.</SOURCE>
55962 <ABSTRACT>Seasonal bands of the hard coral Porites sp. collected from

- three different islands of Lakshadweep (Northwest Indian Ocean) are examined under a scanning electron microscope (SEM). SEM photographs reveal the presence of detrital inclusions in high density bands and their absence in low density bands. It is proposed that during the monsoon season, run-off from the island may bring detrital material that subsequently gets incorporated in coral skeleton. By contrast, calm and dry conditions prevailing during the non-monsoon period preclude such incorporation due to non-availability of detrital material in the water column. In addition to the inclusions of detrital material, the presence of low-Mg calcite and carbonate cementation in seasonal bands are also observed. </ABSTRACT>

- 56026 <SOURCE>Zoologica 42, 3, 122: 1-75; Stuttgart.</SOURCE>
- 56027 <ABSTRACT>A short historical review shows that only very few corals are known from the Nicobars, though about 40 genera should occur there. During the "Xarifa" Expedition 1957/58 (led by Dr. Hans Hass) an extensive amount of coral was able to be collected from the north coast of the island of Great Nicobar and from the south-east of the island of Tillanchong. The corals are deposited in the Hessian State Museum at Darmstadt. * On the north coast of Great Nicobar collections had been made at two places in the Ganges Harbour, and off Tillanchong especially in the Castle Bay and there at the fringing reef, on the bottom of the bay and on steep rocky cliffs at the exit of the bay. A description of the reefs is given and the different collecting places characterized. * The systematic section deals with 110 species of 45 genera and 14 families. They are described and compared with related species and are followed by notes on their distribution. Many species are shown in photographs. The corals are systematically grouped in a list showing which species were collected at which station. * Two species are new, one genus was given a new name. 20 species were found to be also present in the Indian Ocean.</ABSTRACT>

56038 <TITLE>Scléactiniaires des îles Saint Paul et Amsterdam (sud de l'océan Indien).</TITLE>
56039 <SOURCE>Tethys 05, 4: 747-778.</SOURCE>
56040 <ABSTRACT>Etude de 11 espèces de Scléactiniaires récoltées en partie par la Valdivia (1898-1899), en partie récemment lors de campagnes de pêche à la langouste. Cinq espèces vivant en général à des profondeurs bathyales sont communes à l'Atlantique nord-oriental et aux îles Saint Paul et Amsterdam (Desmophyllum cristagalli, Lophelia pertusa, Madrepora oculata, Solenosmilia variabilis, Stenocyathus vermiformis). Certaines de ces espèces sont connues encore plus loin dans l'Océan Indien et même dans le Pacifique. Une espèce minuscule, interstitielle, et plutôt typique des faibles profondeurs, est étroitement apparentée à une forme de l'Atlantique nord-oriental (Sphenotrochus sp.). Caryophyllia profunda, espèce connue seulement dans les mers australes entre l'archipel Tristan da Cunha (sud de l'Atlantique) et les îles Chatham (sud-ouest du Pacifique) est comparée en détail à Caryophyllia cyathus de l'Atlantique nord-oriental. Compte tenu des méthodes de prélèvement et du nombre d'opérations effectuées dans des fonds probablement peu variés, un nombre assez réduit d'espèces de Scléactiniaires vivant dans les parages des îles Saint Paul et Amsterdam a été récolté. On ignore, en particulier, la faune de Scléactiniaires des fonds rocheux à faible profondeur.</ABSTRACT>

56078 <SOURCE>Bern [University?] Thesis; x + 141 pp., 49 figs, 17 tabs, 4 pls.</SOURCE>
56079 <ABSTRACT>The subject of this work are recent, massive hermatypic reef corals of the genera Pontes LINK and Platygyra Ehrenberg. Geochemical analyses of the aragonitic skeletons were used to investigate ecological aspects of the degraded littoral ecosystem of Mauritius Island. Water and sediment samples of the reef complex also were analyzed and correlated with coral analyses. [...] Eutrophication of the littoral ecosystem is one possible reason for the reef degradation in Mauritius Island. The detrimental influence of elevated heavy metal concentrations together with high phosphate concentrations on the vitality of reef corals can be shown. 56116 <TITLE>The foralgal crust facies of the deeper fore reefs in the Red Sea: a deep diving survey by submersible.</TITLE>
56117 <SOURCE>Geobios 23, 3: 261-281.</SOURCE>
56118 <ABSTRACT>Autochthonous organic frameworks from the deeper fore reef (-50 m to -110 m) of the Red Sea are composed predominantly of incrusting calcareous algae and foraminifera. This foralgal crust facies is represented by three types. The first is a pure foralgal crust community which forms small buildups with bumpy surfaces. Calcareous red algae and incrusting foraminifera comprise more than 60% of the biogenous fabric. The second type is a framework in which foralgal crusts are secondary binders around the hermatypic deep water scleractinian *Leptoseris fragilis*. The third type occurs on drowned reefs, exhibiting a mixture of Pleistocene shallow water and present day deep water binding species. Therefore, the morphology of this subfacies is more governed by an inherited relief, characterized by pinnacles and barrel shaped towers. This present day deep water foralgal community started to develop within the Cretaceous in shallow water environments, composed predominantly of corallineans, peyssoneliaceans, and subordinately of acervulinid foraminifera. With the beginning of the Neogene, the shallow water community of reef binding foraminifera and calcareous algae changed and became dominated by the foraminifera *Acervulina*. The living foralgal crust of the deeper fore reef in the Red Sea represent a binding community of Upper Cretaceous and Palaeogene shallow water environments which has shifted in greater water depths with time.</ABSTRACT>

56169 <SOURCE>Paleoceanography, 15, 4: 404-416.</SOURCE>
56170 <ABSTRACT>Stable isotope records from sclerosponges collected at 10-20m depth in the Indonesian Seaway and Solomon Islands are particularly well suited for reconstructing century-scale trends in ambient temperature variability and the oceanic uptake of fossil fuel carbon. Basal U/Th dates demonstrate that the sclerosponges analyzed [Astrosclera willeyana] are 85-100 years old. Isotopic records from the Indonesian specimens suggest a strong subsurface cooling over the past 20 years that is not manifested in either surface instrumental or shallower coral proxy records. However, analysis of observed subsurface temperatures in Indonesia, observed winds in the west Pacific, and simulated subsurface temperatures from a steady state general circulation model hindcast forced by observed winds combine to suggest that thermocline adjustments could account for at least part of the recent cooling inferred from the Indonesian sclerosponges. If so, the sclerosponge data suggests that, on average, the west Pacific thermocline has shoaled significantly over at least the past 2 decades. [original abstract]</ABSTRACT>

- 56195 <SOURCE>Journal of the Marine Biological Association of the United Kingdom 90, 1: 203-212.</SOURCE>
- 56196 <ABSTRACT>Sponges are rare in extreme environments, and very little is known about their adaptations to such settings. Evidence from two species in a marine-derived midwater stratified crater lake on Satonda Island (Sumbawa, Indonesia) suggests their production of gemmules (resting bodies), a rare trait in marine sponges but common in freshwater forms, may be a survival mechanism in the lake's harsh environment. With its epilimnion hydrochemistry characterized by changing alkalinity, salinity, and O₂ levels over the region's wet and dry seasons, the lake sustains only a few marine macroscopic organisms, among them the suberitid sponges *Protosuberites lacustris* comb. nov. and *Suberites* sp. (Hadromerida: Suberitida). Both species belong to the same group as sponges reported from other marine-derived lakes with strongly varying and extreme environmental (especially chemical) parameters. The morphological characters, taxonomic position, ecological adaptations, environmental conditions, and biota associated with the sponges in this ecologically unique site are presented here.</ABSTRACT>

- 56222 <ABSTRACT>In the fringing reefs of Ilisi Island, landwards from sea, the following facies can be recognized: a) sandy plain with isolated bathymetric heights (depth 8-12 m); b) high steepness fore-reef slope densely covered by corals (Sarcophyton) and branched poritids; c) reef rim covered by extensive masses of branched porites; d) flat reef characterized by little covering of corals and wide-spreading of biogenic coarse gravel-sized pieces; e) isolated patch reefs in the very thick thriving plain; f) upper subtidal-intertidal zone. Well developed Thalassodendron grasslands render an important contribution to the sediment production; most parts of the carbonate material derives from the mechanical destruction of the incrusting carbonate Red Algae growing around the stems. These muffs support the flourishing population of articulate corallinaceans. [original summary] </ABSTRACT>

- 56299 <SOURCE>Geologica Romana 35: 111-149.</SOURCE>
- 56300 <ABSTRACT>The Somali coast south of Kisimayo has been investigated and a modern depositional model is proposed. Several evolutive phases have been identified, corresponding to eustatic sea-level variations starting from isotope stage 5e, which led to the present coastal setting, characterized by mixed carbonate-terrigenous sedimentation and conditioned by climatic factors. The sea level fall below the continental shelf edge during the last glacial period caused subaerial exposure, erosion and weathering of the sedimentary substratum. As a consequence a braided fluvial net developed on the coastal belt and coastal dune ridges migrated toward the shelf edge, influencing the distribution pattern of the modern sedimentary and ecological environments. The Holocene inundation of the shelf caused the drawing of the channels, the overflowing of the interdune areas, the formation

of the Bajuni barrier island, of which coastal lagoons and channelized tidal flats. The relation among inherited morphology, supply of terrigenous material and development of coral communities is shown in a series of ecological profiles and sketch maps of facies distribution. The depositional systems of outer shelf, marine passes, coastal sound and braided channels have been investigated in detail in some key areas. The types of coral colonization as well as their interactions with seagrass meadows have been examined. In outer shelf corals grow in form of fringing reefs and coral carpets around the abraded flat of the islands and along some morphological steps corresponding to old sea-level stillstands. In the marine passes crossing the barrier island, the hard substrate is colonized by fringing and pinnacle reefs, coral carpets and knobs and their distribution is controlled by the energy dispersion of the tidal currents. In the coastal sound corals grow to form at places small fringing reefs and carpets along the protected edges of the islands and near the channel mouths, whereas patch and table reefs are found on isolated erosion remnants inside wide Thalassodendron meadows. The braided channelized area of the coastal belt is characterized by the development of mangal and salt flat depositional systems where the facies distribution is controlled by the extension of the tidal prism.

 56324 <TITLE>The Northern Bay of Safaga (Red Sea, Egypt): An Actuopalaeontological Approach. I. Topography and Bottom Facies.</TITLE>
 56325 <SOURCE>Beiträge zur Paläontologie Österreichs 15: 103-147.</SOURCE>
 56326 <ABSTRACT>Topographically the Northern Bay of Safaga can be subdivided into 4 parts: the East area; with water depths down to 55 m exposed towards the open sea, the shallow North area; the West area; with a central basin of 30 to 38 m depth, and the Southwest channel; which is connected to the Southern Bay. Mapping of the sea bottom allowed several bottom facies to be distinguished: 1) Coral reefs, which can be subdivided into fringing reefs, patch reefs (platform reef, miniatoll, pinnacle reefs), and coral patches. 2) Rock bottom, representing subtidal rocky substrate without or with sparse sediment cover and lack of dense stony coral settlement. 3) Coral carpet, showing areal covering of hard bottom by abundant stony corals without vertical zonation. 4) Sand bottom, where in addition to pure sands several other subtypes occur (sand with coral patches, sand with seagrass, sand with macroids, muddy sand). 5) Mud bottom, rich in infauna and lebensspuren. 6) Rocky tidal flats. 7)

- Mangrove. The bottom facies distribution is mainly controlled by the underlying morphology and by water currents. </ABSTRACT>

- 56339 <ABSTRACT>The use of video images saves considerable amounts of expensive underwater working time. Nevertheless a substantial amount of time is needed during image analysis. Further advantages and disadvantages of the video system, as well as its future use are discussed in detail. This study is a result of a larger programme which used video recordings to assess the health situation of coral reefs after the Gulf war. The more comprehensive findings of this programme are reported elsewhere (Vogt 1994). [end fragment of extensive summary]</ABSTRACT>

- 56352 <ABSTRACT>Holocene reef growth, present date bioerosion and recorded carbonate production were studied in the fringing reef at Aqaba, Red Sea. Water depth, wave impact as well as nutrient availability were considered. The carbonate production was measured for several coral samples. Samples of Porites colonies were collected from several depths and sites near the Marine Science Station at Aqaba. Growth rate depends on water depth, size and age of colonies. Within the coral optimum of water depth growth rates vary between 5 and 16 mm/yr. Coral carbonate production was calculated on the base of annual growth increments and skeletal density using transects from shallow subtidal down to 40 m water depth. High resolution stable isotope data were measured to prove the origin of growth increments. Long-term trends of sea surface temperature and carbon isotope shift (1800-today) fit to the known global deviations. Bioerosion rates were determined using standard dead coral substrates exposed in different water depths and environmental settings. Rates vary between 0.6 and 1.4 kg/m2yr. Sediment export evaluated by means of simple sediment traps ranges between 0.3 and 0.7 kg/m2yr. Gross carbonate production, mainly built up by scleractinian corals, amounts to ca. 1.57 kg/m2yr. Bioerosion alters approx. 1.3 kg/m2yr of hard substrates into sediment. Sediment export is estimated to be ca. 0.4-0.6 kg/m2yr. Thus a net production of ca. 0.7 to 0.9 kg/m2yr should remain in the present reef, which is proved by the

- recorded carbonate production (reef drillings). Net production preserved in the reef can be given with ca. 800 kg/m²kyr (=0.8 kg/m²yr).

- 56365 <ABSTRACT>Mayotte foreslopes exhibit a distinct pattern in the overall morphology, starting in the deep with an unlithified sedimentary wedge and slope, followed upwards by a cemented slope, and finally by a steep, almost vertical wall. On top of the wall, drowned reefs occur. Dated corals may reveal the history of sealevel changes indicating reef growth during isotope stage 3 (50-26 kyrs BP) at a present-day water depth that is deeper than 80 m and also has developed a coeval reef talus facies. A maximum sealevel drop of 150 m occurred during the last glacial maximum followed between 22-18 kyrs BP. This lowering of sealevel is documented by karst features such as small caves and corroded and jagged surfaces. The phase of deglaciation is recorded by two give-up reef levels at 100 m / 90 m water depth and 65 m / 55 m water depth which we may relate to the Belling (14 kyrs BP) and post Younger Dryas (11.5 kyrs BP) meltwater pulses, known from the deep-sea record.</ABSTRACT>

- 56378 <ABSTRACT>The present day coral growth and stable isotopic record from three latitudinal different islands in the western Indian Ocean were analyzed. All colonies grow at a water depth between 2m and 7m. Stable isotope records were obtained with a sampling distance of 1mm from the upper part of the cores that comprise between 3 and 6 years of coral growth. For the core from Mayotte additional annual samples were taken. Their record reaches back to the year 1920. From the southernmost location off La Reunion the most accentuated seasonal oxygen isotopic signal was found, indicated also by Sr/Ca ratios. The Mayotte samples showed a clear seasonal signal, where deposition of HD-bands is linked to rising seawater temperatures. From Mahe the oxygen isotopic signal

is less clear than at the other sites. Cores through the Holocene reefs of La Reunion and Mayotte indicate a reef growth of about 20m during the 9,000 years. There is a pronounced change in reef growth strategy, starting with a catch up mode in the order of 7m/1,000 years followed by a decreased reef growth after 5,000 years BP in the order of 1m/1,000 years. This difference in growth is related to the early Holocene Climatic Optimum and the fact that sealevel reached its present position about 3,000 years BP.</ABSTRACT>

56389 <TITLE>Subtropical Coral-reef Associated Sedimentary Facies Characterized by Molluscs (Northern Bay of Safaga, Red Sea, Egypt).</TITLE>

56390 <SOURCE>Facies 38, 1: 229-254.</SOURCE>

56391 <ABSTRACT>The shallow marine subtropical Northern Bay of Safaga is composed of a complex pattern of sedimentary facies that are generally rich in molluscs. Thirteen diver taken bulk-samples from various sites (reef slopes, sand between coral patches, muddy sand, mud, sandy seagrass, muddy seagrass, mangrove channel) at water depths ranging from shallow subtidal to 40m were investigated with regard to their mollusc fauna >1mm, which was separated into fragments and whole individuals. * Fragments make up more than 88% of the total mollusc remains of the samples, and their proportions correspond to characteristics of the sedimentary facies. The whole individuals were differentiated into 622 taxa. The most common taxon, *Rissoina cerithiiformis*, represented more than 5 % of the total mollusc content in the samples. The main part of the fauna consists of micromolluscs, including both small adults and juveniles. Based on the results of cluster-, correspondence-, and factor analyses the fauna was grouped into several associations, each characterizing a sedimentary facies: (1) *Rhinoclavis sordidula* - *Corbula erythraeensis* - *Pseudominolia nedyma* association; characterizes mud. (2) *Microcirce* sp.- *Leptomyaria* sp. association; characterizes muddy sand. (3) *Smaragdia* spp.- *Perrinia stellata* - *Anachis exilis* - assemblage; characterizes sandy seagrass. (4) *Crenella striatissima* - *Rastafaria calypso* - *Cordites akabana* - assemblage; characterizes muddy seagrass. (5) *Glycymeris* spp.- *Parvicardium sueziensis* - *Diala* spp.- assemblage; characterizes sand between coral patches. (6) *Rissoina* spp.- *Triphoridae* - *Ostreoidea* - assemblage; characterizes reef slopes. (7) *Potamides conicus* - *Siphonaria* sp. 2- assemblage; characterizes the mangrove. The seagrass fauna is related to those of sand between coral patches and reef slopes with respect to gastropod assemblages, numbers of taxa and diversity indices, and to the muddy sand fauna on the basis of bivalve assemblages and feeding strategies of bivalves. The mangrove assemblage is related to those of sand between coral patches and the reef slope with respect to taxonomic composition and feeding strategies of bivalves, but has a strong relationship to those of the fine-grained sediments when considering diversity indices. Reef slope assemblages are closely related to that of sand between coral patches in all respects, except life habits of bivalves, which distinctly separates the reef slope facies from all others.</ABSTRACT>

56404 <ABSTRACT>In the southern Red Sea lies the tiny Tongue Island. It is a small circular parasitic volcano derived from the large neighbouring island Djeoel Sukar. It is irregular in height, some parts are above, some beneath sea level. The rocks consist of dark brown lava and tuff-like breccia. It encloses a 40 m deep lagoon, about 555 m in diameter. The upper submerged parts of the crater are typically overgrown by corals. To depths of 2 to 11 m they include mainly Acroporidae (22 species), Poritidae (13) and Faviidae (25). In contrast, on the rubble of the fore-reef, in quieter waters 10 to 25 m deep, among others there are mainly mushroom corals (9) as well as rolling coral lumps of Cyphastrea serailia and Siderastrea savignyana. These same species lived in both habitats, although they differ in their growth form. This circular isle with its recent coral communities is reminiscent of an atoll. According to Alexander Von Humboldt (1806) atolls were formed on the scoria of volcanoes. Should the remaining parts of this crater ring become submerged in the future, Tongue Island would become a circular reef according to Humboldt's theory. This is quite a rare type of reef, distinct from the true atolls in Darwin's sense.</ABSTRACT>

56559 <SOURCE>Téthys, supplément 5: 133-156.</SOURCE>
56560 <ABSTRACT>Le secteur étudié correspond à la partie sud du Grand Récif de la Baie de Tuléar. Les facteurs du milieu pris en considération sont: les vents, la houle et les marées. Les courants de flot et de jusant ont des actions différentes sur les édifices récifaux particulièrement si l'on considère leurs actions sur les transferts sédimentaires. Ces facteurs déterminent différents types d'édifices récifaux. Leurs particularités sont définies si l'on considère les positions relatives des axes topographiques, morphologiques et de croissance par rapport aux directions de la houle et du vent. * Pour les analyses sédimentologiques, les valeurs des indices sont obtenues par calculatrice IBM 360/44. Je considère d'abord les faciès sédimentaires à l'intérieur de chaque zone morphologique. Ils sont déterminés en appliquant une nouvelle technique mathématique. Celle-ci est basée sur les propriétés d'une nouvelle représentation graphique qui est une spirale logarithmique. Par rapport aux autres représentations graphiques des sédiments, la spirale est définie par son équation mathématique. Les indices sédimentologiques des échantillons de faciès ont des valeurs déterminées qui ont une signification hydrodynamique. Un nouvel indice: le facteur hydrodynamique (FH) est aussi défini. Pour chaque unité morphologique de ces récifs, je donne rapidement la description des traits morphologiques et j'explique l'évolution sédimentaire en relation avec les houles et les courants de marée. * Cette étude précise la sédimentation et les mouvements des sables fins qui recouvrent la pente interne des édifices récifaux de ce secteur.

56571 <TITLE>The physiographic zonation and ecological conditions of some south Indian and Ceylon coral reefs.</TITLE>
56572 <SOURCE>In Proceedings of the Second International Symposium on Coral Reefs (22nd June to 2nd July 1973, Brisbane); Published by The Great Barrier Reef Committee; vol. 2: 3-30.</SOURCE>
56573 <ABSTRACT>On the occasion of the First International Symposium on Coral Reefs, 1969 in Mandapam Camp, South India, the ecological and sociological conditions of nine different reef sections off the coast of South India and Ceylon were examined with special emphasis on their morphological and structural aspects, their water movement and their light intensity. Coral growth and species distribution of corals were analyzed as well as the growth and distribution of the most abundant and predominant sea weeds and benthic animals. The results of these investigations were combined and compared with one another, and therefore allow characterization of typical physiographic zones, especially within three carefully analyzed reef areas: one reef composed of numerous small patches along Manauli Island near Mandapam Camp, one fringing reef plate with three steps to the open sea south of Hikkaduwa, Ceylon, and one typical small lagoon reef in front of the same place. All these investigations are part of a greater program concerning the influence of different abiotic ecological factors, especially of water exchange, lighting and substrate, on coral growth and reef zonation.</ABSTRACT>

- 56638 <ABSTRACT>L'analyse de la disposition et de la morphologie des édifices récifaux de la région de Tuléar et du modèle continental élaboré au début du Quaternaire, permettent de retracer les grandes lignes de la morphologie de cette période. Les édifices récifaux de la première génération (récifs externes), est-à-dire contemporains de la première transgression (tatsimienne), se sont implantés en suivant étroitement le canevas imposé par le réseau hydrographique. Cette implantation ne s'est pas faite uniformément sur le rebord du plateau continental mais uniquement selon les interfluves des vallons. Il s'est ainsi constitué une chaîne d'unités récifales qui, ultérieurement, sont devenues coalescentes. Les récifs internes et les bancs récifaux ont suivi, mais à un degré moindre, le canevas imposé par l'érosion fluviale.</ABSTRACT>

56677 <ABSTRACT>The present work is a comparative study of the coral reefs of the Mascarene Archipelago (La Réunion, Mauritius, Rodrigues). * The first part is a brief survey of the environmental factors. The second is a descriptive study of the main reef structures analyzed in terms of morphology and ecology: outer slope (from 0 to 15m, spurs and grooves zones of coral morphogenesis, from 15 to 25m, spurs and grooves zone of volcanic morphogenesis, from 25 to 50m, volcanic flagstone) lagoon formations, morphological discontinuities (passes, outer creeks and outfalls, inner creeks and reef pools). * The last part is a discussion on the common features and on the peculiarities of each island. The author gives also the distribution of hermatypic scleractinian coral

- genera in the Archipelago.</ABSTRACT>

56766 <TITLE>Patterns of accretion of reefs in the Sudanese Red Sea.</TITLE>
56767 <SOURCE>Marine Geol. 46: 297-325.</SOURCE>
56768 <ABSTRACT>Reefs in the North Towartit and Shambaya Groups of the Sudanese Red Sea rest on major blocks which have been defined by large-scale fault movement. The dominant surface features in these areas have been formed by the sub-aerial sculpting of the Tertiary and later limestones during late Pleistocene periods of low sea-level stand. This has resulted in the formation of large numbers of closed depressions reaching -60m depth. These punctuate a surface lying between -20 and -30m which is itself probably a residual of an older, undulating, higher level surface. The margins of depression are submarine cliffs, the smooth floors are blanketed with Recent sediments while the intervening ridges have become the sites for reef accretion. Riffbildnern des Roten Meeres.</TITLE>
56806 <SOURCE>Mitt. Geol.-Palaont. Inst. Univ. Hamburg 56 [Festband Georg
Knetsch]: 143-156.</SOURCE>
56807 <ABSTRACT>The isotopic composition of the carbonates in skeletons of
ecologically significant, benthonic genera (mainly corals) derived from
Red Sea fringing reefs and coral islands was studied. Between genera
and biozones distinct differences were noticed in the O18/O16 and
C13/C12 ratios. Corals from the reef edges have "lighter"
carbonates (down to -2% δC13 and 4% δO18) than organisms from
the lagoons (up to +4% δC13 and -2% δO18). * This trend was
noticed everywhere and is explained by higher salinities in the lagoons
(increase of δC13) and strong evaporation on the reef flats
(decrease in δO16). The regional depression of the δO18
ratios for about 1% in lagoonal carbonates is related to the general
rise in surface water temperatures from North (Egypt) to South (Saudi
Arabia). * In view of the isotope fractionations on the reef flats and
within the lagoons an indication of the temperatures should be
restricted to carbonates from corals of the reef edges. * Fossil reef
organisms (Pleistocene fringing reefs) have similar O18/O16 and C13/C12
ratios as their living counterparts. In spite of diagenetic changes,
the facies remains isotopically marked. [original summary]</ABSTRACT>

56818 <TITLE>Late Quaternary reef growth and sea level in the Maldives (Indian Ocean).</TITLE>
56819 <SOURCE>Marine Geology 250, 1-2: 104-113.</SOURCE>
56820 <ABSTRACT>Based on rotary drilling and radiometric and U-series dating, we present the first comprehensive data on Holocene reef anatomy and sea-level rise as well as nature and age of underlying Pleistocene limestone in the Maldives. Holocene reefs in Rasdhoo Atoll, central Maldives, are composed of four facies including (1) robust-branching coral facies, (2) coralline algal facies, (3) domal coral facies, and (4) detrital sand and rubble facies. Branching coral and coralline algal facies predominate the marginal reefs and domal corals and detrital facies preferentially occur in a lagoon reef. In addition, microbialite crusts are found in lower core sections of marginal reefs. Microbialites formed during the early Holocene in reef cavities. Holocene reef thickness ranges from 14.5 m to 22 m. Reef growth started as early as 8.5 kyr BP. Marginal reefs accreted in the keep-up mode with rates of 15 m/kyr. Rate of sea-level rise significantly slowed down from 7-6 kyr BP and subsequently gradually rose with rates of 1 m/kyr. The lagoon reef accreted in the catch-up mode with rates of around 4 m/kyr. Even though no indications of a higher than present sea level were found during this study, it is not entirely clear from the data whether the sea gradually rose to or exceeded present level in the late Holocene. Submarine cementation in Holocene reefs studied is rather weak, presumably as a consequence of high accretion-rates, i.e., short time available for consolidation. Pleistocene coral grainstone was encountered in one core at 14.5 m below present level and three U-series dates indicate deposition during marine isotope stage 5e ca. 135 kyr BP. 56870 <TITLE>Generation times and the Quaternary evolution of the reef-building corals.</TITLE>
56871 <SOURCE>Paleobiology 10, 1: 48-58.</SOURCE>
56872 <ABSTRACT>Faunal stasis among Indo-Pacific reef-building corals is explained as the result of chronic environmental disruptions preventing evolutionary processes from approaching completion since the Late Pliocene. The model assumes shallow reefal habitats (<20m) on the continental shelves are major sites of scleractinian evolution and explores ecological and evolutionary consequences of high-frequency sea-level fluctuations and their associated transgression-regression cycles. Because single generations, dominated by a few large clonal genotypes, may persist indefinitely, local populations may not have experienced enough generations to approach evolutionary equilibrium with their environments during the estimated average duration (ca. 3200 yr) of existence of shallow habitats. Persistent consequences of chronic evolutionary disturbance may be the extensive intraspecific variation so characteristic of the dominant genera of shallow Indo-Pacific corals and the apparent paucity of recently evolved endemic species. The same disturbances may have accelerated speciation rates among reefal organisms with much shorter generation times. (Original summary)</ABSTRACT>

56898 <ABSTRACT>The book contains results of the 1974-1977 expeditions of the
Institute of Marine Biology of the Far Eastern Science Center and other
institutes of the USSR Academy of Sciences to coral reefs of the
central Indo-Pacific Oceans. Papers included are on many subjects,
including methods for underwater research, reef community structure and
zonation, and the ecology and zoology of dominant reef organisms.
Particular attention is given to the life-forms of corals and their
associations with reef facies, problems of coral regeneration and
problems of reef ecosystem modelling. * It is hoped that this book will
be of interest to a wide range of specialists including reef
biologists, ecologists, biogeographers and paleogeographers.</ABSTRACT>

</TITLE>
56910 <SOURCE>Biologiya korallovykh rifov [B.V. Preobrazhenskiy & E.V.
Krasnov (eds)]: 159-175, 3 figs, 7 tabs.</SOURCE>
56911 <ABSTRACT>The paper offers a literature survey of different physical
and chemical methods of determination of annual linear growth rates.
There is comparison of results and an estimation of influence of
ecological factors on the form and annual increase of colonial reef
corals in paper. The best results were obtained using method of X-ray
in combination with staining of alizarine red in living corals. This
method permits determination not only of annual growth rate, but as
well to measure density of skeleton matters and of seasonal growth rate
of good preservation modern and fossil corals. * Seasonal layers
skeletal matter of the high density are formed in more high
temperatures, but layers of low density - in minimum temperature of sea
water. Layers with low density of skeleton matter are broader than

- layers with high density. The greatest linear growth is observed on the depths 9-10m. In the presence of zoochorella in endoderm the process of polyp's calcification is more rapid in light than in the darkness as well as at branches and at massive colonies.</ABSTRACT>

- </SOURCE>
56950 <ABSTRACT>The results on distribution patterns of the three most important coralline sponge taxa and related microbialites from Indo-Pacific coral reef caves are presented. The stromatoporoid taxon *Astrosclera*, the chaetetid *Acanthochaetetes*, and the thalamid *Vaceletia* are not equally distributed throughout the investigated areas. Distinctive distribution patterns were observed. All taxa are living in cryptic habitats, but *Astrosclera* was also found in dim-light zones and shaded overhangs. The related microbialites vary in relation to the sedimentological setting of the environment. Very well developed microbialites were found in environments influenced by the weathering of crystalline basement rocks (e.g. Lizard Island) and deep large caves within a carbonate basement (e.g. Marigondon Cave, Cebu / Philippines). Poorly developed microbialites were observed in open oceanic environments with carbonate basement rocks (e.g. Osprey Reef and reefs of the outer Great Barrier Reef).</ABSTRACT>

56961 <TITLE>The Reef Cave Dwelling Ultraconservative Coralline Demosponge *Astrosclera willeyana* Lister 1900 from the Indo-Pacific.</TITLE>
56962 <SOURCE>Facies 38, 1: 1-88.</SOURCE>
56963 <ABSTRACT>*Astrosclera willeyana* Lister 1900 is a pyriform-half spherical, predominantly bright orange colored, coralline demosponge with a mean size of about 20 mm in height and maximum head diameter. The habitat of *Astrosclera* is generally restricted to cryptic and light reduced environments of the Indo-Pacific, found mainly in reef caves, but sometimes also in the dim-light areas of cave entrances and overhangs, where it is green colored at the side towards the light. Caves of Indo-Pacific coral reefs were divided into four major facies zones, named 1 to 4 with decreasing light intensities. *Astrosclera* occurs in reef caves on a carbonate basement in Zone 2, 3, and 4, reaching maximum abundance in Zone 3 and the proximal part of Zone 4, but rare in the distal, very dark areas of Zone 4. Other abundant coralline sponges in reef caves are *Spirastrella* (*Acanthochaetetes*) *wellsi* and *Vaceletia crypta*. *Astrosclera* is the most common coralline sponge throughout the studied sites of the Indo-Pacific.</ABSTRACT>

56974 <TITLE>Description of a new species and subspecies of *Fieldingia*, erection of a new family *Fieldingidae* and a new order *Fieldingida* (Porifera; Hexactinellida; Hexasterophora).</TITLE>
56975 <SOURCE>Bolletino Mus. Inst. Biol. Univ. Genova 68 [M. Pansini, R. Pronzato, G. Bavestrello & R. Manconi (eds): *Sponge Science in the New Millennium*]: 623-637.</SOURCE>
56976 <ABSTRACT>Re-investigation of *Fieldingia* collected in the Indonesian Archipelago and described by Schulze (1887) as *F. lagettoides* and discovery of new similar specimens from the South China Sea and South

Central Pacific enable Schulzes specimen to be confidently accepted as Fieldingia. A new species, *F. valentini*, and a new subspecies, *F. valentini tizardi*, are described. The presence of complete spicule sets allow settlement of the problems with both dictyonal framework construction and loose spicule specification of the poorly known genus. These data provide the basis for erection of the Fieldingidae, a new family with a single recent genus. Based on the unique construction of the dictyonal choanosomal and dermal skeletons together with some other characters of loose spicules, a new order Fieldingida is established.

56988 <SOURCE>Precious Corals & Octocoral Research 1: 14-19.</SOURCE>

56989 <ABSTRACT>*Symphodium salomonense* Thompson & Mackinnon 1910, from Chagos Archipelago is found to be a species of *Corallium* morphologically similar to *Corallium tortuosum* Bayer 1956, from the Hawaiian Islands. Sclerites of both nominal species have been compared and illustrated by scanning electron microscope and demonstrated to represent a single species. Owing to minor differences in sclerites and wide geographical separation of type localities, the Hawaiian population is here treated as a subspecies of the senior nominal species.</ABSTRACT>

57026 <TITLE>New Species and a New Species-group of the Coral Genus Acropora (Scleractinia: Astrocoeniina: Acroporidae) from Indo-Pacific Locations.</TITLE>
57027 <SOURCE>Invertebr. Taxon. 8: 961-88.</SOURCE>
57028 <ABSTRACT>Eleven new species of the circum-tropical coral genus Acropora (Scleractinia: Astrocoeniina: Acroporidae) are described from material collected during a study of the biogeography of the genus worldwide. Previously known Indo-Pacific species of this genus mostly have broad distributions. The newly described species have been overlooked because they have more restricted distributions and in some cases they occur in deeper, rarely sampled, habitats; they thus contribute new information for assessment of the ecology and distribution patterns of the genus. Seven of the new species have low numbers of radial corallites relative to axial corallite number, a phenomenon uncommon amongst wellknown (and widely distributed) species. It is suggested that this character would result in low reproductive output and may be responsible for the limited range of the species concerned. The new species are assigned to existing species-groups and a new species-group is suggested to accommodate two new species and three other valid species.</ABSTRACT>

57039 <TITLE>A multidisciplinary approach to the definition of species boundaries in branching species of the coral genus Psammocora (Cnidaria, Scleractinia).</TITLE>
57040 <SOURCE>Zoologica Scripta 37, 1: 71-91.</SOURCE>
57041 <ABSTRACT>The Indo-Pacific coral genus Psammocora Dana (1846) has never been formally revised, and its phylogeny has only been partially explored. Several synonymies have been proposed for the 11 nominal species which have highly plastic branching growth forms. In the present study, the definition of genetic and morphologic boundaries among three currently recognized branching morpho-species, Psammocora stellata, Psammocora contigua and Psammocora obtusangula, is addressed through a joint morphometric and molecular study using corallite and branch measurements, and a portion of the β -tubulin gene as a marker. The results show a morphological and partial phylogenetic distinction between P. stellata specimens and a complex composed of P. contigua and P. obtusangula, which is interpreted as a synonym species of P. contigua. Among the factors that could be responsible for the lack of reciprocal monophyly of the three species, hybridization is considered the most likely, due to the presence of interspecific recombinant sequences. Type material of nominal species of branching Psammocora is examined and classified based on genetically defined groups, and compared with synonyms in the literature. Among the morphological

- characters used, corallite variables were best for discriminating between the two lineages and allow recognition of putative hybrid specimens. *Psammocora stellata* is reported for the first time in the western Indian Ocean (Mayotte), thus greatly extending its known distribution range. Finally, a hybrid swarm is identified in the Arabo-Persian Gulf, while no genetic structure is detected elsewhere in the Indo-Pacific region. [original abstract] </ABSTRACT>

57169 <TITLE>Searching for new morphological characters in the systematics of scleractinian reef corals: comparison of septal teeth and granules between Atlantic and Pacific Mussidae.</TITLE>
57170 <SOURCE>Acta Zoologica 90, 2: 142-165.</SOURCE>
57171 <ABSTRACT>Recent molecular analyses have challenged the traditional classification of scleractinian corals at all taxonomic levels

suggesting that new morphological characters are needed. Here we tackle this problem for the family Mussidae, which is polyphyletic. Most of its members belong to two molecular clades composed of: (1) Atlantic Mussidae and Faviidae (except *Montastraea*) and (2) Pacific Mussidae (*Cynarina*, *Lobophyllia*, *Scolymia*, *Symphyllia*) and Pectiniidae. Other Pacific mussels (e.g. *Acanthastrea*) belong to additional clades. To discover new characters that would better serve as phylogenetic markers, we compare the skeletal morphology of mussid genera in different molecular-based clades. Three sets of characters are considered: (1) macromorphology (budding; colony form; size and shape of corallites; numbers of septal cycles), (2) micromorphology (shapes and distributions of septal teeth and granules), and (3) microstructure (arrangement of calcification centres and thickening deposits within costosepta). Although most traditional macromorphological characters exhibit homoplasy, several new micromorphological characters are effective at distinguishing clades, including the shapes and distribution of septal teeth and granules, the area between teeth, and the development of thickening deposits. Arrangements of calcification centres and fibres differ among clades, but the fine-scale structure of thickening deposits does not. [original abstract] </ABSTRACT>

57182 <TITLE>Scientific Results from Investigations of Microbial Borers and Bioerosion in Reef Environments.</TITLE>

57183 <SOURCE>Goettinger Arbeiten zur Geologie und Palaeontologie, Special Volume 2 [Reitner J., Neuwiller F. & Gunke F. (eds): Global and Regional Controls on Biogenic Sedimentation I. Reef Evolution]: pp ???</SOURCE>

57184 <ABSTRACT>Experimental investigations at research sites in the Atlantic and Pacific have been designed to assess the factors that influence the distribution and abundance of microborers in reef environments. Results from the Bahamas indicate that site, depth, substrate type, and length of exposure period are important in controlling microborer populations and their rates of bioerosion. Cyanobacteria dominate intertidal limestone, a diverse assemblage of chlorophytes and cyanobacteria characterizes sites at depths between 2-30m, and the chlorophyte *Ostreobium quekettii* and heterotrophs are present from 100 to 300m water depth. Macro-bioerosion by grazers and borers also show site and depth differences. Investigations of experimental nutrient enrichment on the Great Barrier Reef suggest that the impact of the treatments on bioeroders may be masked by the natural nutrient levels within the endolithic habitat.</ABSTRACT>

57195 <TITLE>7. Jurassic coral genera from ODP site 639, Atlantic Ocean, west of Spain.</TITLE>

57196 <SOURCE>Proceedings of the Ocean Drilling Program, Scientific Results

- 103 [Boillot G., Winterer E. L. et al (eds)]: 89-103.</SOURCE>
57197 <ABSTRACT>1) The generic identification suggested for the corals studied in thin section from hole 639D includes Stylosmilia, Enallhelia, Pseudocoenia, Trocharea, Microsolena, cf. Calamoseris, cf. Dimorphastraea, Fungiastraea, cf. Thecosmilia, cf. Calamophylliopsis, cf. Dermosmilia, Lochmaeosmilia, and Intersmilia. 2) The sampling, though limited, emphasizes the importance of pennular and stylinid corals in the diversified coral collection. 3) The presence of Stylosmilia pumila (Quenstedt) indicates a Late Jurassic age, which does not contradict the presence of the other genera recorded. 4) The occurrence of the corals at hole 639D is episodic. At the base (cores 103-639D-13R through 103B-639D-11R, 103B-639D-8R, and 103-639D-7R), the corals are rare, tiny fragments that occur as oncoid nuclei or micritized grains. Their appearance indicates corrosion through transport from small colonies in muddy environments. In cores 103-639D-4R and 103-639D-5R, corals are common and are associated with calcareous and siliceous sponges, echinoderms, agglutinated benthic foraminifers, bivalves, and some calpionellids. They are in situ and although commonly heavily bored, definitely indicate that they were not transported. 5) The microfacies of the corals from cores 103-639D-4R and 103-639D-5R are characterized by a high content of mud; this mud seems to have been initially calcitic. 6) The corals do not reveal the proximity of a reef environment; rather, they were dwellers of soft muddy substrates below wave activity. In cores 103-639D-4R and 103-639D-5R, the associated organisms suggest a depth range from 30 to 70 m below sea level.</ABSTRACT>

57208 <TITLE>Remarks on the genus Arctangia wells, 1937, with the re-description of the type species Thecocyathus nathorsti Lindström, 1900 (Anthozoa: Scleractinia) from the Lower Cretaceous of Norway.</TITLE>
57209 <SOURCE>Proceedings of the Biological Society of Washington 118, 3: 479-482.</SOURCE>
57210 <ABSTRACT>The genus Arctangia wells is a poorly known group that consists of only the type species Thecocyathus nathorsti Lindström, 1900. The original description is the only documentation of the species. Including the first description of the genus Arctangia by wells (1937), all of the later interpretations of the species represent only adaptations of Lindström's original report. The present paper gives the re-description of the type species and also provides the first photographic images of this species based on newly discovered material.</ABSTRACT>

57221 <TITLE>Therese Mound: a case study of coral bank development in the

- Belgica Mound province, Porcupine Seabight. </TITLE>
- 57222 <SOURCE>International Journal of Earth Sciences (Geologische Rundschau) 96, 1: 103-120.</SOURCE>
- 57223 <ABSTRACT>High-resolution seismic profiles, swath bathymetry, side-scan sonar data and video imageries are analysed in this detailed study of five carbonate mounds from the Belgica mound province with special emphasis on the well surveyed Therese Mound. The selected mounds are located in the deepest part of the Belgica mound province at water depths of 950 m. Seismic data illustrate that the underlying geology is characterised by drift sedimentation in a general northerly flowing current regime. Sigmoidal sediment bodies create local slope breaks on the most recent local erosional surface, which act as the mound base. No preferential mound substratum is observed, neither is there any indication for deep geological controls on coral bank development. Seismic evidence suggests that the start-up of the coral bank development was shortly after a major erosional event of Late Oligocene-Quaternary age. The coral bank geometry has been clearly affected by the local topography of this erosional base and the prevailing current regime. The summits of the coral banks are relatively flat and the flanks are steepest on their upper slopes. Deposition of the encased drift sequence has been influenced by the coral bank topography. Sediment waves are formed besides the coral banks and are the most pronounced bedforms. These seabed structures are probably induced by bottom current up to 1m/s. Large sediment waves are colonised by living corals and might represent the initial phase of coral bank development. The biological facies distribution of the coral banks illustrate a living coral cap on the summit and upper slope and decline of living coral populations toward the lower flanks. The data suggest that the development of the coral banks in this area is clearly an interaction between biological growth processes and drift deposition both influenced by the local topography and current regime.</ABSTRACT>

- 57236 <ABSTRACT>This paper presents the results of a synthetic compilation of the studies of Neogene marine deposits recognized on the northeastern Atlantic coast from Morocco to northern France. The shoreline fluctuations as well as the tectonic and climatic events are discussed [...] * Marine Upper Chattian is well represented in the Aquitaine Basin (France), with various facies formed in a tropical climate. * During the Aquitanian and the Burdigalian, the transgressions extended in wide neritic gulfs in France, Portugal, Spain and North of Morocco. * The Middle Miocene transgression is well pronounced in the different areas. In the Betic-Rifian realm, overthrusts are established and the flysch resorption is concluded at the end of that time. * During the Upper Miocene, the marine realm is locally back from the preceding one; outstanding events occurred in the tectonic Betic-Rifian basin, the eastern part of which was affected by the Mediterranean salinity crisis during the Messinian. * Finally, in the Pliocene, most of the features of the modern palaeogeography are evidenced, even when the coastal

- frontage of several areas is still affected by little transgressions.

57313 <SOURCE>Revista Brasileira de Geociências 12, 4: 531-535.</SOURCE>
57314 <ABSTRACT>Four seismic refraction profiles on the Coroa Vermelha Reef, Abrolhos Bank, revealed the presence of a wave-velocity disconformity. Diagenetic alteration observed on a drill core from the same site at about the depth of the disconformity indicates that such a surface, developed on a limestone reef, is due to processes related to subaerial exposure. This evidence of subaerial exposure correlated with the last Pleistocene low stand of sea level, plus the morphology of the subsurface sequence as well as its faunal composition indicate that the underlying substrate of the Holocene Coroa Vermelha Reef is a reef limestone of a probable Pleistocene age. 57326 <SOURCE>Ciências da Terra 8: 22-24; Lisboa.</SOURCE>
57327 <ABSTRACT>The Abrolhos reefs, off the coast of Eastern Brazil, are the southernmost coral reefs in the Atlantic and are significantly

- different from the well known reefs in the Caribbean. These differences are in the reef-building organisms, the morphology, the surrounding sediments and the Quaternary history of the area. The reefs form two arcs which occupy a total area of approximately 6000 km². The basic element of most of the reefs is the *chapeiros*, mushroom-shaped pinnacles. In the coastal arc, the top of the adjacent *chapeiros* coalesces to form bank or platform reefs, 1 to 20 km long and with varied shapes. These bank reefs do not display the well marked zones of the Caribbean reefs. The outer arc, in waters 15 to 20 m deep, surrounds the volcanic island of the Abrolhos Archipelago and is formed by *chapeiros* that do not coalesce.

57339 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 179, 3-4: 159-171.</SOURCE>
57340 <ABSTRACT>Records of skeletal $\delta^{18}O$ in monthly and Sr/Ca ratios in half-yearly resolution were obtained from a Bermuda coral (*Diploria labyrinthiformis*) for the time period 1520-1603 (± 15 yr) AD within the Little Ice Age. Annual and decadal averages of both sea-surface temperature proxies indicate temperature variabilities of 0.5°C (standard deviation) and 0.3°C, respectively. Both numbers are close to recent instrumental observations. Approximately 30% of the interannual time series variance of $\delta^{18}O$ is concentrated in broad bands centered at periods of ~ 30 , 16 and 7.8 yr, the last two reflecting the influence of the North Atlantic Oscillation. Although this large-scale climate signal is present in the record, there is no correlation with other contemporaneous northern hemisphere proxy data, resulting from spatial differences in climate variability.</ABSTRACT>

57351 <TITLE>Large deep-water coral banks in the Porcupine Basin, southwest of Ireland.</TITLE>
57352 <SOURCE>Marine Geology 188, 1-2: 193-231.</SOURCE>
57353 <ABSTRACT>The Porcupine Basin, southwest of Ireland, was one of the earliest sites from where the deep-water corals *Lophelia* sp. and *Madrepora* sp. were recovered. These deep-water corals have since been found all along the Atlantic margins of Europe, in water depths ranging from 50 to more than 2000m. Recent geophysical studies have demonstrated the mound-building potential of deep-water corals. Available data indicate that three major provinces of coral bank occurrences can be identified in the Porcupine Basin: (1) high-relief surface mounds which have a dimension of 1 by 5km and a height up to 200m (*Hovland* mounds), flanked to the north by (2) a swarm

of buried mounds, somewhat smaller (up to 90m), and with more irregular shapes than those recognised in area 1 ('Magellan' mounds), and (3) outcropping or buried, conical mounds (single or in elongated clusters, up to 150m high) occurring on the southeastern slope of the basin ('Belgica' mounds). As far as can be inferred from shallow cores, the surface lithology predominantly consists of an upper layer rich in foraminiferal sand and terrigenous silty clay with intercalations of biogenic rubble. The banks host a remarkable number of colonies of living and dead *Lophelia pertusa* and *Madrepora oculata*. The living and dead assemblages are underlain by a significant layer of coral debris in a muddy matrix. Deep-water coral debris together with a living association of the same species covers the surface of the 'Belgica' and 'Hovland' mounds, which may suggest that these corals have played a significant role in the development of the mound structures. The capacity for mound formation by scleractinian corals in the aphotic zone has been known for some time. Examples are found at different locations along the shelves and the continental margins of the North Atlantic. The role of the corals in these deep-water build-ups is still a point of debate. Though the genesis and initial control of mound settings in this basin might be related to hydrocarbon seeps, it appears that the major development of the Porcupine coral banks in recent geological times has most likely been controlled by oceanic circulation and dynamics in water masses and nutrient supply. 57364 <TITLE>Morphology and environment of cold water corals carbonate mounds on the NW European margin.</TITLE>

57365 <SOURCE>International Journal of Earth Sciences (Geologische Rundschau) 96, 1: 37-56.</SOURCE>

57366 <ABSTRACT>Cold-water coral carbonate mounds, owing their presence mainly to the framework building coral *Lophelia pertusa* and the activity of associated organisms, are common along the European margin with their spatial distribution allowing them to be divided into a number of mound provinces. Variation in mound attributes are explored via a series of case studies on mound provinces that have been the most intensively investigated: Belgica, Hovland, Pelagia, Logachev and Norwegian Mounds. Morphological variation between mound provinces is discussed under the premise that mound morphology is an expression of the environmental conditions under which mounds are initiated and grow. Cold-water coral carbonate mounds can be divided into those exhibiting "inherited" morphologies (where mound morphology reflects the morphology of the colonised features) and "developed" morphology mainly reflecting dominant hydrodynamic controls). Finer-scale, surface morphological features mainly reflecting biological growth forms are also discussed.</ABSTRACT>

57390 <TITLE>A new species of Tanacetipathes from Brazil, with a redescription of the type species T. tanacetum (Pourtales) (Cnidaria, Anthozoa, Antipatharia).</TITLE>
57391 <SOURCE>Zootaxa 890: 1-12.</SOURCE>
57392 <ABSTRACT>The type species of Tanacetipathes Opresko, 2001 is Antipathes tanacetum Pourtalès, 1880. Pourtalès did not designate a holotype for A. tanacetum, nor did he indicate which form he thought was the most "typical" of the species. Because of the similarities of some of the syntypes with other nominal species, it is necessary to select a lectotype from one of the two groups with predominantly uniserial pinnulation. A specimen with short curved primary pinnules was chosen because it has a very distinctive pinnulation pattern that has been previously associated with Tanacetipathes tanacetum. With a lectotype of T. tanacetum designated, potential new species of Tanacetipathes can now be evaluated and compared directly with the type species. This is the case for T. paula n.sp., which is described here from the littoral of Archipelago of Saint Peter and Saint Paul (Brazil). This species has a corallum pseudo-dichotomously branched, with primary pinnules arranged in four rows and in alternating biserial groups of two pinnules each. The primary pinnules are up to 1.9cm in length. The secondary pinnules usually occur bilaterally, on both sides of the primary pinnules, and often in subopposite pairs, especially near the base of the primary pinnules. There are usually 3-9 secondary pinnules per lateral primary pinnules. The anterior primary pinnules always with only two secondary pinnules arranged in subopposite pair nearer the base of primary. The axial spines are relatively large, conical, acute and slightly papillose; the polypar spines up to 0.25mm tall and abpolypar spines up to 0.17mm. Polyps are not present on the type specimen.</ABSTRACT>

57403 <TITLE>The genus Igernella (Demospongiae: Dendroceratida) with description of a new species from the central Atlantic.</TITLE>
57404 <SOURCE>Bulletin de l'Institut royal des sciences naturelles de Belgique, Biologie 66, suppl. 1996 [Willenz P. (ed.): Recent advances in sponge biodiversity inventory and documentation]: 153-163.</SOURCE>
57405 <ABSTRACT>The genus Igernella Topsent, 1905 includes those dendroceratid sponges characterised by an irregularly reticulate

skeleton arising from a spongin plate and the presence of diactinal, triactinal, or tetractinal spiculoids. To date, two species of this genus are described : *Igernella mirabilis* Levi from the Indo-Pacific and *Igernella notabilis* (Duchassaing and Michelotti) from the central Atlantic. A re-examination of material previously assigned to the genera *Igernella* and *Darwinella* allowed us to detect the existence of a second species of *Igernella* in the central Atlantic. *Igernella vansoesti* sp.nov. is erected to include the specimens from the Cape Verde Islands assigned to *I. notabilis* by Van Soest (1993), and one specimen from the Gulf of Mexico formerly recorded under the name *Darwinella muelleri* Schulze by De Laubenfels. The specimen described as *Darwinella joyeuxi* Tosent by Little (1963) probably belongs to this species as well. The new species is distinguishable from *I. notabilis* by its massive growth habit -without conspicuous tubes-, a minutely conulose surface, small oscules, and a skeletal network, made of narrow primary and secondary fibres, denser than that of *I. notabilis*. There is an important amount of foreign material embedded in the mesohyl whereas it is scarce within the fibres or even absent. The absence of debris in the fibres of some species of *Igernella* suggests a close relationship between this genus and other genera of the family Darwinellidae. This is in agreement with a recent proposal of moving the genus *Igernella* from the family Dictyodendrillidae to the family Darwinellidae on the basis of their chemical affinities. 57416 <TITLE>A revision of Atlantic *Asteropus* Sollas 1888 (Demospongiae), including a description of three new species, and with a review of the family Coppatiidae Topsent 1898.</TITLE>

57417 <SOURCE>Bijdragen tot de Dierkunde 62, 1: 3-19.</SOURCE>

57418 <ABSTRACT>Various records of *A. simplex* Carter 1879 from the Atlantic are assigned to three new species of the sponge genus *Asteropus* Sollas 1888, viz.: *A. brasiliensis* sp.n., *A. vasiformis* sp.n., and *A. niger* sp.n., whereas *A. simplex* s.s. is restricted to the Indo-Pacific. A worldwide study of *Asteropus* specimens resulted in the conclusion that two species groups exist, namely *Asteropus simplex*-like species (with true sanidasters), and *Asteropus sarasinorum*-like species (with spiny microrhabds), as previously observed by Bergquist (1965, 1968). A newly discovered microsclere complement of trichodragmata in the first group strengthens the need for generic distinction of both lineages, and accordingly the name *Meloplus* Thiele 1899 is reinstated for the *Asteropus sarasinorum* species group. A key to the west Atlantic species of *Asteropus* is provided. The family allocation of *Asteropus* and associated genera in the Coppatiidae Topsent 1898 is discussed, with the conclusion that the family is undoubtedly a polyphyletic assemblage related to various astrophorid groups (Hooper 1986; van Soest 1991).</ABSTRACT>

57429 <TITLE>Soft tissue organization of the deep water hexactinellid Schaudinnia arctica Schulze 1900 from the Arctic Seamount Vesterisbanken (Central Greenland Sea).</TITLE>
57430 <SOURCE>Berliner geowissenschaftliche Abhandlungen E13: 301-313.</SOURCE>
57431 <ABSTRACT>Histology and ultrastructure of the hexactinellid arctic deep sea sponge Schaudinnia arctica are investigated. Various techniques of fluorescence microscopy proven to be very informative for the study of pofiferan soft tissues are applied. These methods for use in sponge research are explained in detail. The histology shows that Schaudinnia arctica on the whole corresponds with earlier models of hexactinellid organization. However, the collagenous mesolamella are surprisingly thick compared with those of other hexactinellids described so far. Spectacular accumulations of granular cells with larger inclusions are observed throughout the entire sponge body. Transitional cell types indicate an ontogenetic succession from archaeocytes to granular cells in Schaudinnia arctica. According to observations in UV-fluorescence microscopy with different staining methods, the large inclusions of these granular cells contain little glycogen, but high Ca²⁺-contents. According to comparisons with similar cells of demosponges, it is suggested that the granular cells may function as storage cells for lectins, which play an important role in the metabolism of sponges.

57442 <TITLE>Skeletal reorganisation affects geochemical signals, exemplified in the stylasterid hydrocoral Errina dabneyi (Azores Archipelago).</TITLE>
</TITLE>
57443 <SOURCE>Marine Ecology Progress Series 397: 197-208.</SOURCE>
57444 <ABSTRACT>The pure white fans of the stylasterid Errina dabneyi are a conspicuous feature on the upper bathyal slopes in Azorean waters and were documented and recovered alive with the aid of a submersible in the southern Faial Channel. Etched vacuum-epoxy-casts of the aragonite skeleton, studied by scanning electron microscopy, reveal the 3-dimensional internal architecture comprising coenosarc canal meshwork, dactylopores, gastropores and ampullae. Near the surface, the canals are narrow and interconnected in a regular 3-dimensional meshwork. Deeper inside, the canals are less abundant, more irregular and wider. This pattern implies that the skeletal architecture is modified during growth, with more central canals being enlarged by dissolution, and other canals, gastropores and dactylopores in turn being filled with aragonite reprecipitates. The skeleton is primarily composed of irregular spherulitic aggregates and overprinting during growth is evident from ghost structures in the form of successive semi-spherulitic infill of former canals. Due to differential dissolution and reprecipitation, this internal rebuild process inevitably involves an alteration of initial geochemical signatures such as stable isotope ratios ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$), trace element signals and the distribution of radiogenic isotopes of carbon and uranium. This has to be taken into account when applying radiometric dating techniques and when using stylasterids as a geochemical archive.

57455 <TITLE>The Stylasteridae (Cnidaria, Hydrozoa) of the BIOFAR project.
</TITLE>
57456 <SOURCE>Northurlandahusith arsrut 1991-92: 78.</SOURCE>
57457 <ABSTRACT>Stylasteridae are calcified colonial hydroids. Their polyps are differentiated into gastrozooids (feeding polyps) and dactylozooids (defensive polyps) that are housed in the corresponding gastro- and dactylopores of the skeleton. Taxonomy is essentially based on these and other skeletal characters. There has been confusion of Stylasteridae with Bryozoa, and vice versa. Previous records of stylasterids are rare from around the Faroe islands and adjacent areas, where the earliest records date back to 19th century expeditions. BIOFAR has now provided abundant new information on the stylasterid fauna of Faroese waters. Four species have been collected from 54 stations (depth 133-1099m) around the islands: Pliobothrus symmetricus Pourtales 1868, Stylaster erubescens Pourtales 1868, S. gemmascens (Esper 1794), S. norvegicus (Gunnerus 1768). The two genera are morphologically very different, Pliobothrus having gastro- and dactylopores randomly arranged, Stylaster having gastro- and dactylopores arranged in cyclo-systems. Although containing only these few species (previously recorded by the Danish INOOLF expedition in 1895/96 and studied by Broch in 1914), the BIOFAR collection is the richest and includes all species ever obtained in high latitudes of the N Atlantic. S. gemmascens and S. norvegicus occur only from Norway to Denmark Strait, Rockall plateau being the southern outpost. On the contrary, P. symmetricus recorded from Norway to SE of Iceland and S. erubescens recorded from the Faroes to Denmark Strait, also occur at much lower latitudes in the N Atlantic and are even amphiatlantic in distribution, a pattern rare in this group of corals if compared with the scleractinians. The high latitude populations of S. erubescens differ in some details from the typical low latitude ones of the W Atlantic (Yucatan through Florida to South Carolina). Polynoid polychaetes and Pedicularia gastropods, known to be frequent symbionts of stylasterids world-wide, are absent from the high latitudes (northernmost occurrence of Pedicularia on P. symmetricus and S. erubescens at 48°38'N in the Celtic Sea). Distribution of stylasterids in relation with water masses in the N Atlantic deserves special attention. Previously available data on occurrence in high latitude suggested that stylasterids do not occur deep in the Arctic basin beyond a line connecting, roughly, Norway, the Faroes, Iceland and Greenland. 57481 <TITLE>The unpublished plates for A. E. Verrill's unfinished report on the Alcyonaria of the A. Blake's expeditions.</TITLE>
57482 <SOURCE>Dept. of Zoology, National Museum of Natural History, Washington, DC; 8pp + 156 pls.</SOURCE>
57483 <ABSTRACT>This publication deals with a very limited set (50) of the unpublished octocoral plates of A. E. Verrill (1839-1926) was one of the most prolific and influential marine invertebrate zoologists of the late nineteenth and early twentieth centuries, having published over 350 papers in which he described over 1000 new species pertaining to almost every marine group. When he died at the age of 87 he left behind an unfinished monograph on the western Atlantic octocorals consisting of over 1000 pages of text and 156 meticulously drawn plates, much of the artwork done by Verrill's son Alpheus Hyatt Verrill. The text was lost, but over the years Dr. Frederick (Ted) Bayer, curator emeritus in the Department of Zoology, accumulated a unique, complete set of plates and a copy of Verrill's captions to those plates, in which Verrill alludes to the names of several hundred new taxa. Bayer painstakingly reassembled the plates, transcribed and annotated the captions, and then had 55 copies of the work published for general distribution. Thus, 78 years after his death, at least a part of Verrill's magnum opus can be used to help illustrate the deep-water western Atlantic octocorals, this work constituting the last publication of this prolific naturalist. The plates alone constitute an invaluable resource on the taxonomy of this group, and should be consulted by any serious student of the group.</ABSTRACT>

57585 <TITLE>Norwegian corals: radiocarbon and stable isotopes in Lophelia pertusa.</TITLE>
57586 <SOURCE>Boreas 11: 163-171.</SOURCE>
57587 <ABSTRACT>The ahermatypic coral Lophelia pertusa which produces aragonitic skeletons is widely distributed along the Norwegian coast. Specimens from a number of localities have been analyzed for oxygen and stable carbon isotope composition and 14C age. Stable isotope ratios of recent corals provide information on growth rate and seasonality of oceanographic conditions. Lophelia can be useful in paleoenvironmental reconstructions. 14C dates of fossil Lophelia from Dribak in the Oslofjord, collected from 20 m above and 40 m below present day sea-level, indicate regional extinction between 8700 and 7800 years ago. We suggest that the extinction resulted from the cut-off of deep waters by a rising sill in connection with the postglacial shoreline displacement. Radiocarbon dating of coral bushes suggests a fairly rapid growth rate as older and younger parts of recent corals do not reveal any difference in activity despite the short time scale of the history of bomb-produced 14C in the oceans.</ABSTRACT>

57612 <SOURCE>Northurlandahuih arsrut 1991-92: 78-79.</SOURCE>
57613 <ABSTRACT>Previously published records of scleractinian corals from around the Faroe Islands are rare and include, as a curiosity, a West Indian brain coral (Diploria) found attached to a stem of wood that floated into westmanshavn during the month of March 1891. In addition, some species had been obtained by early expeditions (Lightning, Porcupine, Knight Errant, Triton, Michael Sars, etc.) in areas adjacent to the Faroes (Faroe Channel, Shetlands, Hebrides, northern end of Scotland). Biofar has now provided abundant new information on the scleractinian fauna of Faroese waters. Fifteen species have been collected from 51 stations (depth 180-1099m) around the islands: the solitary species Caryophyllia abyssorum Duncan 1873, C. atlantica (Duncan 1873), C. seguenzae Duncan 1873, C. smithii Stokes & Broderip 1828, Desmophyllum cristagalli Milne-Edwards & Haime 1848; Flabellum macandrewi Gray 1849, Fungiacyathus fragilis G.O. Sars 1872, Leptopsammia britannica (Duncan 1870), Stenocyathus vermiformis (Pourtales 1868), Stepharocyathus moseleyanus (Sclater 1886), S. nobilis (Moseley 1873), Vaughanelia concinna Gravies 1915 and the colonial species Lophelia pertusa (Linnaeus 1758), Madrepora oculata Linnaeus 1758, Solenosmilia variabilis Duncan 1873. 57637 <TITLE>Ahermatypic Coral Banks off Mid-Norway: Evidence for a Link with Seepage of Light Hydrocarbons.</TITLE>
57638 <SOURCE>Palaios 13, 2: 189-200.</SOURCE>
57639 <ABSTRACT>Large (up to 31-meter high) coral banks (or bioherms) occur on the continental shelf off mid-Norway at water depths between 220 and 310 meters. They are built up by the cold-water, ahermatypic, scleractinian coral Lophelia pertusa (L.). A 3-km-wide and 200-km-long traverse was mapped geophysically across a large part of the mid-Norway shelf. A total of 57 suspected individual banks were found. Although

they occur in local clusters of up to 9 banks per km², the mean density along the whole transect is only 0.09 suspected banks per km², with the highest regional density (1.2 banks per km²) occurring above subcropping presumed Paleocene bedrock. A detailed investigation employing an ROV (remotely operated vehicle) was conducted of a cluster consisting of 9 individual banks. Based on geophysical, visual, geochemical, radiocarbon, and other analyses, we conclude that at least some of the coral banks have been forming at the same locality for over 8,000 years, and that there is a strong correlation between coral-bank occurrence and relatively high values of light hydrocarbons (methane, ethane, propane, and n-butane) in near surface sediments. To explain the structure and distribution of these coral banks, we propose a model where they form as a consequence of local fertilization that results from focused hydrocarbon micro-seepage of deep thermogenic hydrocarbons migrating to the surface along inclined, permeable sedimentary strata. A direct corollary of this model is that if and when the source of local fertilization is shut off, the bioherms die out. This possibly could be the reason why extinct bioherms are more common than live ones in some areas of the ocean.

57650 <TITLE>Redescription of *Sclerhelia hirtella* from Saint Helena, South Atlantic, and remarks on Indo-Pacific species erroneously referred to the same genus (*Scleractinia*).</TITLE>
57651 <SOURCE>J. nat. Hist. 1974, 4: 563-575.</SOURCE>
57652 <ABSTRACT>*Sclerhelia hirtella* (Pallas, 1766), type species of *Sclerhelia*, is redescribed from samples from Saint Helena, South Atlantic, and referred to the family Caryophylliidae. Up to now there is no confirmation on the occurrence of *S. hirtella* at any locality other than Saint Helena. Here, the species lives in rather shallow water but it is unknown whether symbiotic zooxanthellae are present in the soft parts. * The species from the Maldives and Indonesia known as *Sclerhelia formosa* (Alcock, 1898) is not congeneric with *Sclerhelia hirtella* but close to *Madrepora oculata* Linné, a species conventionally placed in the family Oculinidae. * The species from the Marshall Islands, described by wells (1954) as *Sclerhelia alcocki* is a dendrophylliid coral identical with *Dendrophyllia palita* Squires & Keyes, 1967, from New Zealand. The Maldives are the third area where this species is known (the original record having been confused with another dendrophylliid species).</ABSTRACT>

- 57677 <SOURCE>Bulletin Inst. Océanogr. 71, 1429: 1-48.</SOURCE>
- 57678 <ABSTRACT>Des représentants du genre *Javania*, essentiellement bathyaux, sont très répandus dans la faune actuelle du monde entier. Une nouvelle espèce, *J. pseudoalabastra*, est décrite d'après du matériel des Açores (récolté en partie en 1888, par le Prince Albert Ier de Monaco). Confondu longtemps avec le genre *Desmophyllum*, le genre *Javania* doit être attribué à la famille des Flabellidae. Jusqu'à présent, l'absence d'exosarque avait été considérée comme un caractère principal de cette famille. Or, cette conception est à modifier. Chez *Javania*, la fixation au substrat est renforcée par des couches massives concentriques de sclérenchyme qui entourent le pédoncule original. Un exosarque doit être à l'origine de ce sclérenchyme. * Les genres précédemment reconnus par les auteurs dans la famille des Flabellidae sont commentés; une proposition pour redistribuer en neuf groupes les formes actuelles de cette famille est faite. Un tableau comparatif résume les caractères principaux de ces groupes proposés qui pourraient avoir le rang générique.</ABSTRACT>

- 57717 <ABSTRACT>A total of 19 conspicuous species was inventoried by scuba diving along 10 depth-transects, 0 to 33m depth. Multivariate analysis allowed the recognition of 5 cnidarian zones, namely: lower midlittoral zone, Millepora zone, mixed coral zone, overhang zone, gorgonian-antipatharian zone. Species substitution with depth is mainly related to gradients in light intensity and water movement; the possible role of competition and predation is also discussed. Although no true coral reefs exist at Sal, the observed zonation patterns are consistent with those typical of coral reef areas.</ABSTRACT>

57808 <ABSTRACT>Contrasting with what is known about the growth of coral reefs in clear waters with minimal runoff of fresh water and sediment from land, the coastal reefs of Abrolhos, the fringing reefs around the Itaparica Island and the coral constructions at the Guarajuba Beach are surrounded and even infilled with muddy terrigenous sediments. Radiocarbon dates from a Holocene core boring revealed that the reefs accumulated at an average comparable with the average of growth of coral reefs in clear waters. This surprisingly demonstrated that the reef organisms, of the studied areas, are adapted to the previous accepted conditions of an inhospitable environment for reef growth. Yet, the growth forms of the reefs, the strong endemism of their coral fauna as well as the effects of the Quaternary history of the area, make these reefs quite different from the well known Caribbean models.</ABSTRACT>

57820 <SOURCE>XXXII Congr. brasil. Geol. (Salvador, Bahia): 263-299.</SOURCE>
57821 <ABSTRACT>The Itaparica reef, in very shallow waters, has a flat top which stays exposed during low tides. The reef front lacks the Spur and Groove system and the back reef zone is represented by extremely shallow lagoons without patch reefs. Millepores and coralline algae contribute more to this reef than in the Caribbean reefs. In contrast with the predominance of carbonate sediments surrounding most reefs in the North Atlantic, the Itaparica reef is surrounded by sediments with a high amount of siliciclast components. An intensive activity of burrow and boring organisms is detected in the reef area, between the localities of Gamboa and Penha. Molluscs, annellids, sipunculids and arthropods produce distinctive boring structures on the reef structure and rock outcrops in the studied area. Communities of Decapoda (Crustacea), Gastropoda and Polychaeta are the major organisms responsible for excavations, pellets, fecal pipes and track dirt on the sandy and muddy substrates. The limitation of every of these communities can be easily defined, however, superpositions exist in the intertidal zone. [abridged original abstract]</ABSTRACT>

57846 <SOURCE>Facies 47, 1: 179-200.</SOURCE>
57847 <ABSTRACT>Cool-water carbonates in the aphotic zone of deep shelf and continental margin settings in the Northeast Atlantic are produced by deep-water coral reefs with Lophelia pertusa as the major framework builder. Through a compilation of side scan sonar, airgun and manned submersible surveys from several cruises to the mid-Norwegian Sula Reef Complex (SRC), the facies pattern and zonation of one of the largest deep-water reefs in the Northeast Atlantic is described in relation to the overall seabed topography. The late glacial to early postglacial iceberg scour on the crest and shoulder of the Sula Ridge provides settling ground for the scleractinian corals already in the early Holocene. Since then coral growth continues until today but was supposed to be disturbed by an environmental hazard, the so-called second Storegga event. The distinct distribution pattern of individual Lophelia reefs on the Sula Ridge has stimulated a discussion on intrinsic environmental controls such as the benthic-pelagic coupling and the alternative hydrocarbon-based nutrition hypothesis.</ABSTRACT>

57858 <TITLE>Styles of reef accretion along a steep, shelf-edge reef, St. Croix, U.S. Virgin Islands.</TITLE>
57859 <SOURCE>Journal of Sedimentary Petrology 56, 6: 848-861.</SOURCE>
57860 <ABSTRACT>Seven horizontal cores were taken from the reef-dominated margins of Salt River submarine canyon, St. Croix, U.S. Virgin Islands at water depths of 14-30 m. The pattern of east-to-west sediment transport in the area exerts a major control on present-day reef morphology, as well as accretionary styles recorded in the cores. Coral growth is inhibited by sedimentation on much of the eastern (heavily stressed) margin, and slopes are gentle. The regular pattern of

alternating reef growth and sedimentary infill in the eastern cores reflects this highly variable environment. On the west wall, away from the source of incoming bedload sediment, coral cover is much greater, and a vertical reef wall forms the canyon margin. Slumping of the steep reef face has caused numerous repetitions of section and, in some instances, accretion rates higher than the growth rates of calcifying organisms occupying the present or past reef surface. This slumping process, along with the highly dissected character of the reef, results in larger sections of reef framework separated by open or sediment-filled vugs and caverns. ¹⁴C dates indicate that this complex constructional history has resulted in at least 24 m of lateral accretion during Holocene time. Average lateral-accretion rates in the cores varied from 0.84 to 2.55 m/1,000 yr, with the highest rate occurring in the core from deepest water. Intervals of rapid accretion within the cores were not generally related to patterns of in situ coral growth, but rather with intervals of allochthonous material slumped from the shallower portions of the reef complex. The character of the cores illustrates the potential importance of detrital material and late-stage reworking in the accretion of shelf-edge reefs. The high rates of accretion at depth highlight potential problems with reef models based on net accretion paralleling the abilities of the present-day surface organisms to produce calcium carbonate. </ABSTRACT>

57871 <TITLE>Carbonate budget of a cold-water coral carbonate mound: Propeller Mound, Pocupine Seabight.</TITLE>

57872 <SOURCE>International Journal of Earth Sciences (Geologische Rundschau) 96, 1: 73-83.</SOURCE>

57873 <ABSTRACT>High resolutions studies from the Propeller Mound, a cold-water coral carbonate mound in the NE Atlantic, show that this mound consists of ~62% carbonate justifying the name 'Propeller carbonate mound'. Through the last ~ 3000,000 years approximately one third of the carbonate has been contributed by cold-water corals, namely *Lophelia pertusa* and *Madrepora oculata*. This coral bound contribution to the carbonate budget of Propeller Mound is probably accompanied by an unknown portion of sediments buffered from suspension by the corals. However, extended hiatuses in Propeller Mound sequences only allow the calculation of a net carbonate accumulation. Thus, net carbonate accumulation for the last 175 kyr accounts for only less than 0,3 g/cm²/kyr, which is even less than for the off-mound sediments. These data imply that Propeller Mound faces burial by hemipelagic sediments as has happened to numerous buried carbonate mounds found slightly to the north of the investigated area.</ABSTRACT>

57884 <TITLE>Holocene Reefs of Bermuda.</TITLE>

57885 <SOURCE>Sediments 11: 1-62.</SOURCE>

- 57886 <ABSTRACT>Reefs of the Bermuda Pedestal, well north of the Caribbean reef province, have interested scientists since Darwin. The attributes of these reefs, unique to the Atlantic-Caribbean area, are well documented in this new guidebook. The text of this slim volume begins with six single spaced pages of introduction, regional geology, and previous studies followed by seven pages of description outlining the nature of the reefs themselves, their coelobite communities, and their relationship to Caribbean reefs and concludes with six pages discussing the biotic factors which affect the reefs, their diagenesis, and their associated sediments. This is followed by a welcome 12 pages of references. The eight diagrams and 29 photographs (underwater and aerial closeups of the reefs) are on glossy paper and grouped together after the references. Appendix I outlines three whole-day reef trips with a description of each stop. Appendix II is a list of the corals in Bermuda while Appendix III is a key to the corals together with pictures of 18 corals which can be used for identification. This is a clearly printed and easily readable book. It is a scholarly work, an excellent source of up-to-date information on Bermuda reefs by someone who has studied these reefs for over a decade. As such it is both a handy guide and a handy reference. I would have liked slightly larger photographs and interwoven text and figures/photographs, but at this price who can complain. I am writing this review at the Bermuda Biological Station in the final days of a field trip with students and so have field tested this guide. If you are planning such a trip this book is a must, if you are at all interested in living reefs I highly recommend this inexpensive publication. [reviewed by Noel P. James]</ABSTRACT>

57923 <TITLE>The Fauna associated with the coral *Lophelia pertusa* around the Faroes.</TITLE>
57924 <SOURCE>Northurlandahuith arsrut 1991-92: 79 pp.</SOURCE>
57925 <ABSTRACT>Banks of *Lophelia pertusa* have been recorded at several localities round the Faroe islands concentrated on the edges of the banks and the Faroe shelf at depths between 250 and 400m. Coral formations can exceed hundreds of metres in width and tens of metres in height. *Lophelia pertusa* is a colonial, branching, ahermatypic coral. The coral bank is inhabited by a rich associated fauna. We have examined more than 5700 individuals belonging to 301 species from 18kg of coral. Of the list of 301 associated species, 97 are new to "The Zoology of the Faroes". The associated fauna has a calculated Shannon-wiener diversity index of 5,26. This is similar to that found on tropical coral species. This indicates that *Lophelia* coral banks has a link to productive high energy areas. The living part and the dead part of *Lophelia pertusa* house different species. Specialized species are capable of resisting the defence of the living coral. Typically, the number of individuals is much higher on dead coral blocks. Polychaete are the dominating group on the coral bank. We found 72 species and more than 1800 individuals. Sessile epibionts are the most numerous organisms on *Lophelia pertusa*. A lot of these are colonial species, which we have not quantified. The active filter feeders are the most numerous group of feeding types on the coral bank. Decomposition of the corals is carried out primarily by 2 species of boring sponges that erode the coral branches from inside. Comparing the fauna from *Lophelia pertusa* in the Faroe area with other studies on *Lophelia* fauna we find about the same number of species on Norwegian and French *Lophelia* banks. It appears that the associated fauna is rather facultative than being an obligate *Lophelia* fauna.</ABSTRACT>

57936 <TITLE>Facies belts and communities of the Arctic Vesterisbanken Seamount (Central Greenland Sea).</TITLE>
57937 <SOURCE>Facies 27: 71-104.</SOURCE>
57938 <ABSTRACT>The Arctic Vesterisbanken Seamount, situated far offshore in the central Greenland Sea, provides a unique facility for studying modern cold water siliceous carbonate deposits. A nearly year round sea ice cover, which retreats on average only during two months, and a rather constant temperature and salinity structure of the water column characterize the Arctic conditions of the area. Despite predominantly oligotrophic conditions with a pronounced food supply from the pelagic realm only during the ice-free season, the seamount is covered extensively by extended sponge-bryozoan constructions. Three distinct facies belts reveal a pronounced depth zonation which depends on variations in downslope food transfer and which is specifically effective due to the development of a Taylor current regime over the seamount. i) the crest facies from the summit at -133m to -260m, ii) the shallow slope facies from -260m to -400m, iii) the deep slope facies from -400m down to the abyssal plain at about -3000m. Different

biogenic structures and communities are found within these facies belts, including widely extended biogenic mats, sponge-bryozoans-serpulid buildups with mounds, hedges, spurs and flatcake-like structures, bryozoan thickets and sponge-crinoid mounds. Depth zonation, internal structure and controlling parameters in the formation of these biogenic structures are discussed in the context of their significance as a modern end member of the Foramol facies and their implications for the fossil record. In addition, the younger volcanic and hydrothermal history of the seamount is presented with special reference to its bearing on Holocene biogenic colonization patterns.</ABSTRACT>

57950 <SOURCE>Mar. Geol. 110: 213-243.</SOURCE>

57951 <ABSTRACT>Consolidated to friable carbonate rocks found in the Lee Stocking Island area in the Exuma Cays include: (1) reef rock, (2) channel stromatolites, (3) shallow-water hardgrounds, (4) beachrock rimming the islands and (5) Pleistocene bedrock. The most common cement fabrics observed are: aragonitic fibers, which include acicular fan-druse and square-tipped coarse fibers cementing beachrock and stromatolites; and an isopachous needle-fiber rim cementing hardgrounds and stromatolites. 57962 <TITLE>Nordic Cold-water Carbonates: Occurrences and Controls.</TITLE>

57963 <SOURCE>Goettinger Arbeiten zur Geologie und Palaontologie, Special Volume 2 [Reitner J., Neuwiller F. & Gunke] F. (eds): Global and Regional Controls on Biogenic Sedimentation I. Reef Evolution]: pp ???</SOURCE>

57964 <ABSTRACT>Along a latitudinal transect from cool-temperate to Arctic environments, various carbonate production zones were investigated. Biogenic carbonate sediments formed on high latitudinal shelves of the northern Hemisphere became established during the last glacial to interglacial transition. Major sites of production are: 1) rocky coastal platforms with a complex morphology providing habitats for coralline algae and kelp forests, 2) the shallow shelf where intense mixing of nourished waters favors the formation of bryozoan- or barnacle-dominated biocoenoses, 3) the deep aphotic zone where topographically-guided gyres promote the development of azooxanthellate coral mounds. True polar carbonate factories exist along the flanks of the seamount Vesterisbank. Due to local downwelling, bryozoan-siliceous sponge buildups benefit from the benthic-pelagic coupling of food particle transfer. The largest open shelf carbonate platform, the

Spitsbergenbank, western Barents Sea, is fringed by a distinct oceanographic frontal system, the Polar Front. This oceanographic boundary is a local high-productivity area releasing large fluxes of digestible particles which maintain huge quantities of filter feeding communities especially barnacles, bivalves, benthic foraminifera and bryozoans. Although carbonate production rates of specific framework-producing organisms, such as coralline algae and azooxanthellate scleractinians, fall in the magnitude of tropical reef systems, the accumulation rate of bioclastic carbonates is much lower. Generally, cool-temperate to Arctic carbonates consist of bioclastic sands and gravels and sometimes mud. Cementation of carbonate particles is sparsely developed and precipitation of internal sediments is almost linked to decay of organic matrixes. Therefore, the hydrodynamic regime and various forms of bioerosion play an intrinsic role in shaping the skeletal carbonate particles postmortally. </ABSTRACT>

57975 <TITLE>Modification of coral reef zonation by terrigenous sediment stress.</TITLE>

57976 <SOURCE>Palaios 04: 92-100.</SOURCE>

57977 <ABSTRACT>Four coral reefs near Ponce, Puerto Rico were examined for the effects of terrigenous influx into a reef environment. The four coral reefs are successively farther from a point source of frequently occurring, westward-moving terrigenous sediment plumes which are generated by resuspension of fine-grained sediments. The coral cover was measured from linear photographic transects parallel to each 5 meter depth. Living coral was marked on each photograph, the species identified, and area of cover was measured with a Jandel digitizer pad and SigmaScan program. Statistics were compiled for percent cover by species, total cover, and number of colonies. Total coral cover was reduced near the source of terrigenous sediment influx. Coral cover and diversity increased with distance from the source and amounts of sediment trapped on the reefs decreased, suggesting that the plume influx was an important factor contributing to the deterioration of these reefs. Sediment stress has drastically reduced the coral cover and number of species. The reefs with high sediment inputs showed decreased coral species diversity and percent cover. Sediment-resistant coral species tolerated this adverse environment and their percent of cover remained relatively constant. The effects from sediment influx include partial or total burial of coral colonies, bleaching, and colonization of the coral surface by filamentous blue-green algae and sponges. The reduced light levels resulted in domination of the community by deeper fore-reef coral.</ABSTRACT>

58054 <SOURCE>Mem. Mus. nat. Hist. Nat. Paris A 153; 136 pp.</SOURCE>
58055 <ABSTRACT>Stylasteridae are calcified and highly modified hydroids, occurring worldwide over a wide range of depth. Considerably less numerous in species, they are also less known than scleractinian corals. Some stylasterids resemble bryozoans and other colonial scleractinians, convergences that have caused confusion in recent and ancient faunas, and may also have limited our knowledge of their geological record. 20 species in 6 genera are known in the northeastern Atlantic, only one of which also occurs in the Mediterranean. All are described in detail, with abundant illustrations of the colony shape and of the minute structures essential for identification (illustrations include SEM stereo views). In the study area various symbionts leave characteristic traces on the stylasterid skeleton or cause modifications: the gastropod Pedicularia (on 8 species) and polynoid and eunicid polychaetes (each on one species). The reliable record of fossil Stylasteridae is scarce in Europe and the Mediterranean basin (as it is elsewhere). It ranges from the Lower Paleocene to the Plio-Pleistocene whereas Pedicularia, an obligate symbiont of Stylasteridae, is known from the Messinian (Upper Miocene) and from the Lower Pleistocene.</ABSTRACT>

- 58081 <ABSTRACT>From the northern margin of the Adriatic platform 22 species of Paleocene corals belonging to 15 genera were systematically described. Two species (Rhizangia padricensis and Goniopora hrpeljensis) are new. * The most convenient circumstances for the beginning of coral growth were at the edge of the platform near to the open sea. Here in Dolenja was as first the local dendroid-phaceloid coral association thrived. Then, toward the hinterland, perhaps in more stages, toward Sopada, Padriciano, Hrpelje-Kozina, Golez to Breg, new generations of massive and phaceloid corals settled which built smaller or larger patch reefs. * Corals found in Adriatic platform can be compared with similar findings of species in the wide area from Greenland to volga and Egypt.</ABSTRACT>

- 58106 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 258, 1-2: 71-88.</SOURCE>
- 58107 <ABSTRACT>During the Oligocene and Miocene, shallow-water carbonates of the Mediterranean region were rich in scleractinian corals thriving within various depositional settings, including different reef types. Their diversity patterns, although related to a complex interplay between a suite of environmental factors and palaeobiogeography, are considered to be strongly controlled by climate variability and changes

in sea-surface water temperature. By using the quantitative relationship between present-day coral taxonomic richness and prevailing sea-water temperature, underlined by the so-called [energy hypothesis](#); we test zooxanthellate-coral generic richness values from a selection of 102 Oligocene-Miocene localities of the Mediterranean region as a proxy for relative palaeotemperatures. For each Oligocene-Miocene stage, generic richness values per z-coral site are firstly examined, together with variations of the Mediterranean z-coral generic pool. For better testing the method and assessing its potential application, patterns of generic richness and inferred palaeotemperatures are then compared with global palaeoclimatic curves based on marine oxygen stable isotopes data or other climate proxies, such as palaeoclimatic records from European continental floras and from fossil coral linear extension rate. Results clearly show that fluctuations of coral richness-derived palaeotemperatures correspond relatively well with global changes of sea-water temperature especially for the entire Oligocene, the Chattian-Aquitainian boundary and the Late Miocene. The well known Mid-Miocene Climatic Optimum, however, is not recorded, suggesting that regional factors, acting together with important palaeogeographical changes, exerted a strong control on the generic richness of Mediterranean z-coral communities. A remarkable decline of taxonomic richness is recorded after the Burdigalian, together with a gradual decrease of palaeotemperatures in the region. From the Middle Miocene onwards to the Messinian, however, an increase in the temperature range of z-coral localities is clearly visible, indicating that z-coral communities were able to thrive and adapt to a wider temperature range, as the Mediterranean was gradually migrating northwards, outside the tropical belt. The [energy hypothesis](#); if used at global or regional scale, can be considered a promising and reliable method for estimating Cenozoic palaeotemperatures, from coral or other suitable fossil assemblages of shallow-water carbonates.

58118 <TITLE>Systematics of the Oligocene to Miocene reef coral *Tarbellastraea* in the northern Mediterranean.</TITLE>

58119 <SOURCE>Palaeontology 39, 3: 515-560.</SOURCE>

58120 <ABSTRACT>Multivariate statistical analyses are used to distinguish species of the common reef-building coral *Tarbellastraea* at Oligocene and Miocene localities within the Aquitaine Basin, western Mediterranean, and central Paratethys regions; and to trace their distributions through geological time. Thirteen measurements or counts are made on thin sections of 126 colonies collected at 13 widely scattered localities, whose geological ages are newly updated. The data are analyzed using average linkage cluster analysis and canonical discriminant analysis to distinguish clusters of colonies representing morphometric species. Names are assigned by qualitatively comparing measurements on the statistically recognized species with those of primary types of all previously described species of *Tarbellastraea*. The results show that *Tarbellastraea* originated during the Oligocene (Rupelian) and became extinct during the Early Messinian. A total of 12 species (including two new species from the Italian Oligocene, and two species described previously as varieties) lived in the investigated areas during Oligocene and Miocene time. Except during the Oligocene, all but one species (*T. ellisiana*) were widespread. Although species

- richness within the genus remained constant at 5-7 species throughout much of its stratigraphical range, morphological disparity decreased significantly through time. The observed constancy in richness contrasts with the decrease reported overall in the Mediterranean reef coral fauna. Species originations were highest during the Burdigalian, when temperatures across the region increased. Species extinctions remained constant until the latest Miocene, when the extinction rate increased as cold Atlantic waters entered the Mediterranean. New species described are *Tarbellastraea bragai*, *T. chevalieri*, *T. russoi* and *T. salentinensis*.

58131 <TITLE>Shallow-buried Pleistocene Madrepora-dominated coral mounds on a muddy continental slope, Tuscan Archipelago, NE Tyrrhenian Sea.</TITLE>
58132 <SOURCE>Facies 50, 3-4: 419-425.</SOURCE>
58133 <ABSTRACT>Subfossil azoxanthellate deep-sea coral mounds occur at 355-410m on the continental slope of the NE Tyrrhenian Sea between Gorgona and Capraia islands, Tuscan Archipelago. The shallow-relief patch reefs are at present buried by a thin muddy drape. Their age is latest Pleistocene. The colonial scleractinian *Madrepora oculata* is the major frame builder, in association with the solitary coral *Desmophyllum dianthus* and the colonial coral *Lophelia pertusa*. These NE Tyrrhenian *Madrepora*-dominated coral mounds represent one of the few known Mediterranean examples of deep-sea coral colonization of a muddy, low-gradient continental slope.</ABSTRACT>

58144 <TITLE>Paleoecology of a Pliocene coral reef in Cyprus: Recovery of a marine community from the Messinian Salinity Crisis.</TITLE>
58145 <SOURCE>N. Jb. Geol. Palaont. Abh. 213, 1: 103-118.</SOURCE>
58146 <ABSTRACT>Paleoecological analysis of the reef community shows that, apart from corals, it was dominated by epifaunal molluscs. It represents one of the most diverse fossil communities found on Cyprus following the Messinian Salinity Crisis (MSC), with 38 identified species of macrofossils and 8 species of foraminifera. When compared to patch reefs on Cyprus formed just prior to the MSC, this Pliocene reef shows both the biological devastation of the event and the quick and complete recovery of the reefal biodiversity.</ABSTRACT>

58183 <TITLE>Tarbellastraea (Scleractinia): A new stable isotope archive for Late Miocene paleoenvironments in the Mediterranean.</TITLE>
58184 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 257, 3: 294-307.</SOURCE>
58185 <ABSTRACT>Geochemical proxy records of sea surface temperature (SST) or sea surface salinity (SSS) variability on intra- and interannual time-scales in corals from geological periods older than Pleistocene are extremely rare due to pervasive diagenetic alteration of coralline aragonite. Very recently, however, stable isotope data ($\delta^{18}\text{O}$; $\delta^{13}\text{C}$) from specimens of *Porites* of Late Miocene age (10 Ma) have been shown to preserve original environmental signatures. In this paper we describe new finds of the zooxanthellate corals *Porites* and *Tarbellastraea* in exceptional aragonite preservation from the island of Crete in sediments of Tortonian (ca. 9 Ma) and Early Messinian (ca. 7 Ma) age. Systematic, comparative stable isotope analysis of massive *Tarbellastraea* and *Porites* sampled from the same beds and localities reveal identical stable isotope fractionation patterns in both genera. Therefore, extinct *Tarbellastraea* represents an additional environmental archive fully compatible and mutually exchangeable with *Porites*. Provided that seasonal variations in $\delta^{18}\text{O}$ reflect SST changes only, seasonal SST contrasts of 7.3 °C for the Tortonian and 4.8 °C for the Early Messinian are inferred, implying warmer summer and cooler winter SSTs during the Tortonian than during the Messinian. [first fragment of extensive summary]</ABSTRACT>

58196 <TITLE>The "Southern" Astroides calycularis in the Pleistocene of the northern Mediterranean - an indicator of climatic changes (Cnidaria, Scleractinia).</TITLE>
58197 <SOURCE>Geobios 28, 1: 9-16.</SOURCE>
58198 <ABSTRACT>Although presently limited at 37°38'N on the coast of Spain and 40°48'N on the coast of Italy, Astroides calycularis lived on the continental coast of France at 43°42'N; -44'N and on the coast of Corsica at 42°58'N during part of the Pleistocene. Thus it has been found at Nice in the Upper Silician and at Monaco in the Upper Tyrrhenian (interstages, respectively, of the Riss and Wurm glaciations), and at Cap Corse in the Tyrrhenian (Riss-Wurm interglacial). The species apparently took advantage of slightly higher surface water temperatures than those prevailing now in the northern Mediterranean. Although present-day temperatures allow survival, for many years, of transplanted colonies, they are not suitable for successful reproduction.</ABSTRACT>

58210 <SOURCE>Geodiversitas 30, 1: 181-209.</SOURCE>
58211 <ABSTRACT>This work consists in a systematic revision of upper Miocene Mediterranean hermatypic scleractinian corals, concerning the whole perimediterranean area. An abundant material allowed an accurate and reliable analysis of the taxonomic characters. Eighteen specific attributions, belonging to eight genera, are proposed. Nomenclatural revisions were required because of the abundant, dispersed and qualitatively diverse literature on this subject. Comparisons with older works were made difficult because of ancient identifications and datations by precedent authors. The biogeographic and stratigraphic distributions are detailed. Discussions about paleoecological features allow a better understanding of this coral fauna evolution, particularly regarding the so-called "salinity crisis" that affected the Mediterranean area at the end of the Miocene. - 58262 <SOURCE>Facies 47, 1: 91-112.</SOURCE>
- 58263 <ABSTRACT>An integrated study of the early Messinian reef complex cropping out along the eastern coast of the Salento Peninsula (southern Italy), including stratigraphy, facies analysis and paleoecological aspects, is here presented. Fourteen facies types belonging to three main facies associations (back-reef and shelf. Shelf-edge, slope) have been recognized. They document a wide spectrum of depositional environments, reef building organisms and growth fabric, in response to depth and other environmental factors in different parts of the reef complex. The biotic structure of the reef is also described and discussed in detail. It consists of different types of reef building organisms and of their bioconstructions (mainly Porites coral reefs, Halimeda bioherms and vermetid-microbial "trottoirs"), that differs in composition and structure according to their position on the

- shelf edge-to-slope profile. Results indicate that the reef complex of the Salento Peninsula has strong similarities with the typical early Messinian reefs of the Mediterranean region. However, the recognition of some peculiar features, i.e. the remarkable occurrence of *Halimeda* bioherms and of vermetid-microbial *trottoirs*, gives new insights for better understanding reef patterns and development of the reef belt during the Late Miocene in the Mediterranean. </ABSTRACT>

58287 <TITLE>Commensalism in the fossil record: Eunicid polychaete bioerosion on Pliocene solitary corals.</TITLE>
58288 <SOURCE>Acta Palaeontologica Polonica 54, 1: 143-154.a pp.pan.pl/article/item/app54-143.html</SOURCE>
58289 <ABSTRACT>Some solitary caryophylliid (Caryophyllia, Trochocyathus, and Ceratotrochus) and flabellid (Flabellum) scleractinian corals from Pliocene of western Mediterranean exhibit long groove-shaped bioersional structures running along the surface of the thecae. They are epigenic structures produced by an episkeletozoan and therefore, they are described as Fixichnia. Here we propose Sulcichnus as a new ichnogenus, with three new ichnospecies (Sulcichnus maeandriiformis, S. helicoidalis, and S. sigillum) to name these traces. Sulcichnus is attributed to the activity of polychaetes. Similar structures are recently produced by Lumbrineris flabellicola, a symbiotic eunicid which maintains a commensalistic relationship with solitary corals. In the fossil record, Sulcichnus occurs associated to shallow marine environments whereas their Recent counterparts are described on deep-marine corals. We interpret this as a consequence of a change in the environmental requirements of the coral/worm pair. [original abstract]</ABSTRACT>

58339 <TITLE>The taxonomic status of some Mediterranean clionids (Porifera:
Demospongiae) according to morphological and genetic characters.</TITLE>
58340 <SOURCE>Bulletin de l'Institut royal des sciences naturelles de
Belgique, Biologie 66, suppl. 1996 [Willenz P. (ed.): Recent advances
in sponge biodiversity inventory and documentation]: 185-195.</SOURCE>
58341 <ABSTRACT>The taxonomic status of some Cliona species living
sympatrically in two Ligurian localities has been studied on the basis
of morphological (spicule shape and size, boring pattern, arrangement
of choanocyte chambers studied by corrosion casts) and genetic
analyses. Results from this study indicate a remarkable specificity in
the choice of substrata by the Cliona larvae. This comprehensive
approach confirmed distinct differences between C. viridis and C.
nigricans. C. viridis is a superficial species boring only calcareous
algae (alpha-stage), whereas the electrophoretic data demonstrate the
identity of different growth forms of C. nigricans boring biogenic
substrata or living in massive form on detritic bottoms and on
Posidonia rhizomes (beta- and gamma-stages). The calcareous veins

- embedded in sedimentary rocks along the Ligurian coast are generally bored by *C. celata* but, in the same habitat, another species has been detected. This species, that shall be described afterwards on a wider lot of specimens coming from different localities, is very close to *C. celata* in spicule shape, but the spicules are smaller. Moreover the two species are clearly distinguishable on the basis of their boring pattern. Finally the genetic analysis ascertained that there is no gene flux between the two species. 58366 <SOURCE>Bulletin de l'Institut royal des sciences naturelles de Belgique, Biologie 66, suppl. 1996 [Willenz P. (ed.): Recent advances in sponge biodiversity inventory and documentation]: 175-184.</SOURCE>
58367 <ABSTRACT>we describe in this study a new Mediterranean species of the genus *Sphinctrella* Schmidt. *Sphinctrella aberrans* sp.nov. is characterized by the presence of malformed ortho-plagiotriaenes and pseudocalthrops, a category of spirasters with a very thick central axis, microxeas with attenuate ringed ornamentation, and a very fine, pore-like fenestration of the ectosome of the exhalant sieves. Apart from *S. aberrans*, three other species of *Sphinctrella* are known from the Mediterranean according to the literature : *Sphinctrella gracilis* Sollas, *Sphinctrella horrida* Schmidt and *Sphinctrella verrucolosa* Pulitzer-Finali. However, the reexamination of the single Mediterranean individual claimed to be *S. horrida* made evident that this specimen was misidentified and the species actually does not exist in the Mediterranean. 58378 <TITLE>Two new genera and species of sponges without skeleton

- (Porifera, Demospongiae) from a Mediterranean cave. </TITLE>
58379 <SOURCE>Zoosystema 20: 5-22.</SOURCE>
58380 <ABSTRACT>Two new genera and species of Demospongiae are described from a northwestern Mediterranean littoral cave characterised by cold homothermy, which shelters deep-sea invertebrates. The two new sponges have neither mineral nor fibrous skeleton. Their cytology is described using transmission electron microscopy. Thymosiopsis cuticulatus gen. et sp.nov. (Chondrillidae) shares some characters with Thymosia Topsent, but lacks the diagnostic spongin fibres. Myceliospongia araneosa gen. et sp.nov. is unusual in anatomy, cytology, and mode of growth. No clear relationship with any order of the Demospongiae is indicated and the sponge is classified as incertae sedis within the Demospongiae.</ABSTRACT>

58391 <TITLE>Problematiques de la protection des facies a gorgonaires sur les fonds cotiers de "Cinque terre" (Mar Ligure, Italie).</TITLE>
58392 <SOURCE>In: Boudouresque C.F., Avon M. & Graves V. (eds): Les Especies Marines a Proteger en Mediterranee; Publ. GIS Posidonie: 65-70.</SOURCE>
58393 <ABSTRACT>C.R.E. studied the gorgoniarian facies of the coastal bottoms of "Cinque Terre". for scientific and practical reasons; this zone was chosen by the Italian legislation for the creation of a Marine National Park. Gorgonians can be considered as the most important systematic group of the Cnidaria for the characterisation of the coralligenous and the presence of their different species allows environmental inferences (on irradiation, sedimentation rate, etc.). These benthic assemblages are of great importance for tourism (i.e. SCUBA divers) and, for a correct coastal management, they must be located with accuracy. This work analyses the main factors of distribution and the dangers that threaten the gorgonians in the area studied. Some proposals are made in order to guarantee the protection of the gorgonian facies in the Western Mediterranean Sea.</ABSTRACT>

58404 <TITLE>Biomass, carbonate standing stock and production of the Mediterranean coral Cladocora caespitosa (L.).</TITLE>
58405 <SOURCE>Facies 44, 1: 75-80.</SOURCE>
58406 <ABSTRACT>The Mediterranean coral Cladocora caespitosa often occurs in large beds, i.e. populations of hemisphaerical colonies with stock densities varying between 1,9 and 4 colonies . m-2. Laboratory measurements of volume, skeleton weight, surface and number of corallites per colony, coupled with mean annual growth rates evaluated through sclerochronology, allowed for the estimation of biomass, skeleton bulk density, calcimass (carbonate standing stock) and secondary production (both organic and inorganic) of two C. caespitosa beds at 4 and 9 m depth. The mean colony biomass varied between 0,73

and 0,99 kg dw . m⁻², corresponding to a calcimass between 2 and 5 kg CaCO₃ . m⁻². Organic secondary production was 215.5 - 305.4 g dw of polyps . m⁻² . y⁻¹, while the potential (mineral) production was 1.1 - 1.7 kg CaCO₃ . m⁻² . y⁻¹, for the year 11996-1997. These values show that *C. caespitosa* is one of the major carbonate producers within the Mediterranean and one of the major epibiotic species originating stable carbonate frameworks both in recent and past times.</ABSTRACT>

58417 <TITLE>Present-day bioconstructions of the hard coral *Cladocora caespitosa* (L.) (Anthozoa. Scleractinia), in the Eastern Ligurian Sea (NW Mediterranean).</TITLE>

58418 <SOURCE>Biologia Marina Meditteranea 1, 1: 371-372.</SOURCE>

58419 <ABSTRACT>*Cladocora caespitosa* is the only hermatypic coral living in the Mediterranean. Large-sized formations were recorded between 1700 and 1900m in the Marseille region but presently this coral is found chiefly in the eastern Mediterranean: Gulf of Gabes, Tunisia, Aegean Sea, Jonian coasts of Calabria. During 1992, two massive bioconstructions of *C. caespitosa* were found in two Ligurian localities: Bonassola and Riomaggiore. Both were on coralligenous bottoms 26 to 29 m deep, with large amounts of siltation due to natural and / or anthropogenic causes. These bioconstructions have been mapped by scuba diving using photomosaic techniques. In situ examination of the two structures and the analysis of the photographic maps led to estimate their surface area, volume, and carbonate mass. The two bioconstructions differ greatly in their morphology: that of Bonassola is oblong in shape and reaches a total length of over 3.5m, whereas that of Riomaggiore is smaller and looks like a stout pillar about 0.6m high. The inferred developmental patterns also differ. At Bonassola, the bank progresses chiefly in a horizontal way, through coalescence and fusion of satellite colonies, its growth in height is enhanced by the cementing action of sediment, filling interstices among corallites. The Riomaggiore formation has a prominent vertical growth through accretion of subsequent colonies, which makes its upper surface irregular. Both environmental (high turbidity) and topographic features (both bioconstructions occur in small grooves conveying sediments and currents) at the two sites are consistent with data from literature (Laborei 1961, Lumare 1966, Zibrowius 1980) which, however, always concern shallower zones.</ABSTRACT>

58430 <TITLE>Preliminary Report on Holocene Submarine Accumulations of *Cladocora caespitosa* (L. 1767) in the Mediterranean.</TITLE>

58431 <SOURCE>Goettinger Arbeiten zur Geologie und Palaeontologie, Special Volume 2 [Reitner J., Neuwiller F. & Gunke F. (eds): Global and Regional Controls on Biogenic Sedimentation I. Reef Evolution]: pp ???</SOURCE>

- 58432 <ABSTRACT>In the sublittoral of the North and Middle Aegean investigations of *Cladocora caespitosa* (L. 1767) (Anthozoa, Scleractinia, Faviidae) as scaffolder of sedimental hard structures were undertaken by diving from 1990 to 1994. The structures appeared in two forms: first as ledges, which had been formed by many colonies of the coral (bioherms) around 5,900 to 3,200 years before present (yrs BP) according to AMS ¹⁴C datings and secondly as blocks which consisted of only one colony of coral (biochores) and had been formed 2,000 to 100 yrs BP. Both structures were exclusively formed by the densely dendroid, hemispheric growing form of *C. caespitosa*, whose corallites landing together functioned as centers of sedimentation, where silt and biogenic hard particles could be established in between. On the *Cladocora caespitosa* ledges, living colonies of the same species are growing at present which show a continuous growth of the ledge surface. However, the ledges themselves already died out more than 3,000 yrs BP. For the so-called Atlantic time these ledges can be pointed as transitional structures between merhmotypic [?] single corals and tropical coral reefs. Due to deteriorated environmental conditions in the Mediterranean, at present no more recent transitional structures exist compared to tropical coral reefs.</ABSTRACT>

- 58445 <ABSTRACT>X-radiographs of corallites of the zooxanthellate coral *Cladocora caespitosa* (L.), collected in the Ligurian Sea between 3 and 27m depth, were examined. *C. caespitosa* deposits 2 bands yr⁻¹; the high density band is deposited during winter (November to March) while the low density band is deposited in summer. Average growth rates ranged from 1.36 ± 0,58 to 4.42 ± 1,61 mm yr⁻¹. No differences in the timing of band deposition were found between shallow and deep colonies. A comparison of the band pattern with monthly temperature-irradiance measurements from the Ligurian Sea, and with literature data on the photosynthetic efficiency of zooxanthellae, led us to hypothesise a mechanism of growth with low dependency on autotrophy.</ABSTRACT>

- 58470 <SOURCE>Helgolaender wiss. Meeresunters. 26: 153-173.</SOURCE>
- 58471 <ABSTRACT>A large colony of Oculina patagonica growing on a cliff (depth 0,5 to 2m) about 1km from Savona harbour (Gulf of Genoa, Italy) was discovered in 1966 and was found prosperous and spreading when surveyed again in 1971 and 1972. Water temperature in the area was found to vary from about 11°C to about 26°C; during the greater part of the year it remains far below temperatures generally considered necessary for growth and even survival of hermatypic scleractinians. In spite of the local pollution which favours dense and prosperous populations of barnacles and ascidians, the encrusting colony of O. patagonica (now measuring 1,2m x 1,5m) tends to cover these other organisms. The Savona record of O. patagonica is the first one of a living colony since nothing was known on the actual range of the species, probably living on the Atlantic coast of South America. Previously, O. patagonica was known only from worn fragments, fossil or sub-fossil, from Argentina. Liberation of larvae (one of which settled on the surveyed cliff) by a mature colony that came to Savona waters on a ship bottom, is the only acceptable explanation for the highly surprising arrival of the exotic scleractinian in the Northwestern Mediterranean. Transplantation of samples of O. patagonica broken off the Savona colony to clean water off Marseilles has proven very successful. The discovery of O. patagonica in the Mediterranean has provided material for a detailed redescription of the species and an opportunity for a systematic and biogeographic survey of the genus Oculina, as well as for remarks on hermatypic corals in extra tropical waters.</ABSTRACT>

58521 <TITLE>Excavating and endolithic sponge species (Porifera) from the Mediterranean: species descriptions and identification key.</TITLE>
58522 <SOURCE>Organisms, Diversity & Evolution 2: 55-86.</SOURCE>
58523 <ABSTRACT>The present study is a review of the excavating and endolithic sponges present in the Mediterranean. A dichotomic key to 22 species is presented. Detailed species descriptions are provided based on newly collected material and previous descriptions from the literature. In the case of Cliona viridis (Schmidt, 1862), an in-depth histological study has also been performed. Discussions on problematic taxonomic issues are also included. Dotona pulchella Carter, 1880 subspecies mediterranea n.subsp. n. is described. The previously enacted synonymy between Pione vastifica Hancock, 1849 and Pione lampa (de Laubenfels, 1950) is restricted to those specimens identified as "forma occulta". Cliona amplicavata Rützler, 1974 is recorded

for the first time in the Mediterranean. *Clionba cretensis* Pulitzer-Finali, 1983 is proposed to be synonymous to *Cliona thoosina* Topsent, 1887. *Cliona copiosa* Sará, 1959 and *Cliona tremittensis* Sará, 1961 are considered synonymous to *C. viridis*. The spicule complement of *Scantilleta levispira* (Topsent, 1898), *D. pulchella* and *C. amplicavata*, is enlarged, and some spicule types are better described based on light microscopy and SEM observation. *Pione vastifica* shows great variability in the microrhabds, seemingly related to depth. Regarding excavating patterns, several species appear to selectively excavate particular substrate types, whereas others are not selective among calcareous material. *A. labyrinthica*, *P. vastifica*, *Cliona janitrix* Topsent, 1932, *C. viridis* and *C. lobata* Hancock, 1849 have asexual reproduction. Excavating ability, bud production and the way the sponge genus grows inside the substrate are biological features common to distant taxa such as Clionidae and *Aka* ssp. That may constitute convergent (analogous) characters. </ABSTRACT>

 58536 <ABSTRACT>Living boring sponges belonging to eight species of the genera Siphonodictyon, Cliona and Clionothosa, were collected from the limestone seafloor of the Apulian coast. Samples were taken in zero to -20 m water depth. Spicule preparations from the sponges, and epoxy casts of the borings, facilitated a comparison of the animal and its work. The borings were analyzed ichnotaxonomically and attributed to 11 ichnospecies of Entobia. Direct correlation between biospecies and ichnospecies was not found in all cases. Several ichnospecies are new, and some of these are named using Pleistocene material. The new ichnospecies are Entobia gigantea, E. magna and E. parva.</ABSTRACT>

 58548 <SOURCE>Bulletin de l'Institut royal des sciences naturelles de Belgique, suppl. 66: 109-115.</SOURCE>
 58549 <ABSTRACT>A cladorhizid sponge which has been shown to be carnivorous, is described as a new species of Asbestopluma, A. hypogea. The sponge lives in a Mediterranean cave, 17 to 22m deep, between 15 to 60m inside from the cave opening, in a trapped mass of cold water (13 - 14.7°C). Preserved specimens differ significantly in shape from the living ones and variations also occur according to the feeding status. Forcep spicules are present only during spermatogenesis. The nearest species is A. hydra Lundbeck, from the Arctic (from 1847 to 2394m).</ABSTRACT>

58560 <TITLE>Deep-sea sponges in a Mediterranean cave.</TITLE>
58561 <SOURCE>Biosystematics and Ecology Series 11 [Uiblein F., Ott J. & Stachowitsch M. (eds): Deep-sea and extreme shallow-water habitats: affinities and adaptations]: 299-312. [Austrian Academy of Sciences, wien]</SOURCE>
58562 <ABSTRACT>Submarine caves share several ecological features with deep-sea habitats and could be considered as a natural mesocosm of the bathyo-abyssal zone, in spite of differences in temperature. A unique Mediterranean cave which entraps a cold water mass, resulting in stable temperature conditions throughout the year, is a specially interesting "bathyal island" in the littoral zone. It has been colonized by deep-sea invertebrates, the likely source of propagules of which being a nearby canyon, 100 to 3000m deep. The example of sponges shows that various general problems of deep-sea biology could be successfully addressed to in the cave. A representative of the deep-sea hexactinellid sponges reproduces here year round - enabling the first observations of larval behaviour and ultrastructure to be carried out on this phylogenetically important group of invertebrates, and opening the unknown area of larval ecology of deep-sea sponges. The presence of a species of the deepest known genus of sponges, Asbestopluma (at 8840m depth in the Central Pacific) is a fascinating opportunity to investigate the biology of the strange deep-sea cladorhizid sponges, which can live in the most oligotrophic abyssal basins. A highly unexpected result is that cladorhizids are non-filter-feeding 'sponges' with a carnivorous feeding habit.</ABSTRACT>

58612 <TITLE>Small bathyal (sponge) species from East Mediterranean revealed by new soft bottom sampling technique.</TITLE>
58613 <SOURCE>Ophelia 57, 3: 145-160.</SOURCE>
58614 <ABSTRACT>This first study of soft bottom sponges from the Levantine bathyal employed a device comprising a plankton net secured atop a Marinovich type semi-balloon trawl. All of the nearly 500 specimens collected were identified to four sponge species. All four species are of a very small body size. Sponges were not retained by the larger mesh Marinovich trawl net. The study describes a new polymastiid species *Tentorium levantinum* n.sp., and a new Rhizaxinella *shikmonae* n.sp. in addition to two Calcareans: *Sycon faulkneri* n.sp. and a *Plectronia* sp. that appears to be a new species. These sponges, which inhabit soft bottom environments, have evolved morphological features such as unattached ground-based cones with a broad base (*Tentorium levantinum*), or a basal anchoring tuft (*Rhizaxinella shikmonae*). The absence of these species from previous records of the Mediterranean bathyal may have resulted either from overlooking the small sized species in soft bottom environments for lack of adequate collecting technique or scarcity of studies. It was thus impossible to confirm or reject the pattern of wide geographical distribution of deep-water sponges seen elsewhere, including the western Mediterranean. The new calcareous species was found at greater depths than most other calcareous sponges published so far, while *Plectronia* sp. was found at greater depth than all but one record for this genus. It is expected that other small, benthic species may be discovered using the appropriate equipment. [original abstract]</ABSTRACT>

58627 <ABSTRACT>Bacteria associated with the mediterranean sponges Chondrosia
reniformis and Petrosia ficiformis were examined by cultivation and
culture-independent analysis. On agar-plates, numerous culturable
bacteria with distinct colony-morphologies could be observed. Further
sponge associated bacteria were detected in situ and phylogenetically
characterized by hybridization with 16S rRNA-directed fluorescent
oligonucleotide probes. For both sponges, all bacteria detected by this
method cluster in the gamma and alpha subclass of Bacteria. No
Archaeobacteria nor member of the beta subclass of Proteobacteria could
be found. Oligonucleotides complementary to probe-specific regions of
the 16S rRNA of culturable and isolated bacteria were used for PCR
amplification. Purified PCR products were taken for DNA sequence
analysis.</ABSTRACT>

58638 <TITLE>Do associated zooxanthellae and the nature of the substratum
affect survival, attachment and growth of Cliona viridis (Porifera:
Hadromerida)? An experimental approach.</TITLE>
58639 <SOURCE>Marine Biology 114: 503-507.</SOURCE>
58640 <ABSTRACT>Massive specimens of Cliona viridis, collected off the coast
of Blanes (North-western Mediterranean Sea) in January, 1987, were
exposed to different light (natural day-night irradiance/constant
darkness) and substrata (calcareous/siliceous) conditions to assess
their influence on growth, survival and attachment rates. Sponges
cultured under natural irradiance displayed higher growth rates with
increasing temperature; those cultured in the dark did not respond to
increased temperature, but adapted faster to laboratory conditions.
Differences in growth rates between these two culture conditions are
ascribed to the presence of a healthy symbiotical zooxanthellae
population on individuals cultured under conditions of natural
irradiance. Attachment rates of the hut sides of the sponges which were
in direct contact with the substratum, also increased with increasing
temperature, whilst sponge survival was not significantly dependent on
temperature. The chemical nature of the substratum clearly affected
survival rates, which were higher on calcified than on siliceous
substrata.</ABSTRACT>

58651 <TITLE>Cytological evidence for cryptic speciation in Mediterranean Oscarella species (Porifera, Homoscleromorpha).</TITLE>
58652 <SOURCE>Canadian Journal of Zoology 74: 881-896.</SOURCE>
58653 <ABSTRACT>Three new sponge species without a skeleton, Oscarella viridis, O. microlobata, and O. imperialis, were found in sublittoral caves and on vertical walls along the coast of Provence (western Mediterranean Sea, France). Their morphology, anatomy, and cytology are described and they are compared with the two other valid Mediterranean Oscarella species, O. lobularis and O. tuberculata. Reproductive and internal anatomical characters are uniform in the genus, but details of external morphology and especially cytological characters (mesohylar cells with inclusions) provide good diagnostic features at the species level. Careful observation of morphological and cytological characters is essential for clarifying the systematics of Oscarella and reveals an unexpected biodiversity of this genus in the Mediterranean Sea.

- 58704 <SOURCE>FC&P 04, 1: 8-10.</SOURCE>
- 58705 <ABSTRACT>Thirty-four geologists and biologists participated in a symposium of 22 papers on Caribbean reef systems: Holocene and ancient, in Guadeloupe, French West Indies, in early July. The Symposium was arranged by S.H. Frost and M.P. Weiss, of Northern Illinois University, as part of the Vllth Caribbean Geological Conference convened by the French government and chaired by Roger Causse. Gatherings of geologists to consider carbonate materials and their genesis are a commonplace of recent years; although important and constructive, many failed to treat reefs as wholes. Modern treatments of reef morphology and history are also numerous, but many are only geologic and/or refer to the Indo-Pacific region. Much more cooperation is needed between geologists and biologists, one 2-day symposium cannot do the job, but a start was overdue. We also hoped to increase participation and interest in both modern and fossil reefs all over the Caribbean. [first part of a report, sent also to Geotimes] </ABSTRACT>

- 58717 <SOURCE>Revista mexicana de ciencias geológicas 26, 1: 93-103.</SOURCE>
- 58718 <ABSTRACT>Although ten species are currently assigned to the Early Cretaceous coral genus Holocoenia, its characteristics are poorly known. Using both material from the type locality of the type species *Astrea micrantha* along with described and undescribed material from France, Mexico, Poland and Spain, the genus is revised. It has a cerioid form with small calices, compact septa, a styliform columella, and an incomplete septothecal to synapticulothecal wall. Provisionally, it is assigned to the family *Thamnasteriidae*, being closely related to *Mesomorpha* and *Thamnasteria*. The genera *Stereocaenia* and *Paretallonia* are considered junior synonyms of *Holocoenia*. According to the present revision the genus contains only two species, which range from the Valanginian to the Aptian. *Holocoenia micrantha* is restricted to the central Tethys whereas *Holocoenia jaccardi* extends geographically from South America (Aptian of Argentina) and southern North America (Aptian of Puebla, Mexico) to the eastern Tethys (Hauterivian of Georgia). The

indication of the genus in the San Juan Raya area in Puebla is the first indication in Central America. While the genus has been indicated in only eleven outcrop areas, making it rather rare, in many of these localities samples of *Holocoenia* are common. [original abstract]

58730 <SOURCE>Facies 51: 1-4: 185-196.</SOURCE>

58731 <ABSTRACT>A complete account of the faviid genus *Cladocora* within the Caribbean is presented. In the Caribbean this genus represents an extant group that had its earliest occurrence during the Campanian-Maastrichtian of Jamaica. Recent forms have been reported throughout the Caribbean. The following forms were found (with stratigraphic ranges in the Caribbean): *C. arbuscula* (Pliocene-Recent), *C. debilis* (Pleistocene-Recent), *C. gracilis* (Middle-Upper Maastrichtian), *C. jamaicaensis* (Campanian- Maastrichtian and Eocene), *C. johnsoni* (Pliocene), and *C. recrescens* (Middle-Upper Oligocene). The occurrence of the genus *Cladocora* in the Caribbean is largely continuous from the Campanian to Recent, during which the majority of the Caribbean species show affinities to European assemblages. For the time intervals Paleocene, Lower Oligocene, and Miocene the taxon has not been reported from the Caribbean.</ABSTRACT>

58742 <TITLE>Eocene Caribbean reef corals: A unique fauna from the Gatuncillo Formation of Panama.</TITLE>

58743 <SOURCE>Journal of Paleontology 66, 4: 570-594.</SOURCE>

58744 <ABSTRACT>Forty-three species of 25 genera are described in a collection of 170 large, massive reef corals from the upper Eocene Gatuncillo Formation near Lago Alahuella in central Panama. Comparisons with type material for other Eocene Caribbean reef corals suggest that 27 of these species are new. Twenty-four of these species are named herein. Like other Eocene Caribbean reef-coral faunas, the fauna is rich in *Astrocoenia*, *Actinacis*, and *Astreopora* however, unlike other faunas, plocoid and meandroid members of the family *Faviidae* (e.g. *Montastrea*, *Agathiphyllia*, *Goniastrea*, and *Colpophyllia*) are abundant. Also present are the oldest known representatives of the genera *Meandrina*, *Coscinaraea*, *Alveopora*, *Heliopora*, and *Pocillopora*, as well as the only recorded occurrences of *Coscinaraea* and *Cyathoseris* from the Caribbean. Comparisons with Oligocene and Recent Caribbean reef-coral faunas suggest that the generic composition of Cenozoic Caribbean reefs became established during the Eocene. With exception of the family *Mussidae*, much of the post-Oligocene history of the Caribbean is one of extinction at the generic level (19 of the 28 Eocene genera became extinct) and proliferation of species within the

- surviving genera.</ABSTRACT>

58781 <TITLE>Oligocene-Miocene Extinction and Geographic Restriction of Caribbean Corals: Roles of Turbidity, Temperature, and Nutrients.</TITLE>
58782 <SOURCE>Palaios 9: 576-598.</SOURCE>
58783 <ABSTRACT>About half the Caribbean hermatypic corals died out in the Caribbean during the latest Oligocene through Early Miocene, about 24-16 Ma. The majority of those corals that died out in the Caribbean are extant in the Indo Pacific, i.e., they suffered geographic restriction, rather than extinction. The coral and coral associate faunas of three Upper Oligocene and three Middle Miocene fossil reefs in western Puerto Rico were compared. Coral genera at these sites suffered 50% regional extinction (extinction or restriction), equivalent to earlier reports of this Caribbean coral extinction/restriction event. Nearly all coral genera tolerant of both turbidity and cool water survived; those tolerant of cool water or turbidity alone survived in much lesser proportions. Corals occurring on both patch reefs and shelf edge reefs survived in much greater proportions than those occurring on only patch reefs or only shelf edge reefs. There are no shelf edge barrier reef complexes documented from the Early or Middle Miocene in the Caribbean; the uppermost Miocene shelf edge reefs of Mona Island are the only known Miocene shelf edge

reef deposits in the Caribbean. Coral associates, the endolithic sponges, bivalves, worms, and barnacles that live in coral skeletons, were almost completely unaffected by this event. Likewise, reef and off-reef gastropods, bivalves, and echinoids suffered only insignificant reductions in diversity. Only corals and large benthic foraminifera were strongly affected by the extinction. It is significant that zooxanthellate organisms were the primary victims of this extinction. Miocene endolithic sponge borings are significantly larger than their Oligocene counterparts, suggesting more intense bioerosion on Miocene than Oligocene reefs. Bioerosion is generally correlated with nutrient levels, and the apparently more intense bioerosion of Miocene corals may indicate enhanced nutrient availability on Miocene Caribbean reefs. Extensive Miocene phosphorites throughout the Caribbean indicate enhanced upwelling in the region during the time of the coral extinction/restriction. Biogeographic evidence from corals, coral associates, and molluscs corroborates this pattern, along with the evidence from bioerosion levels. Enhanced upwelling could account for the extinction/restriction by generally increasing nutrient levels and cooling Caribbean coastal surface waters, thus restricting reef development to on-shelf patch reefs, where corals would be subject to more intense sedimentation. Modern reefs of the Eastern Pacific may provide a modern analogue to Miocene Caribbean reefs. This regional extinction was important in dividing a previously cosmopolitan reef fauna into several modern provincial faunas. This biogeographic separation was completed in the mid-Pliocene with the rise of the isthmus of Panama. Coral associates, which universally survived the Oligocene-Miocene event, also have much more cosmopolitan distributions than do corals. </ABSTRACT>

58794 <TITLE>Boring of various faunal elements in the Oligocene - Miocene Bluff Formation of Grand Cayman, British West Indies.</TITLE>

58795 <SOURCE>Journal of Paleontology 62, 3: 348-367.</SOURCE>

58796 <ABSTRACT>Molds of corals, bivalves, and gastropods in the Oligocene-Miocene Bluff Formation of Grand Cayman Island contain casts of Entobia (nine ichnospecies including the new ichnospecies *E. dendritica*), Trypanites (three ichnospecies), Gastrochaenolites (two ichnospecies), Maeandropolydora (one ichnospecies), Talpina (one ichnospecies), and Caulostrepsis (one ichnospecies) as well as the new ichnogenus Uniglobites, indeterminate ichnogenus A, and a problematical boring. Entobia accounts for about 75 percent of the borings, while Uniglobites and Trypanites together account for 15 percent of the borings. Comparison of Uniglobites with modern borings of known affinity suggests that it was produced by adociid and / or clionid sponges while indeterminate ichnogenus A was probably formed by bivalves. The amount of boring, which ranges from 0 to 75 percent, varies from skeleton to skeleton or, in some cases, from branch to branch of the same coral colony. The branching coral Stylophora was particularly susceptible to boring, probably because of its small size and high surface area. The average boring of about 38 percent compares favourably with the amount of boring found in modern corals. Analysis of the borings suggest that sponges were responsible for most of the borings in the corals from the Bluff Formation. Comparison with bioerosion in modern reefs suggests that similar patterns of bioerosion were also occurring in Oligocene-Miocene times.</ABSTRACT>

58807 <TITLE>Preferential survivorship of brooding corals in a regional extinction.</TITLE>
58808 <SOURCE>Paleobiology 21, 2: 200-219.</SOURCE>
58809 <ABSTRACT>Approximately half of the Caribbean Oligocene reef coral fauna became locally extinct during the Early Miocene; roughly two thirds of the genera driven to local extinction still survive in the Indo-Pacific. Coral genera with lecithotrophic larvae (brooders) preferentially survived, over those with planktotrophic larvae (broadcasters). Among 37 genera for which we inferred reproductive mode, 73% of brooding genera survived the Oligocene / Miocene extinction events, while only 29% of the broadcasting genera survived. The proportion of brooders to broadcasters also increased markedly. During the late Oligocene, 47% of Caribbean reef coral genera were broadcasters, but in the middle Miocene, only 32% of the genera were broadcasters. Survivorship in Puerto Rican reefs was correlated with tolerance of cold and turbid conditions. Genera tolerant of both cold water and turbidity had much higher survival rates than those tolerant of turbidity alone. Only 25% of the genera that could tolerate neither cold water nor turbidity survived. Most of the eurytopic genera were brooders, while most of the stenotypic genera were broadcasters. We present two hypotheses that may account for the preferential survivorship of brooders: the recruitment hypothesis, and the dispersal hypothesis. The recruitment hypothesis holds that brooders survive preferentially because lecithotrophic larvae have higher recruitment success than do planktotrophic larvae in marginal habitats, such as upwelling zones. This is supported by the correlation of brooding and eurytopy. The dispersal hypothesis suggests that brooders survive preferentially because lecithotrophic larvae, which typically inherit zooxanthellae from the egg, have a longer larval lifespan and, hence, a wider potential dispersal range, than planktotrophic larvae, which typically capture zooxanthellae from the water column. Biogeographic range data, however, do not support this second hypothesis: modern Indo-Pacific brooding and broadcasting genera have nearly identical ranges, and many brooding species have narrower longitudinal ranges than do broadcasting species. Preferential survivorship of brooding corals contrasts sharply with survivorship patterns among molluscs during extinction events; among molluscs, broadcasters are favored over brooders. A major increase in upwelling at the Oligocene / Miocene boundary was probably responsible for this extinction / geographic restriction event. Preferential survival of brooding and mixed mode coral genera appears to be a product of their being better able to recruit and survive in marginal conditions such as upwelling zones.

- 58820 <TITLE>Evolution of Cenozoic Caribbean coral Faunas.</TITLE>
58821 <SOURCE>Memoirs of the Vith Conf. Geol. Carib., Margarita, Venezuela:
461-464.</SOURCE>
58822 <ABSTRACT>Examination of extensive new coral collections from the Lower Eocene-Lower Miocene of Chiapas, Mexico and the Middle Eocene-Pliocene of Jamaica plus the reevaluation of published studies of Duncan, Vaughan, Wells, and others allows some generalizations to be made about ecological distribution and evolution of Caribbean Tertiary coral faunas: (a) Paleocene and Lower Eocene hermatypic and ahermatypic corals are rare in the Caribbean. In addition to the dominantly ahermatypic faunas of the Gulf Coast Paleocene and Lower Eocene, sparse Paleocene hermatypic corals occur in northern British Honduras (Belize) and in the Lower Eocene of Chiapas, Mexico; (b) Middle Eocene reefs existed in Chiapas, Mexico, possibly in Jamaica, and mixed hermatypic-ahermatypic assemblages are present in collections from St. Bartholomew and the Gulf Coast. Tethyan genera dominate the assemblages. (c) Upper Eocene mixed hermatypic / ahermatypic basin-slope faunas existed in Chiapas, Mexico, Gulf Coast and sparsely at other localities. By the end of the Eocene, most of the older elements of the Caribbean coral fauna had disappeared, leaving groups which still exist on modern reefs. (d) The greatest development of Tertiary hermatypic corals occurred in the Oligocene, where cosmopolitan genera such as *Diploastrea* and *Antiguastrea* of Vaughan & s " Antiquan coral fauna " built fringing reefs in Chiapas, Mexico, and possibly Antigua, and patch reefs on the Gulf Coast, Puerto Rico, Cuba, Northeastern Mexico and Panama. This fauna is closely comparable to contemporaneous faunas which existed in the Mediterranean and Pacific. (e) Cosmopolitan elements of the hermatypic " Antiquan coral fauna " disappeared in latest Oligocene time. This apparently due to the cut off of access of the Caribbean to the Eastern Pacific equatorial counter current by the establishment of land barriers across Central America. Lower Miocene hermatypic faunas are dominated by *Montastrea* and *Porites* although some genera, now extinct in the Caribbean but living in the Indo-Pacific, persisted. (f) Middle Miocene through Upper Pliocene faunas are marked by the steady disappearance of genera still living in the Indo-Pacific. Many of the classic Miocene and Pliocene assemblages are hermatypic / ahermatypic deep fore-reef faunas and do not provide much insight into the species composition of reef-crest hermatypic assemblages. A change in the composition of reef-crest or reef-buttruss assemblages is marked by the evolution of wave-resistant *Acropora palmata* in latest Pliocene or earliest Pleistocene time. Rapidly growing species of *Acropora*, *Porites*, and other genera appear to have increased greatly in species diversity and abundance since the Late Pliocene and appear to be well on their way to dominate the shallow water-high wave energy habitats of modern Caribbean reefs.</ABSTRACT>

58833 <TITLE>Tracing the long-term evolution of a species complex: Examples from the *Montastraea* " *annularis* " complex.</TITLE>
58834 <SOURCE>Palaeoworld 19, 3-4: 348-356.</SOURCE>
58835 <ABSTRACT>Recent molecular work has revealed numerous species complexes of scleractinian reef corals. Although species within complexes are distinct through much of their distribution, hybridization has been discovered at species margins, and has been hypothesized as playing an

important role in mediating responses to changing environments. In the present study, I examine the long-term evolution of the *Montastraea annularis* complex over the past 5 million years to determine when speciation, extinction, and hybridization took place over the past 6.5 million years, with the eventual aim of understanding how these events corresponded with environmental changes in the Caribbean region. The material consists of colonies collected in the Mio-Pliocene of the Dominican Republic and the Plio-Pleistocene of Costa Rica and Panama. Genetically characterized colonies from the Recent of Panama are included in the analyses for comparison. Species are distinguished in the fossil material using a landmark-based morphometric approach that focuses on the size and shape of architectural features within corallites in transverse thin sections. Evolutionary relationships among species are examined using phylogenetic analyses based on parsimony. Phylogenetic characters are derived from the results of multiple comparisons tests, which statistically evaluated differences among species using morphometric data. * The results show that the *Montastraea annularis* complex originated during late Miocene time, and consisted of 12 species during the Pliocene, with a maximum of 4-5 species co-occurring at any one time. The three modern species do not form a monophyletic group but belong to separate clades within the complex. The ranges of two of the three modern species may extend back to 2.9-3.5 Ma, indicating that they are survivors of the Plio-Pleistocene extinction event in which 80% of Caribbean reef coral species became extinct. Morphologic differences among species (disparity) were higher during the Pliocene than they are today.

58846 <TITLE>Comparison of Caribbean coral reef communities before and after Plio-Pleistocene faunal turnover: analyses of two Dominican Republic reef sequences.</TITLE>

58847 <SOURCE>Palaios 18, 1: 3-21.</SOURCE>

58848 <ABSTRACT>The extent to which origination and selective extinction influenced the structure and dynamics of Caribbean coral reef communities is evaluated by comparing the diversity and distributional patterns of coral species in two Dominican Republic reef sequences prior to an following late Cenozoic Caribbean faunal turnover. The two sequences consist of late Miocene Arroyo Bellaco reef of the Cibao Valley, northern Dominican Republic, and the late Pleistocene 125.ka reef terraces of the southern Dominican Republic. Samples were collected along 20-meter transects (10 Miocene, 10 Pleistocene), species identifications were made using standard sets of characters and morphometrics. In particular, species of *Montastraea annularis*-like corals were distinguished within each sequence using a 2-dimensional landmark technique involving average linkage cluster analysis, discriminant analyses, and non-parametric tests. Four Miocene and four Pleistocene species were recognized. Subsequent community analysis was two-fold: (1) whole coral community, and 2) distribution of *Montastraea annularis* complex. [first fragment of extensive summary]

58873 <SOURCE>Palaios 04: 264-275.</SOURCE>
58874 <ABSTRACT>Three common coral assemblages have been quantitatively identified in the middle Miocene Anguilla Formation of Anguilla (Lesser Antilles) using cluster analysis on three-dimensional coordinates derived from nonmetric multidimensional scaling. The data consisted of tallies of coral species identified at 25 points within 178 1-meter-square quadrats placed haphazardly across vertical exposures of coral-rich lenses at five localities. Eighteen species were recorded. The resulting clusters intergrade and are characterized by moderately high diversities which are not significantly different. They include: 1) a thick-branched assemblage dominated by *Porites porloricensis*, 2) a mound-shaped assemblage including *Porites waylandi*, *Siderastrea conferta*, *Goniopora hilli*, and *G. imperatoris*, and 3) a platy/thin-branched assemblage composed of *Porites macdonaldi* and *Porites baracoensis*. The results of chi-square tests show that the assemblages are randomly distributed, both in space and in stratigraphic sequence. The patchy, intergradational distribution of the assemblages, their equally variable but high diversities, and their association with calcareous sand lenses suggest that they probably all developed as small patch reefs or thickets of varying composition on a shallow, gently sloping backreef platform. The three assemblages developed under similar environmental conditions in one major reef zone on a platform subjected to frequent abiotic disturbance by shifting sand. The mere existence of distinctive assemblages of reef-building corals having different shapes, therefore, needs not in itself imply ecological succession or large-scale physical environmental gradients, as is commonly interpreted in many similar fossil reef sequences.

58885 <TITLE>Lithophaga borings and their influence on the diagenesis of corals in the Pleistocene Ironshore Formation of Grand Cayman Island, British West Indies.</TITLE>
58886 <SOURCE>Palaios 03: 3-21.</SOURCE>
58887 <ABSTRACT>Corals in the Pleistocene Ironshore Formation of Grand Cayman Island have been infested by Lithophaga sp. that formed borings up to 15 cm long and 4 cm in diameter. Although some of the borings were probably generated while the corals were alive most were formed after the corals had died. Some of the large coral heads (up to 1.5m diameter) of Montastrea annularis and Diploria labyrinthiformis have had a 14 to 15cm wide outer band almost totally transformed by the Lithophaga borings. The borings, which have a distinct clavate form, are assigned to the ichnospecies Gastrochaenolites torpedo kelly & Bromley 1984. Many of the borings are lined with laminated, fluorescent cryptocrystalline calcite that may have been formed by the merger of peloids. Similar material also encrusts many of the Lithophaga shells. After death the borings were filled with (1) cryptocrystalline calcite, (2) porous cryptocrystalline calcite, (3) honeycombed cryptocrystalline calcite, (3) pelsparite, and (4) pelmicrite which locally contains small calcitic ostracod(?) shells. The cryptocrystalline calcite is always fluorescent and thus contrasts sharply with the nonfluorescent calcite of the shells and the spar cement. The corallites around the Lithophaga borings are partly or totally occluded by (1) first generation, non-fluorescent aragonite cement, (2) second generation, non-fluorescent spar calcite, (3) fluorescent peloids, and (4) featureless, fluorescent cryptocrystalline calcite. The fact that the cryptocrystalline calcite in the corallites has the same fluorescent character as the cryptocrystalline calcite in the Lithophaga borings suggests that the two may be genetically related. The infestation of the coral heads by Lithophaga played a major role in the evolution of the diagenetic fabric in the coral heads. It is evident that the Lithophaga borings can (1) substantially weaken the coral heads thereby making them more susceptible to erosion, (2) serve to bind the substrate together by virtue of the dense calcareous linings in the borings, (3) liberate substantial amounts of calcium carbonate from the coral heads, (4) increase the rock-area available for further bioerosion by sponges, algae and fungi, and (5) by virtue of the empty borings provide protected sites for sediment accumulation.</ABSTRACT>

58898 <TITLE>Extinction selectivity and ecology of Neogene Caribbean reef corals.</TITLE>
58899 <SOURCE>Paleobiology 21, 1: 52-73.</SOURCE>
58900 <ABSTRACT>We analyze a new compilation of Neogene to Recent (22-0 Ma) Caribbean coral occurrences to determine how ecological and life history traits at the population level affect long-term evolutionary patterns. The compilation consists of occurrences of 175 species and 49 genera in one continuous (> 5 m.y.) sequence and 22 scattered sites across the Caribbean region. Previous study of evolutionary rates using these data has shown that both extinction and origination were accelerated between 4 and 1 Ma, resulting in large-scale faunal turnover. Categories for three morphological and two reproductive variables (colony size, colony shape, and corallite size; and sex, and mode of embryonic development; respectively) are assigned to each

species in the compilation. Comparisons of the ecological variables with evolutionary rates using randomization procedures and modified analysis of variance show that only colony size was strongly related to rates of extinction and origination during either normal background times or times of accelerated extinction. Extinction rates were lower in species with large colonies, because species with small massive colonies tend to live in small, short-lived populations with highly fluctuating recruitment rates. During turnover, extinction rates increased disproportionately in species with small colonies. Origination rates are found to be less related to ecological variables, although species with small massive colonies originated at higher rates prior to turnover. Accelerated turnover may have therefore involved an increase in local population extinction rates that caused increased rates of both species extinction and origination across the entire fauna. Since extinction rates accelerated disproportionately with respect to colony size, the overall result was a relative increase in species with large colonies. After severe disturbance, one might expect that populations of species with large colonies and high rates of fragmentation would be more likely to escape extinction, because of larger population sizes, longer generation times, and more constant rates of population increase. The modern Caribbean reef-coral fauna is therefore structured by large, long-lived colonies that are robust to regional environmental change. Many of the very taxa that allowed reef communities to escape collapse in the past are declining today in response to anthropogenic disturbances, suggesting that Caribbean reef communities may be less resilient in the future in response to ongoing environmental perturbations.</ABSTRACT>

58911 <TITLE>Caribbean chronostratigraphy refined with U-Pb dating of a Miocene coral.</TITLE>

58912 <SOURCE>Geology 36, 2: 151-154.</SOURCE>

58913 <ABSTRACT>An exceptionally well-preserved aragonitic coral of the extinct species *Goniopora hilli* was collected from late Cenozoic sedimentary deposits in the Dominican Republic and dated using U-Pb techniques. Nine coralline subsamples yielded a $^{238}\text{U}/^{206}\text{Pb}$ - $^{207}\text{Pb}/^{206}\text{Pb}$ three-dimensional (3-D) inverse linear concordia age of 5.52 ± 0.15 (2s) Ma, which, when coupled with $^{87}\text{Sr}/^{86}\text{Sr}$ ratios obtained from the same coral, allows for tighter constraints on temporal variability of marine species diversity prior to closure of the Central American Seaway. The recognition that pre-Quaternary aragonitic corals can be suitable for U-Pb dating creates new possibilities for refining the chronologies of late Cenozoic marine sedimentary sequences. - 58952 <ABSTRACT>The scleractinians Acropora palmata and Acropora cervicornis are common framebuilders in the various Pleistocene fringing reefs of Barbados. Both exhibit the same diagenetic fabrics, but the rate of diagenetic alteration varies considerably. A. cervicornis is dominated by dissolution with minor calcite precipitation or neomorphism. This leads to a drastic reduction of the fossil record in older terraces. In contrast, A. palmata still has relics of unaltered microstructure in the older reefs. This difference in record potential is a result of the genetically fixed diameter of the polycrystalline fibers comprising the spherulitic trabecular microstructure; these are distinctly thicker in A. palmata.</ABSTRACT>

- 58964 <SOURCE>Coral Reefs 7: 37-44.</SOURCE>

- 58965 <ABSTRACT>Regression analysis has been used to study the relationship between age, size, shape, and surface area in two ancestral-descendant populations of the Neogene Caribbean coral *Trachypora bilobata*. Analyses of the relationship between size and age show that the relationship is isometric and that little difference occurs between populations in mean corallite length or height and in their rates of growth. Onset of columella growth is significantly earlier, however, in the descendant population. Studies of the relationship between size and shape show that growth is allometric, with shape change occurring in both corallum elongation and pinching of the corallite wall during ontogeny. In the descendant population, pinching and elongation initiate earlier in the ontogeny of the coral. These results suggest that the evolutionary development of the meandroid form in freeliving corals has been accomplished by heterochrony, involving a complex set of disassociated peramorphic changes in ontogeny accompanied by paedomorphic changes in astogeny. Further analyses show that the observed heterochronic changes serve to decrease corallum surface area which may in turn enhance sediment removal and nutrition in unstable habitats.</ABSTRACT>

- 58991 <ABSTRACT>Exoskeletons of scleractinian corals in the elevated late Pleistocene reefs on northern Barbados illustrate a series of diagenetic textures that document aragonite coral alteration under subaerial vadose conditions. Two major solution-precipitation processes are recognized: (1) concomitant solution - precipitation on a fine scale leading to preservation of coral microstructure, and (2) total leaching and destruction of the microstructure followed by later precipitation of void-filling spar. * The pathway of aragonite solution is similar in both processes, and is controlled by the original coral microstructure. Solution begins in the fine equant crystallites forming the axis (center of calcification) of each trabecula and moves outward into the surrounding zone of closely packed aragonite needles by

preferential solution along the linear intercrystalline contacts between needles. This results in the friable aragonite "chalk" commonly observed in Pleistocene corals. * Aragonite "chalk" is also observed as a zone between aragonite and calcite in corals undergoing solution-precipitation on a fine scale. The coral microstructure is preserved by concomitant precipitation of calcite between separated aragonite needles adjacent to the calcite alteration front, incorporating minor impurities and irregularities of the original structure into the calcite crystals. This result is a new calcite texture that mimics the original aragonite one. * Corals completely altered to calcite by concomitant solution-precipitation on a fine scale exhibit a coarse mosaic of blocky calcite with a relict fibrous texture. The once dark trabecular axes are preserved as a clear central canal. A similar calcite trabecular texture is observed in certain Devonian tabulate corals and other fossil calcareous organisms, suggesting that their skeletons may have been aragonite, altered to calcite in a manner similar to that described above.</ABSTRACT>

59015 <TITLE>First record of the Indo-Pacific reef coral genus Isopora in the Caribbean region: Two new species from the Neogene of Curaçao, Netherlands Antilles.</TITLE>

59016 <SOURCE>Palaeontology 51, 6: 1387-1401.</SOURCE>

59017 <ABSTRACT>The coral genus Isopora, a sister group of the modern dominant Acropora until now only known from the Pliocene to Recent of the Indo-Pacific, is recorded in the Caribbean for the first time. Two new species, Isopora ginsburgi and Isopora curacaoensis, are described from the Neogene Seroe Domi Formation of Curaçao, Netherlands Antilles. Study of large collections made systematically through the sequence indicates that Isopora first occurred in the Caribbean during the Mio-Pliocene, at approximately the same time as the origination of many modern Caribbean reef coral dominants including Acropora cervicornis. It last occurred in the region during the late Pliocene as part of a pulse of extinction, in which several genera that live today in the Indo-Pacific became extinct in the Caribbean. Throughout its Caribbean duration, Isopora co-occurred with the two abundant modern Caribbean species of Acropora, A. cervicornis and A. palmata. Comparisons with Neogene collections made elsewhere in the Caribbean indicate that

Isopora was restricted in distribution to the southern Caribbean. Isopora species are viviparous, while Acropora are oviparous, and this difference in reproductive strategy may have played a role in the extinction of Isopora in the Caribbean. The occurrences of Isopora reported in this study are the oldest records to date of Isopora worldwide, and are important for understanding the biogeographic separation between reef coral faunas in the Caribbean and Indo-Pacific regions. 59028 <TITLE>A new, extinct Pleistocene reef coral from the *Montastraea annularis* species complex.</TITLE>
59029 <SOURCE>Journal of Paleontology 81, 3: 472-482. </SOURCE>
59030 <ABSTRACT>A new species of the *Montastraea annularis* species complex is herein described from Pleistocene coral reefs of the Caribbean Sea. The species, *Montastraea nancyi* n.sp., had a broad geographic distribution at mainly insular sites 125Ka. It has a fossil record extending from 600Ka (thousand years) to 82Ka, both first and last occurrences exclusively on the island of Barbados. It also had a broad environmental tolerance, occurring in fringing, windward back-reef and reef-crest, leeward reef-crest, and lagoonal patch-reef environments. In every habitat in which it lived, there are examples that it either dominated the coral fauna or shared dominance with *Acropora palmata*, a dominant shallow water coral in high-energy Pleistocene and modern reefs. The extinction of *Montastraea nancyi* resulted in evolutionary and ecological change in surviving members of the *M. annularis* species complex. [original abstract]

59041 <TITLE>The Suborders Caryophylliina and Dendrophylliina (Anthozoa: Scleractinia).</TITLE>
59042 <SOURCE>Bulletins of American Paleontology 93, 328: 23-43.</SOURCE>
59043 <ABSTRACT>The 20 species of Neogene Scleractinia in the suborders Caryophylliina and Dendrophylliina known from the Dominican Republic are revised and illustrated. This research was based on 1590 specimens obtained primarily from the collections of the Naturhistorisches Museum, Basel, Switzerland; National Museum of Natural History, Smithsonian Institution, Washington, D.C., U.S.A.; and Tulane University, New Orleans, LA, U.S.A. Eight new records are reported for the Neogene of the Dominican Republic, including four new species: *Antillocyathus allatus*, *Trochocyathus chevalieri*, *T. duncani*, and *Paracyathus sinuosus*. Special attention is given to the genus *Asterosmilia*, since half (five) of the known species in this genus occur in the Dominican Republic. Most species described herein are assumed to constitute a deep-water fauna by analogy to depth ranges of the same or similar species known from the Recent. Certain localities

- and parts of formations are inferred to represent deep-water (> 200 m) facies. These inferences may aid in the paleoecological interpretation of other fossils collected from these areas.</ABSTRACT>

- 59093 <TITLE>Stratigraphic distributions of genera and species of Neogene to Recent Caribbean Reef corals.</TITLE>
- 59094 <SOURCE>Journal of Paleontology 68, 5: 951-977.</SOURCE>
- 59095 <ABSTRACT>To document evolutionary patterns in late Cenozoic Caribbean reef corals, we compiled composite Stratigraphic ranges of 49 genera and 175 species using Neogene occurrences in the Cibao Valley sequence of the northern Dominican Republic and faunal lists for 24 Miocene to Recent sites across the Caribbean region. This new compilation benefits in particular from increased sampling at late Miocene to early Pleistocene sites and from increased resolution and greater taxonomic consistency provided by the use of morphometric procedures in species recognition. Preliminary examination and quantitative analysis of origination and extinction patterns suggest that a major episode of turnover took place between 4 and 1 Ma during Plio-Pleistocene time. During the episode, extinctions were approximately simultaneous in species of all reef-building families, except the Mussidae. Most strongly affected were the Pocilloporidae (Stylophora and Pocillopora), Agariciidae (Pavona and Gardineroseris), and free-living members of the Faviidae and Meandrinidae. At the genus level, mono and paucispecific as well as more speciose genera became regionally extinct. Many of the extinct genera live today in the IndoPacific region, and some are important components of modern eastern Pacific reefs. Global extinctions were concentrated in freeliving genera. During the turnover episode, no new genera or higher taxa arose. Instead, new species originated within the surviving Caribbean genera at approximately the same time as the extinctions, including many dominant modern Caribbean reef-building corals (e.g., Acropora palmata and the Montastraea annularis complex). Excluding this episode, the taxonomic composition of the Caribbean reef-coral fauna remained relatively unchanged during the Neogene. Minor exceptions include. 1) high originations in the Agariciidae and free-living corals during late Miocene time; and 2) regional or global extinctions of several important Oligocene Caribbean reef builders during early to middle Miocene time.</ABSTRACT>

59172 <SOURCE>Géologie et paléoécologie des récifs [J. Geister & R. Herb (eds)]: 1.1-1.14.</SOURCE>
59173 <ABSTRACT>Les géologues et paléontologues qui abordent la recherche dans les récifs actuels, le font avec l'intention de pouvoir mieux interpréter les récifs fossiles après. Mais un des premiers résultats qui émergent de tels recherches est que les récifs récents se comparent assez mal avec la plupart des récifs fossiles. Pour être plus précis: * il existe une ressemblance assez étroite sur le plan structurel et géomorphologique entre récifs pleistocènes et actuels; * mais il existe aussi une dissemblance marquée entre récifs actuels et récifs pré-quaternaires. * La cause de ce changement brusque de la structure et de la géomorphologie des récifs est à chercher dans un changement du milieu marin dès le début du Quaternaire. Le changement le plus marqué était certainement dû aux oscillations abruptes et fréquentes du niveau de la mer associées aux glaciations et déglaciations du Quaternaire. Ces oscillations eustatiques ont connu des amplitudes de plus de 100 m. * Retenons que la plupart des récifs actuels se sont formés vers la fin de la transgression holocène. Pour cette raison les âges des récifs holocènes dépassent rarement les 6000 années, ce qui contraste avec une durée de plus d'un million d'années chez beaucoup de complexes récifaux mésozoïques qui peuvent comprendre plusieurs zones biostratigraphiques. 59197 <TITLE>Caribbean shallow water black corals (Cnidaria: Anthozoa: Antipatharia).</TITLE>
59198 <SOURCE>Caribbean Journal of Science 41, 3: 492-507. [http://caribjsci.org/dec05 special issue/41_492-507.pdf](http://caribjsci.org/dec05%20special%20issue/41_492-507.pdf)</SOURCE>
59199 <ABSTRACT>Our aim is to provide a complete key and guide to the species of black corals from the Caribbean reefs at depths shallower than about 100 m. The key to the species is mostly based on colonial features that are recognized in the field, although some closely related species can

only be differentiated by microscopic skeletal features. Each species is illustrated with one or more photos showing the size and shape of the colony; many photos were taken in the natural environment to facilitate underwater identification. Additionally, a short description is provided of each species and their microscopic diagnostic characters are illustrated with the aid of the Scanning Electron Microscope (SEM). Fifteen black coral species are found in relatively shallow-water in the Caribbean, Gulf of Mexico, and other parts of the tropical western Atlantic; these belong to the families Myriopathidae [*Tanacetipathes hirta* (Gray), *T. tanacetum* (Pourtales), *T. barbadensis* (Brook), *T. thamnea* (Warner), and *Plumapathes pennacea* (Pallas)]; Antipathidae [*Antipathes lenta* Pourtales, *A. rubusiformis* Warner and Opresko, *A. furcata* Gray, *A. umbratica* Opresko, *A. atlantica* Gray, *A. gracilis* Gray, *A. caribbeana* Opresko, *Stichopathes lutkeni* Brook, and *S. occidentalis* (Gray)]; and Aphanipathidae [*Rhipidopathes colombiana* (Opresko and Sánchez)]. We hope that this guide will facilitate research on black corals on Caribbean reefs, where population surveys are urgently needed to evaluate or modify conservation policies.

</TITLE>

59211 <SOURCE>Bulletin de l'Institut royal des sciences naturelles de Belgique, Biologie 66, suppl. 1996 [Willenz P. (ed.): Recent advances in sponge biodiversity inventory and documentation]: 205-218.</SOURCE>

59212 <ABSTRACT>A new coralline sponge, *Willardia caicosensis*, assigned to the family Timeidae, is described from the deep fore reef off the Turks and Caicos islands, tropical western Atlantic ocean, where it is common at depths ranging from 100 to 119m. Individuals vary up to 15-20cm in width. The relatively thin aragonitic skeleton is covered with delicate pillars up to + 1mm. The living tissue is restricted to the spaces between pillars and a thin sheet lying above the calcareous skeleton. Exhalant canals converge upon regularly spaced central oscules on the sponge surface. Siliceous spicules include tylostyles and amphiasters which are secondarily embedded in the aragonitic moiety of the skeleton. In addition, ultrastructural characters of the choanocytes, such as periflagellar sleeves are typical of the Order Hadromerida. Two types of cells with dense spherules are abundant in the mesohyl: spherulous cells packed with large heterogeneous inclusions, protruding at the surface of the sponge, and glycoytes with smaller ovoid corpuscles, mainly grouped along the basal calcareous skeleton. Rough collagen fibrils extend in tracts from the base of the sponge to the ectosome. Sparse bacteria are scattered in the mesohyl. [original abstract]</ABSTRACT>

59262 <TITLE>Southern Caribbean cryptic scleractinian reef corals from Bonaire, NA.</TITLE>
59263 <SOURCE>Palaios 02: 205-218.</SOURCE>
59264 <ABSTRACT>At 14 sites along the west coast of the southern Caribbean island of Bonaire, Netherlands Antilles, 5045 living scleractinian corals in 1101 reef-growth-framework cavities over the depth range 12 m to 43 m were identified and counted. The sample comprises 28 hermatypic coral taxa, the ahermatypic Tubastrea coccinea, and the hydrozoan Millepora alcicornis. Although there is no known fossil record of scleractinian reef corals in cavities, there is a record for the taxa living on the reef surface that also inhabit modern reef cavities. This permits speculation that the modern Caribbean cryptic scleractinian coral assemblage may have roots extending into the Tertiary, and at the family level, possibly into the Mesozoic. The common presence of 8

genera, amounting to 44% of the southern Caribbean cryptic coral assemblage, in reef cavities in both the southern Caribbean and the southwestern Pacific, supports the antiquity of the cryptic coral biota, by suggesting that at least those genera may have already been in cavities before the rise of the Isthmus of Panama. </ABSTRACT>

59276 <SOURCE>Origin, Evolution, and Modern Aspects of Biomineralization in Plants and Animals [R.E. Crick (ed.)]: 175-199; Plenum Press, New York.</SOURCE>
59277 <ABSTRACT>The size and morphology of calcium carbonate crystals of the exoskeletons of the Caribbean Scleractinian coral species of the genus Acropora are described. The fundamental units of the skeleton are the trabeculae, which are linearly aggrading spherulitic fans of polycrystalline aragonite fiber bundles. Each spherulitic fan originates from a center of calcification (Ogilvie 1896; Wells 1956) that is composed of packets of submicron calcium carbonate crystals in an amorphous matrix. The nucleating packets appear to have an intracellular origin and their production stimulated by zooxanthellate photosynthesis.</ABSTRACT>

- 59316 <ABSTRACT>22 species of ahermatypic corals belonging to 4 suborders, 7 families and 15 genera obtained on stations at the depths 50-1650m in the Gulf and Caribbean were studied. * Affinities of the examined corals to the ahermatypic madreporaria of the Northeastern Atlantic, Gulf of California, Pacific coasts of the USA were shown. They are slightly traced between those of the Caribbean and Gulf and those of the Mediterranean. * The examined fauna of the ahermatypic corals of the Caribbean was more closely related to the coral fauna of the Mediterranean during Miocene period than to the recent coral fauna of this region. * The taxonomic status of *D. italicus* and *D. agassizi* is given.</ABSTRACT>

59353 <TITLE>Cnidaria, Scleractinia, Siderastreae, Siderastrea radians (Ellis & Solander, 1786): Hartt Expedition and the first record of a Caribbean siderastreid in tropical southwestern Atlantic.</TITLE>
59354 <SOURCE>Check List 6, 4: 305-510. www.checklist.org.br</SOURCE>
59355 <ABSTRACT>Samples of Siderastrea collected by the geologist C. F. Hartt during expedition to Brazil (19th century), and deposited at the National Museum of the Natural History, Smithsonian Institution, have been re-examined. Taxonomical analyses resulted in the identification of a colony of S. sidera from offshore northern Bahia state. Following recent studies, the occurrence of Caribbean siderastreids to western South Atlantic provides new criteria to assess intra- and interpopulational morphological variation of the endemic S. stellata, refuting historical trends of synonymizations possibly biased by long-term taxonomical misunderstandings. 59379 <TITLE>Micromorphology and ultrastructure of Caribbean sclerosponges. I. Ceratoporella nicholsoni and Stromatospongia norae (Ceratoporellidae; Porifera).</TITLE>
59380 <SOURCE>Marine Biology 103: 387-401.</SOURCE>
59381 <ABSTRACT>Fine structural analysis of living tissue of the sclerosponges Ceratoporella nicholsoni (Hickson) and Stromatospongia norae Hartman collected near Discovery Bay, Jamaica, between 1984 and 1996, was carried out using transmission and scanning electron microscopy (TEM and SEM). The thick dermal membrane of these spongiae is covered by exopinacocytes having a "" shape in sections perpendicular to the surface. A dense complex glycocalyx is produced at the surface of these cells. Choanocyte chambers are diplodal and unusually small. The inhalant and exhalant canals of both species are characterized by the presence of valvules, made by transverse lamellipodial processes of the endospongiocytes lining them. An abundant and diversified bacterial community occupies almost 20% of the mesohyl. A single layer of active basopinacocytes lines the mesohyle at the interface between the living tissue and the aragonitic skeleton. Sclerocytes and spongocytes are abundant in the vicinity of the siliceous spicules. Typical lophocytes releasing smooth collagen fibrils are common in the dermal membrane as well as in the choanosome

where they can be grouped in bundles. Uniquely, *C. nicholsoni* elaborate rough intercellular fibrils [are] characterized by periodically spaced thickenings. The endolithic algae *Ostreobium* sp. is present in the most apical zones of the aragonitic skeleton, but does not seem to interfere with its development. The striking micromorphological resemblances between both species are discussed and compared to demosponges.

59498 <ABSTRACT>The coral reef at Parque Nacional Cahuita, Limon, Costa Rica, is a reef under stress due to siltation. The amount of suspended sediments is high and resuspension of bottom sediments is also high. Growth rates of corals, live coral coverage and diversity were low. Colonies are generally larger than in other areas studied, and recruitment of planulae seems to be low. Most of the corals present are good at rejecting sediments and morphologies of some change to better resist the sediments (vertical fronds of *Agaricia agaricites*) or to receive more light (shingles of *Montastrea annularis* and *Porites astreoides*).</ABSTRACT>

59524 <ABSTRACT>In a few selected reef stations of San Andrés Island time-series of submarine photographs were taken during a period of up

to 33 years. Reviewing these photographs we shall virtually drift with time from 1968 to present, recognizing changes in the composition of reef associations, development of diseases, effects of bleaching, algal invasions, hurricane impact and the process of bioerosion. It can shown that the degradation of Acropora thickets and soft algal invasions began already in the 1970s, long before, and thus not related to the mass bleachings of 1983/84 and the 1983 die-off of the grazing urchin *Diadema antillarum*.</ABSTRACT>

59535 <TITLE>30 Jahre im Leben eines karibischen Korallenriffes - Thirty years in the life of a Caribbean coral reef.</TITLE>

59536 <SOURCE>Profil 16: 1-11.</SOURCE>

59537 <ABSTRACT>A lush and picturesque shallow-water coral patch at Little Reef, San Andres Island (western Caribbean Sea, Colombia) has been revisited and photographed episodically for over 30 years. The corals were observed to be flourishing between 1969 and 1979. A return visit to the site in 1994 showed heavy degradation with extreme mortality rates, especially among the *Acropora palmata* colonies. At the time of this visit *Diploria strigosa* was under full attack by the Blackband Disease. Coral mortality increased further until 1996, as indicated by the demise of most of the remaining *Porites porites* stands. In 1998 more corals were found dead, with their skeletons attacked by boring organisms and heavily overgrown by soft algae. However, encouraging signs of local recovery of reefs since 1993 (especially of *Acropora palmata* thickets) from elsewhere on the San Andres shelf suggest that degradation has essentially come to an end and we may look forward to a decade of renewal and restructuring of the local reef ecosystem. The sequence of events that led to the extensive destruction of this formerly flourishing coral patch is recorded by a time series of underwater photographs. These were taken from the site from westerly and southwesterly directions. Two major *Diploria strigosa* colonies are marked on the pictures for better comparison of differently orientated shots. The life and death chronicle of the coral patch at Riffstation C; word and picture.</ABSTRACT>

59550 <ABSTRACT>A series of underwater photographs, taken between 1968 and 1999, at five reef stations of San Andres Island (western Caribbean Sea, Colombia), document and date the following biotic changes and processes in the reef environment: the presence and absence of corals

and accompanying reef fauna, increase and decrease of live coral coverage, partial and total coral mortality, impact of coral diseases, storm fragmentation of corals, growth and regeneration of coral colonies, bioerosion of coral heads and invasion of soft algae into the reef environment. * The photographs indicate that degradation of *Acropora palmata* and *Acropora cervicornis* thickets had already begun in the 1970s, considerably preceding the well recorded mass bleaching events of the 1980s. Encroachment by soft algae in the reef and lagoon environment was first noticed in 1973, but increased in the following years. Extensive algal proliferation witnessed in Caribbean reefs since the 1980s was apparently not caused by, but was accelerated by the 1983 die off of the grazing urchins *Diadema antillarum*. A series of photographs of reef biotopes over time permits retrospective analysis of changes that otherwise would go unnoticed. [original abstract]

59563 <ABSTRACT>The effects of predominant currents on the morphology of coral reefs has been studied in the leeward patch reefs of Anegada, British Virgin Islands. Measurements of current velocity and direction and sediment characteristics together with mapping of approximately 31 patch reefs within a 2 km² area suggest that even under relatively low but constant velocities (surface current to 20 m sec⁻¹) the major reef-building corals show definite distribution patterns on the reef. The currents also appear to be responsible, in part, for marked orientation and elongation of patch reefs in a north-west / south-east direction and for a gradation of patch-reef type across the study area.

59602 <ABSTRACT>This large (25x34 cm) colourful reef volume (text by H. von Prah1, submarine photos by A. Brando) gives an excellent visual introduction to the beauty of the Colombian reefs. There are many bright and colourful close-ups of interesting reef organisms accompanied by an easily accesible explanatory text. This is not a highly technical book, but may be welcome also to specialist because of the features shown on the plates. It is aimed to introduce a wider public in Latin America to the beauty of the endangered coral reefs. The senior author, Professor Henry von Prah1, was the leading Colombian reef scientist. He died tragically toward the end of last year. [book review by Joern Geister]</ABSTRACT>

59613 <TITLE>Storm features on a southern Caribbean fringing coral reef.</TITLE>
59614 <SOURCE>Palaios 7: 213-221.</SOURCE>
59615 <ABSTRACT>Although there have been many studies that have documented various effects of storms in coral reefs, to date there have been no systematic studies of the depth distribution of storm features and few discussions of the potential for preservation of evidence of storm activity in reefs. After hurricane Gilbert and tropical storm Joan passed through the Caribbean late in 1988, an opportunity became available to study storm features and to relate them to water depth in the leeward reefs of the southern Caribbean island of Bonaire. In January 1989, sixty indicators of storm impact on the reefs of Bonaire were found over the depth range 1.5m to 37m at 5 localities. These are grouped in 3 broad categories, comprising effects on sediment, effects on reef-dwelling organisms, and the deposition of terrestrial vegetation on the reef. Damage to the reef consisted of direct damage due primarily to wave impact and surge, and indirect damage by secondary factors such as burial by sediment. The evidence of direct physical damage was pronounced in the shallow parts of the reef, and indirect damage dominated in the middle and deeper parts of the reef. Taking all storm features together 3 to 4 months after the storms, the greatest number of storm-related features (66%) was in the 11m to 20m depth range, so that although during the storms the greatest physical damage to the reef was in the shallower parts, the post-storm

distribution of identifiable storm-related features did not reflect this. The depth distribution of potentially preservable storm features (45% of the total) is almost the same as the depth distribution of all storm features. However, the proportion of potentially preservable features is greatest in the shallowest (83%) and deepest (60%) parts of the reef. Therefore, following a short period of adjustment after storms Gilbert and Joan: 1) the remaining storm-related features were not evenly distributed with respect to depth, 2) the greatest number of storm-related features remaining were in intermediate water depths, 3) the greatest number of potentially preservable storm features were also in intermediate depths.</ABSTRACT>

59626 <TITLE>Holocene coral patch reef ecology and sedimentary architecture, northern Belize, Central America.</TITLE>

59627 <SOURCE>Palaios 7: 591-601.</SOURCE>

59628 <ABSTRACT>The biotic composition, growth and relationship to sea level history, and diagenetic attributes of a representative Holocene patch reef ("Elmer Reef") in the Mexico Rocks complex in northern Belize are described, and compared to those of Holocene patch reefs in southern Belize. Elmer Reef has accumulated in shallow (2.5m) water over the last 420 yr, under static sea level conditions. Rate of vertical construction is 0.3-0.5 m/100 yr, comparable to that of patch reefs in southern Belize. A pronounced coral zonation exists across Elmer Reef, with Montastrea annularis dominating on its crest and Acropora cervicornis occurring on its windward and leeward flanks. The dominance of Montastrea on Elmer Reef is unlike that of patch reefs in southern Belize, in which this coral assumes only a subordinate role in reef growth relative to that of Acropora palmata. Elmer Reef locally is extensively biodegraded and marine, fibrous aragonite and some bladed high-magnesium calcite cements occur throughout the reef section, partially occluding corallites and interparticle pores in associated sands. Patch reefs in southern Belize have developed as catch-up and keep-up reefs in a transgressive setting. In contrast, the dominant mode of growth of Elmer Reef, and perhaps other patch reefs in Mexico Rocks, appears to be one of lateral rather than vertical accretion. This style of growth occurs in a static sea level setting where there is only limited accommodation space because of the shallowness of the water, and such reefs are referred to as "expansion reefs". [original summary; comments on this paper are given by William F. Precht in Palaios 8, 1993: 499-502]</ABSTRACT>

59639 <TITLE>Sedimentation on Three Caribbean Atolls: Glovers Reef, Lighthouse Reef and Turneffe Islands, Belize.</TITLE>

59640 <SOURCE>Facies 31: 243-254.</SOURCE>

- 59641 <ABSTRACT>The chief mode of carbonate sedimentation on the Belizean atolls Glovers Reef, Lighthouse Reef and Turneffe Islands is the accumulation of organically-derived particles. Variations in the distribution of the composition and grain-sizes of surface sediments, collected along transects across the atolls, are environmentally controlled. Two major sediment types may be distinguished. (1) Reef and fore reef sediments are dominated by fragments of coral, coralline algae and Halimeda. Mean grain-sizes range from 1-2mm. (2) Back reef sediments contain more mollusk fragments, more fine-grained sediment (<125µm) and appear to have fewer Halimeda fragments. In addition, sediments from inner platforms and shallow lagoonal parts of Glovers and Lighthouse Reefs comprise non-skeletal grains, namely fecal pellets. Sediments from lagoonal patch reefs may contain up to 20% coral fragments. Mean grain-sizes range from 0.1-1mm and are finest on the inner platform and lagoon floor of the backreef environment. Within the reef and fore reef environments, it is not possible to distinguish sub-environments on the basis of textural and compositional differences of the sediments. Sediments from patch reefs contrast with those from back reef lagoons and inner platforms and are similar in terms of grain-sizes and compositions to reef and fore reef surface sediments. Non-skeletal grains forming in shallow parts of the back reef in Glovers and Lighthouse Reefs are interpreted to be indurated by interstitial precipitation of calcium carbonate from warm, supersaturated water flushing the sediment. The lack of hardened non-skeletal particles in the back reef sediments of Turneffe Islands is most probably due to the abundance of muddy, organic-rich sediment in the well protected lagoon. Fine sediment is less permeable and organic films prevent cement overgrowth on particles.</ABSTRACT>

- 59653 <SOURCE>Geology 23, 4: 341-344.</SOURCE>
- 59654 <ABSTRACT>Calcic dolomite cements compose an average of 5% of the upper 4.3m of subtidal deposits <5600 yr old in the Cangrejo shoals in Belize. Mean δ180 (+2%) compositions of the high-Sr dolomites (mean 1000 ppm), together with near-normal salinity and inherently normal Mg/Ca ratio of pore fluids, suggest precipitation from near-normal seawater. Tidal and wind-driven circulation of seawater through the sediments supplies most of the Mg for dolomitization, which appears to be promoted by elevated pore-water alkalinity resulting from bacterially mediated oxidation of organic matter and, locally, early stages of methanogenesis. Rapid dolomitization here supports the idea that significant quantities of dolomite can form syndepositionally, from normal seawater, in shallow subtidal deposits.</ABSTRACT>

59706 <ABSTRACT>Aqualungs were used for the study of the coral reefs of Cuba, about which comparatively little has been known so far. Their small dimensions and their position close to the coastline or in the central part of the island plateau, instead of along the shelf edge, can be attributed to the inhibiting and delaying influence of glacial periods. The different types of reefs and other coral habitats originated as a result of geological, hydrological and biological factors, while the formation of coral associations was dependent on the prevailing physical and chemical features of the environment. The following is a description of the cross-bar reef and the coral terrace, two coral habitats. The present work continues earlier articles related to the subject and published in this periodical.</ABSTRACT>

59796 <SOURCE>Bulletin de l'Institut royal des sciences naturelles de Belgique, Biologie 66, suppl. 1996 [Willenz P. (ed.): Recent advances in sponge biodiversity inventory and documentation]: 143-151.</SOURCE>
59797 <ABSTRACT>An unusually large agglutinated foraminifer was found to be common in semishaded habitats on Caribbean coral reefs. The tree-shaped organism attains 50 mm in height and builds its test using siliceous sponge spicules exclusively. A new genus and species, Spiculidendron coralliculum, are established in the Textulariina family Astrorhizidae. The new taxon is characterized by a complexly branching tubular test that is attached to hard substrate and has a simple wall lacking septae and apertures. Electron microscopy shows a spongin-like organic cement and various cell organelles and inclusions, including dinophycean symbionts. Cytoplasm resides in substrate cavities and in the hollow base of stem and branches that form the test. Observations suggest that in life cytoplasm flows also outside the test along its thin distal

- branches where it cements new spicules in place and takes up food (pseudopodia). [original abstract] </ABSTRACT>

- 59823 <ABSTRACT>Atolls are the product of a wide range of variables, including hurricanes, isostatic movements, and biosynthesis. Processes of atollization encompass saponification, enzymatic effects of odours, and carbonate cementation. A new theory, the storm-tide theory, conceives of sea-floor spreading away from nodal centres, as being the mechanism by which atollization is effected. Turks and Caicos Islands are located in that part of Orbis terrarum known as the Tropics, where ecosystems are particularly affected by the saltations of the Earth in its lunar-solar journey in the Plane of the Ecliptic.</ABSTRACT>

59847 <TITLE>New and old Scleractinian Corals from Jamaica.</TITLE>
59848 <SOURCE>Bulletin of Marine Science 23, 1 [Coral Reef Project - Papers in Memory of Dr. T.F. Goreau. 2.]: 16-58.</SOURCE>
59849 <ABSTRACT>The underwater studies of Jamaican reefs carried out during the past 17 years by the late T.F. Goreau and his colleagues have turned up a number of new species of scleractinian corals and disclosed the common occurrence at depth of several species previously thought to be rare. The new forms include one species of Madracis, one of Agaricia, three of Mycetophyllia, one of Gardineria, and new forms of Eusmilia fastigiata and Agaricia fragilis. Earlier named but poorly known species discussed and figured are: Agaricia undata (Ellis & Solander), Agaricia lamarcki Milne Edwards & Haime, A. tenuifolia (Dana), Helioseris cucullata (Ellis & Solander), Colpophyllia breviserialis Milne Edwards & Haime, Mycetophyllia danaana Milne Edwards & Haime, and Dichocoenia stellaris Milne Edwards & Haime.</ABSTRACT>

59886 <TITLE>Carbon isotope records from extant Caribbean and South Pacific sponges: evolution of δ13C of surface water DIC.</TITLE>
59887 <SOURCE>Earth and Planetary Science Letters 139, 1-2: 291-303.</SOURCE>

- 59888 <ABSTRACT>Stable isotope records of demosponges from the Caribbean and Coral Sea are described for the purpose of studying the influence of fossil fuel CO₂ on the carbon isotopic composition of dissolved inorganic carbon (DIC) in surface water. The slow-growing sponges precipitate calcium carbonate in isotopic equilibrium with ambient sea water and are used to detect changes in $\delta^{13}\text{C}_{\text{DIC}}$ from pre-industrial times (early 19th century) to the present. We observed similar shapes and ranges in $\delta^{13}\text{C}$ curves measured on Caribbean specimens collected from water depths of 25, 84 and 91m as well as [in] a specimen collected in shallow waters off New Caledonia. The records reveal a highly significant correlation with atmospheric $\delta^{13}\text{C}_{\text{CO}_2}$. $\delta^{13}\text{C}_{\text{DIC}}$ values for Caribbean and Coral Sea surface waters were calculated using the $\delta^{13}\text{C}$ sponge records. While $\delta^{13}\text{C}$ of atmospheric CO₂ decreased by about 1.4% from the early 19th century to 1990, $\delta^{13}\text{C}_{\text{DIC}}$ of Caribbean and Coral Sea surface waters decreased by $0.9\pm 0.2\%$ and $0.7\pm 0.3\%$, respectively. No isotopic equilibrium between surface water DIC and atmospheric CO₂ was observed, either during the pre-industrial steady state or during the last 100 years. The lower amount of depletion in the surface water $\delta^{13}\text{C}_{\text{DIC}}$ with respect to the atmospheric anthropogenic signal is explained by the dilution of the surface waters by biologically altered subsurface water DIC. The lower $\delta^{13}\text{C}$ decrease in the Coral Sea points to a stronger influence of the subsurface water source compared to the Caribbean. [original abstract]</ABSTRACT>

- 59901 <ABSTRACT>Competition for space among reef corals includes interspecific destruction by extracoelenteric digestion, rapid growth, and overtopping. No Caribbean species excels in all strategies, and on western Caribbean coral reefs, there is a positive correlation between coral abundance and diversity. On eastern Pacific coral reefs, however, Pocillopora damicornis excludes other corals, and on these reefs there is an inverse relation between coral abundance and diversity, except in areas where disturbances, such as Acanthaster predation, offset space monopolization.</ABSTRACT>

59938 <TITLE>Cenozoic biogenic mounds and buried Miocene(?) barrier reef on a predominantly cool-water carbonate continental margin - Eucla basin, western Great Australian Bight.</TITLE>
59939 <SOURCE>Geology 23, 5: 427-430.</SOURCE>
59940 <ABSTRACT>The southern continental margin of Australia is the largest area of cool-water carbonate shelf deposition on the globe. Interpretation of 5495km of air gun seismic-reflection data in the western part of the Great Australian Bight indicates that the 700m thick Cenozoic section of the offshore Eucla basin was deposited largely as a prograding cool-water, middle- to high-latitude carbonate ramp, characterized by widespread development of broad, low-relief, biogenic (bryozoan? - sponge), shelf and upper-slope mounds. The succession also contains a spectacular and extensive (>475km long) buried middle Miocene barrier reef (the Miocene Little Barrier Reef) parallel to the modern shelf edge. This rimmed carbonate platform margin represents an episode of warm-water sedimentation during a global climatic optimum, probably coupled with strong eastward flow of a proto-Leeuwin Current. The late Miocene eustatic sea-level fall produced an areally restricted debris-apron sequence at the foot of the reef escarpment. The carbonate platform is capped by a Neogene cool-water carbonate ramp succession typified by aggradational to sigmoidal sequences, punctuated by periods of cold-water, sea-floor erosion. Interpretation of this succession in the light of global and local tectonic and oceanographic events illustrates the dominant influence of water temperature on carbonate platform and reef growth throughout the Cenozoic.</ABSTRACT>

59951 <TITLE>Deep-sea Hexactinellida (Porifera) of the weddell Sea.</TITLE>
59952 <SOURCE>Deep-Sea Research Part II: Topical Studies in Oceanography 51, 14-16: 1857-1882.</SOURCE>
59953 <ABSTRACT>New Hexactinellida from the deep weddell sea are described. This moderately diverse hexactinellid fauna includes 14 species belonging to 12 genera, of which five species and one subgenus are new

to science: *Periphragella antarctica* n.sp., *Holascus pseudostellatus* n.sp., *Caulophacus* (*Caulophacus*) *discohexactinus* n.sp., *C.* (*Caulodiscus*) *brandti* n.sp., *C.* (*Oxydiscus*) *weddelli* n.sp., and *C.* (*Oxydiscus*) n.subgen. So far, 20 hexactinellid species have been reported from the deep Weddell Sea, 15 are known from the northern part and 10 only from here, while 10 came from the southern area, and five of these only from there. However, this apparent high **endemism** of Antarctic hexactinellid sponges is most likely the result of severe undersampling of the deep-sea fauna. We find no reason to believe that a division between an oceanic and a more continental group of species exists. The current poor database indicates that a substantial part of the deep hexactinellid fauna of the Weddell Sea is shared with other deep-sea regions, but it does not indicate a special biogeographic relationship with any other ocean. 59965 <SOURCE>Senckenbergiana maritima 21, 1/4: 87-99.</SOURCE>

59966 <ABSTRACT>At the 1989 **EPOS** Antarctic Expedition hexactinellid sponges of the species *Aulorossella vanhoeffeni* were obtained. Soft tissue samples of these sponges, especially the choanosome, are investigated at SEM. The choanomeses of their large flagellate chambers comprise central flagella and groups of about 40 microvilli arising from the primary reticulum with collagenous material accumulated at its base. The secondary reticulum can be observed; probably an autapomorphy of the Hexactinellida. Clusters of small spherical objects might be spermatocytes from the sponge.</ABSTRACT>

</SOURCE>
59992 <ABSTRACT>This handy book gives a very good introduction into the
topical knowledge about biology and terminology, e.g. spicule types, of
the recent Hexactinellida. The taxonomic system followed is that of
Ijima (1927) with some revisions from Bergquist (1978), Burthorn (1929),
Hartman (1982), and Levi (1964) included. The diverse antarctic
assemblage of Hexactinellida described here includes 16 genera with 26
species distributed in 8 families. The descriptions are illustrated
with drawings after Schulze and Kirkpatrick and supplied with maps of
antarctic distribution of the various species. This book is a must for
anyone working with Antarctic fauna, or with Hexactinellida. By far the
largest number of samples of Antarctic hexactinellids comes from the
shelf. There are only two records from the slope (800-2000m), and 17
from depths around 2000m and downwards. The Antarctic hexactinellid
fauna comprises 28 species as treated here, and a further 10 may be
considered in the distribution analysis because they have been recorded
close to the Antarctic convergence, mainly in deep water. There is a
distinct vertical division into a shelf group of species and a deep
water group. The relatively few species on the shelf are present in
high numbers and give rise to large biomasses. By species number,
however, hexactinellids are a predominantly deep-sea group in
Antarctica, as they are in other oceans.</ABSTRACT>

60056 <SOURCE>Geological Magazine 121, 4: 291-299.</SOURCE>
60057 <ABSTRACT>Reconnaissance geological mapping (1962-75) followed by detailed geological investigations (1979-80) in the Ellsworth Mountains of west Antarctica have established the existence of extensive Middle and Late Cambrian strata. Forms tentatively referred to Archaeocyatha have been examined by F.D. and A.R., who concluded that, despite the commonly held opinion that the phylum became extinct at the boundary of the Lower and Middle Cambrian, the Ellsworth Mountains' forms represented Irregularian Archaeocyatha which survived in protected niches into the Late Cambrian. The age of the fauna containing the archaeocyaths is firmly dated by abundant trilobites including species of Homagnostus, Pseudagnostus, Kormagnostella, Erixanium and Onchopeltis.</ABSTRACT>

60082 <SOURCE>Alcheringa 10: 237-278.</SOURCE>
60083 <ABSTRACT>Thirty one species of Archaeocyaths are described from measured sections of the Nimrod Glacier area, which confirm earlier correlations of Shackleton limestone faunas with the Botomian stage of Siberia. Archaeocyatha from a section in Byrd Glacier area are Botomian or early Toyonian in age. Ten further archaeocyath species are added to the six species already known to be common both for Antarctica and Australia, confirming the existence of a Gondwana supercontinent in early Palaeozoic.</ABSTRACT>

60095 <SOURCE>Geological Society Special Publication 47: 15-28.</SOURCE>
60096 <ABSTRACT>Most Antarctic archaeocyaths have been collected as allochthonous blocks, but some in situ collections provide stratigraphic control. All existing collections are taxonomically revised. Strong faunal affinities are evident at the species level with in situ Early Cambrian faunas in South Australia and allochthonous faunas in South Africa and Antarctica. This allows the recognition of an Early Cambrian Gondwana province and confirms the existence of a Gondwana supercontinent throughout the Paleozoic.</ABSTRACT>

60107 <TITLE>Early Cambrian archaeocyaths from glacial erratic of King George Island, west Antarctica.</TITLE>
60108 <SOURCE>Palaeontologia Polonica 55 [Gazdzicki A. (ed.): Palaeontological Results of the Polish Antarctic Expedition. Part H.]:

- pp?</SOURCE>
- 60109 <ABSTRACT>Twenty six species of archaeocyaths, including one Naimarkcyathus elenae gen. et sp.nov. representing a new family Naimarkcyathidae, are described from the Cambrian limestone erratics of the glacial-marine sediments of the Oligocene Polonez Cove and Early Miocene Cape Melville formations on King George Island (South Shetland Island, West Antarctica). They are accompanied by coralomorphs and calcified cyanobacteria. The archaeocyathan assemblage closely resembles allochthonous ones from the Weddell Sea and Whicaway Nunataks. Current reconstructions of icestream movement and iceberg drift and similarities in species composition suggest the source of these erratics to be the Argentina Range limestone. Some species, namely, Stapicyathus stapipora, Prethmophyllum subacutum, Aporosocyathus mucroporus, "Mennericyathus" dissitus, Paranacyathus sarmaticus and Archaeopharetra irregularis are added to the list of common species for Antarctica and Australia. The archaeocyaths of King George Island, and all other allochthonous and in situ Early Cambrian Antarctic archaeocyathan assemblages (with exception for the Mt Egerton in the Byrd Glacier area) are of the uppermost Botomian age (Syringocnema favus beds) as found in South Australian strata. This means that archaeocyaths did not reach Antarctica until latest Botomian time. Blocks containing archaeocyaths represent different reef facies comparable to the Kooliwurtie Limestone Member of the Yorke Peninsula. The occurrence of small shelly fossils typical of the upper Kulpara Formation-lower Parara Limestone, of archaeocyaths of Syringocnema favus beds, and of Hadimopaneella antarctica and certain brachiopods in erratics of different lithologies suggests a very similar faunal and facies succession for Antarctica and South Australia and therefore probably a comparable basin history.</ABSTRACT>

60161 <ABSTRACT>Confirmation of the extension of the group up to the Upper
Cambrian; despite some differences (lack of individualised walls) these
sponge-like forms belong to the family Archaeocyathidae. They sometimes
consist of composite colonial bodies, branching cups evolving into
catenulate forms. It is probably because of their plasticity and
primitive development that they were able to survive in restricted
niches up to the Upper Cambrian.</ABSTRACT>

60172 <TITLE>A new tube-builder hydractinian, symbiotic with hermit crabs,
from the Cretaceous of Antarctica.</TITLE>
60173 <SOURCE>Journal of Paleontology 68, 6: 1169-1182.</SOURCE>
60174 <ABSTRACT>An Upper Cretaceous (early Maastrichtian) tube-building
hydractinian (Psammoactinia antarctica n.gen. and sp.) from Sanctuary
Cliffs, Snow Hill Island, believed to live in association with hermit
crabs, is described for the first time from Antarctica. Psammoactinia
forms thick, concentric, globular colonies that encrust gastropod
shells and extend the shell aperture by forming an open spiral tube.
The colony consists of concentric layers with chambers and pillars made
of silt and very fine sand grains agglutinated by cellophane, which is
interpreted as a diagenetic modification of an original chitinous

phosphatic material. On the basis of the additional finding of isolated claws of pagurid crabs, assigned to Paguristes sp., the functional analysis of the hydractinian structure, and a comparison with modern and fossil analogous structures it is concluded that the peculiar hydractinian tube is a carcinoecium that housed a symbiotic hermit crab. Paleoenvironmental and paleoecological inferences suggest that the Psammoactinia-Paguristes association is mainly controlled by a fine-grained substrate and by a lack of abundant gastropod shells of different sizes. These factors do not necessarily correlate with absolute water depth, and favorable environments could include either offshore, relatively deep water or shallow restricted depositional settings.</ABSTRACT>

60186 <SOURCE>Antarctic Research Series 65; 96 pp. ISBN 0-87590-8497</SOURCE>
60187 <ABSTRACT>[the book] examines the significance and characteristics of sixteen scleractinian species found in the Upper Cretaceous and Paleocene strata of Seymour and Snow Hill islands, Antarctica. This fossil scleractinian material has revealed nine species described as new, some representing four newly established genera of Turbinoliidae. The objective of this book is to classify the taxa to species level and examine their occurrences with regard to paleoenvironmental and paleogeographic implications. The scleractinian fauna provides a rare opportunity to study both a taxonomic and an ecologic group which apparently was not adversely affected by the Cretaceous to Tertiary transition. 60200 <ABSTRACT>From the Sobral Formation (Paleocene) of Seymour Island solitary coralla of ?Aulocyathus Marenzeller, 1904 (suborder Caryophylliina) and branch fragments of Madrepora sobral Filkorn, 1994 (suborder Faviina) are described. In the overlying strata of the La Meseta Formation (Eocene) scleractinian coral fauna comprises solitary Caryophylliina (Crispatotrochus antarcticus sp.n., Caryophyllia sp., Flabellum sp.) and colonial Dendrophylliina (Tubastraea sp.). Reported are also octocoral holdfasts. The genera recorded from both formations are known also from modern seas. Crispatotrochus antarcticus sp.n. is the earliest representative of the genus. ?Aulocyathus and Tubastraea have no other fossil record. [original abstract]</ABSTRACT>

60239 <ABSTRACT>The solitary scleractinian coral Flabellum rariseptatum Roniewicz & Morycowa, 1985 has been identified in CRP-3 drill core within mudstone lithologies in Unit LSU 3.1. The coral-bearing macrobenthic assemblages include infaunal and epifaunal suspension feeders suggesting a deep muddy shelf environment, characterized by moderate hydrodynamism and turbidity and enrichment in organic matter. Flabellum rariseptatum belongs to the Recent Flabellum thouarsii group and has a known stratigraphic range extending from the early Oligocene to the early Miocene of Antarctica. This is the first known occurrence of Flabellum rariseptatum from the Antarctic mainland.</ABSTRACT>

- 60251 <SOURCE>Palaeontologia Polonica 49: 83-103.</SOURCE>
- 60252 <ABSTRACT>The paper presents results of studies on Flabellum rariseptatum Roniewicz et Morycowa 1985 from the Cape Melville and Destruction Bay Formations (Tertiary) of King George Island, Antarctica. The corals are mainly from thin bedded shales, siltstones and fine sandstone of the glacio-marine Cape Melville Formation, most probably of Lower Miocene age. All post-larval skeletal stages are represented beginning with basal plate with initial septal apparatus composed of 12 protosepta up to large individuals with complete six septal cycles and some septa of higher cycles (S7 and S8). The corals are characterized by variable shape from conical to flabellate, thin pedicel, and low septal density; at the adult stage they are unattached but stand vertically in soft sediment. Corallum morphology, shape of septa and feeble development of columella as well as an initial twelve-septal stage in ontogeny link this species to Recent Flabellum thoursii-group of species known from the Antarctic and sub-Antarctic regions.</ABSTRACT>

60303 <SOURCE>Beringeria 8: 3-69.</SOURCE>
60304 <ABSTRACT>The coral fauna from Bathonian-Oxfordian strata of Kachchh, Western India, originally described by Gregory (1900), is reviewed. Based on large own collections, 52 taxa of corals are described including *Cryptocoenia wegeneri* sp.nov. By far the most prolific coral locality lies within the upper part of the Patcham Formation (Late Bathonian / Early Callovian) at the center of Jumara Dome and yielded 41 taxa. The distribution of the various taxa within the Kachchh Basin is given, as is information on the major coral concentrations.</ABSTRACT>

60329 <SOURCE>Journal of Paleontology 73, 6: 1015-1028.</SOURCE>
60330 <ABSTRACT>The current classification of scleractinian corals based upon gross morphological features has been found unsatisfactory due to additional information from skeletal microarchitecture and microstructure. It is necessary to investigate microstructural details and limits in morphologic variation within and between different coral clades before a revised classification is constructed. Variations in morphologic characters and microstructural details from a population of *Dimorpharaea de Fromentel*, 1861 (Family *Microsolenidae*) from Upper Bathonian (Jumara Dome) strata in Kachchh are described. The data used include the diameter (D) and height (U) of the corallum, number of corallites in the colony (NC), number of septa in the mother corallite at the center of the colony (NS), minimum distance between centers of

central corallite and corallite of the inner ring (CI), minimum distance between corallite centers of the outer ring (C2), septal density (DS) and trabecular density (DT). The principal components analysis reveals that most of the variation is explained by "size " related characters (D and H) while corallite density (NC and CI) and septal structures (DS and DT) contribute to the second and third principal component axes, respectively. The microarchitecture and distribution of characters observed in the Kachchh Dimorpharaea require a re-evaluation of familial-specific concepts and suggest that the population belongs to a single species, *Dimorpharaea stellans* Gregory, 1900, rather than four nominal species (*D. stellans*, *D. distincta*, *D. continua* and *D. orbica*) as has been assumed. 60341 <TITLE>Environmental distribution of scleractinian corals in the Jurassic of Kachchh, western India.</TITLE>

60342 <SOURCE>Journal of the Geological Society of India 57: 479-495.</SOURCE>

60343 <ABSTRACT>Scleractinian corals commonly occur at specific horizons and localities, in carbonate and in siliciclastic sediments, throughout the Jurassic (Bajocian to Oxfordian) of Kachchh as meadows, biostromes, boulder beds and as scattered specimens. In many cases they are part of the autochthonous benthic fauna and in others they suffered short intra-basinal transport. Cerioid forms of low diversity (*Amphiastraea*, *Isastraea*, etc.) abound in high-energy siliciclastic sediments. High diversity coral faunas, which include thamnasterioid (*Microsolena*, *Dimorpharaea* and *Kobya*) and solitary (*Trocharaea* and *Trochoplegma*) taxa with fenestrate septa and plocoid forms (*Stylina*), dominate in carbonate sediments deposited in low energy, deeper-water environments. The solitary *Montlivaltia* exhibits a great physiological tolerance of environmental stress. In all, eight coral assemblages have been recognized within the ?Early Bajocian to Late Callovian sediments of the Kachchh basin. * The distribution of scleractinian coral assemblages has been governed mainly by the rate of sedimentation and particularly by the influx of coarse siliciclastic material. As a consequence the distribution pattern reflects onshore-offshore gradients and the general deepening of the Kachchh basin towards the Oxfordian. [original abstract]</ABSTRACT>

60354 <TITLE>Variability in *Epistreptophyllum* from the Middle Jurassic of Kachchh, western India: an open question for the taxonomy of Mesozoic scleractinian corals.</TITLE>

60355 <SOURCE>Journal of Paleontology 71, 4: 564-577.

<http://www.jstor.org/pss/1306577></SOURCE>

60356 <ABSTRACT>*Epistreptophyllum cornutiformis* Gregory, 1900, is the name assigned to a Middle Jurassic population of scleractinian corals from

- Kachchh, western India. Measurements of ten variables from 84 specimens of this population have been statistically examined by means of univariate and multivariate analyses. A wide range of variation in corallum shape, septal perforation, lateral septal surface ornamentation, nature of the endotheca, and that of the columella is observed. The great majority of specimens are solitary. The wide range of gradational variation observed in this population corresponds to and includes the morphological characters described for various scleractinian genera such as *Protethmos* Gregory, *Metethmos* Gregory, *Frechia* Gregory, and *Epistreptophyllum* Milaschewitsch. The assignment of these genera to this later senior synonym genus is supported by the description of a well-preserved topotype from Nattheim. The ornamentation of the septa in *Epistreptophyllum* is detailed and distances it from typical pennular corals. [original abstract] </ABSTRACT>

60382 <ABSTRACT>The first comprehensive taxonomic description of Jurassic corals from the Jaisalmer Basin, a pericratonic shelf basin on the northwestern slope of the Indian peninsular shield, is based on 75 specimens, which belong to five suborders, seven families, nine genera, and ten species. In Upper Bajocian rocks, all corals belong to the suborder Faviina, in Middle Bathonian rocks 75% of the specimens are members of the Stylinina, whereas corals occurring in the Tithonian all belong to the Caryophylliina. 60395 <ABSTRACT>Cyathophora Michelin 1843, hitherto well known from the Upper Jurassic and Cretaceous, has been found in the Middle Jurassic (Bajocian) of the Kachchh Basin, western India. Eleven specimens of Cyathophora bourgueti (DeFrance 1826) from the Babia Cliff Sandstone member of the Kaladongar Formation, exposed along the northern scarp of the Kala Dongar, Pachchham Island, Kachchh, are described and illustrated as the earliest Jurassic record of the family Cyathophoridae Vaughan & Wells 1943. It is suggested that the monospecific occurrence of Cyathophora bourgueti was controlled by salinity.</ABSTRACT>

60408 <ABSTRACT>From the Late Bathonian sponge biofacies at Jumara Dome, Kachchh (western India) 11 species of 'lithistid'; hexactinellinid and calcarean sponges are described. New taxa are the order Sigmatospirida, the genus Jumarella, and the species Jumarella astrorhiza, Mastosia rhytidodes, Radicispongia kraspedophora, and Hexactinella prisca. The diverse sponge assemblage is associated with a rich fauna of epibenthic bivalves and brachiopods and formed meadows [which] grew on a carbonate ramp at the lower end of the photic zone, in quiet waters below storm wave base. The rate of sedimentation exceeded that of sponge production. This prevented the development of reef-like bodies. In contrast to Mesozoic sponge reefs, growth of the sponge meadows appears to have been confined to the regressive phases of small transgressive-regressive cycles.</ABSTRACT>

60433 <SOURCE>Rivista Italiana di Paleontologia e Stratigrafia 110, 1: 181-190.</SOURCE>
60434 <ABSTRACT>Marine Jurassic sediments (Bajocian-Tithonian) of the Kachchh Basin were deposited in a ramp setting. Except during the Middle and Late Bathonian, when a carbonate regime became established, the fill of the basin consists predominantly of siliciclastics. The sediments represent environments that range from coastal plains (rivers and associated flood plains with caliche nodules), deltas, brackish water lagoons, nearshore sand and iron-oolite bars of the inner ramp, generally situated above fair-weather wave-base, to the middle ramp influenced by storm-waves and by storm-generated currents, and finally to the outer ramp which is characterised by low energy, fine-grained sediments. Changes in relative sea level produced a cyclic sedimentation pattern. The rich benthic fauna of macroinvertebrates is dominated by bivalves, followed by brachiopods, gastropods, corals, serpulids, and sponges. The analysis of 370 statistical samples and more than 27, 000 specimens produced more than 40 benthic associations and assemblages. They show a relationship to several environmental parameters, two of which, salinity and climate, are briefly discussed. The spatial distribution of the facies and biota is outlined for two time slices, the Bathonian and the Callovian-Oxfordian, respectively. [original abstract]</ABSTRACT>

60460 <ABSTRACT>Six hermatypic coral species [Adelocoenia desori (Koby 1897), Isastrea minima Prever 1909, Montlivaltia icaunensis d'Orbigny 1850, Rennensismilia cf. inflexa (Reuss 1854), Phyllocoenia pomeli

- Peron & Thomas 1893, Dimorphastrea grandiflora d'Orbigny 1850] from mixed carbonate - siliciclastic sediments of the Cenomanian (Upper Cretaceous) of the Karai formation (Uttattur Group) of southern India are described. Four of them are colonial and two are solitary corals. The fauna compares well with Early Cretaceous to Cenomanian corals from northern and central Europe in particular. No relationships exist with the Late Albian coral faunas from southern India described in the 19th century, which is attributed to differences in the facies.</ABSTRACT>

- 60473 <ABSTRACT>A single specimen of the new dictyonine hexactinellid species Verrucocoelia biswasi was collected from the Middle Eocene Fulra Limestone from Lakhpat Fort, Kutch, western India. The eurentoid species is broadly bowl-shaped, 7-8cm wide and 5-6cm high, with walls of branched to weakly anastomosed tubes that extend upward and outward from a simple, unfluted, walled spongocoel. Skeletal strands diverge upward and outward from near the gastral surface of each tube. The sponge occurs in silty tan marl with abundant alveolinids and less common other large foraminifera, bivalves, and gastropods in sediments thought to have accumulated in a quiet, sheltered environment, possibly a lagoon. - 60486 <ABSTRACT>A single specimen of the new sponge, Raphidonema indica n.sp., is the first Eocene sponge to be reported from India. It was collected from the Fulra Limestone Formation at Lakhpat, Kutch, India. The undulating, cup-like sponge is most similar to R. farringtonense (Sharpe 1854), but the Indian species has a clustered, mounded excurrent system and numerous tangential canals on the upper, exhalant surface. Skeletal tracts in Raphidonema indica are 0.4-0.5 mm in diameter, in walls that are generally 12-14 mm, but range up to 18 mm thick.</ABSTRACT>

60511 <SOURCE>Marine Geology 16: 79-83.</SOURCE>
60512 <ABSTRACT>Un-recrystallized fossil corals occurring at 2-6m above the present mean low-tide level on the Saurashtra coast (western India) have been dated by 230Th/234U and 234U/238U radiometric methods. The measured ages of the corals, which are in agreement with radiocarbon ages, fall in three groups, 6,000, 30,000 and 120,000 years before present. This observation, coinciding with the high sea-level stands reported in several locations in the world, in the absence of evidence in support of instability of Saurashtra coast, suggests that the coral reefs are remnants of one Holocene and two Quaternary high sea-level stands.</ABSTRACT>

60536 <TITLE>Molecular Biological and Paleontological Evidence that Eumetazoa, Including Porifera (Sponges), are of Monophyletic Origin.</TITLE>
60537 <SOURCE>In: Watanabe Y. Fusetani N. (Eds.): Sponge Sciences. Multidisciplinary Perspectives: 133-156.</SOURCE>
60538 <ABSTRACT>The phylogenetic relationships of the kingdom Animalia

(Metazoa) have long been questioned. Initially, detailed descriptions of animal embryology and adult morphology were used to solve the evolutionary origins of distant groups such as phyla. Focusing on the lowest eukaryotic multicellular organisms, the metazoan phylum Porifera (sponges), it remained unclear if they independently evolved multicellularity from a separate protist lineage (polyphyly of animals) or derived from the same protist group as the other animal phyla (monophyly). Based on constituent characters of the sponges a monophyletic origin of the Porifera can be deduced. The oldest complete fossil sponge has been described from the Early Cambrian, while the earliest spicules date from the late Proterozoic, about 600 million years ago. It is suggested that the first sponges did not contain spicules. After having analyzed those genes from the sponge *Geodia cydonium* which are typical for multicellularity, e.g., those coding for adhesion molecules/receptors and a nuclear receptor, it has to be concluded that all animals, including sponges, are of monophyletic origin. Based on the elaborated molecular biological data we suggest not subdividing Metazoa into Parazoa (including the sponges) and Eumetazoa. In addition it was estimated that the adhesion molecules/receptors from sponges diverged from a common ancestor in the Precambrian, about 800 million years ago. </ABSTRACT>

60549 <TITLE>Phylogenetic analysis of the Hsp70 sequences reveals the monophyly of Metazoa and specific phylogenetic relationships between animals and fungi.</TITLE>

60550 <SOURCE>Mol. Biol. Evol. 15: 647-655.</SOURCE>

60551 <ABSTRACT>To understand the early evolution of the Metazoa, it is necessary to determine the correct phylogenetic status of diploblastic animals. Despite cladistic studies of morphological characters and recent molecular phylogenetic studies, it remains uncertain whether diploblasts are monophyletic or paraphyletic, and how the phyla of diploblasts are phylogenetically related. The heat shock protein 70 (Hsp70) sequences, because of their ubiquity and high degree of conservation, could provide a useful model for phylogenetic analysis. We have sequenced almost the entire nucleic acid sequence of cytoplasmic Hsp70 from eight diploblastic species. Our data support the monophyly of diploblastic animals. However, the phylogenetic relationships of the diploblast groups were not significantly resolved. Our phylogenetic trees also support the monophyly of Metazoa with high bootstrap values, indicating that animals form an extremely robust clade.</ABSTRACT>

60588 <TITLE>Phylogenomics Revives Traditional Views on Deep Animal
Relationships.</TITLE>
60589 <SOURCE>Current Biology 19, 8: 706-712.</SOURCE>
60590 <ABSTRACT>The origin of many of the defining features of animal body
plans, such as symmetry, nervous system, and the mesoderm, remains
shrouded in mystery because of major uncertainty regarding the
emergence order of the early branching taxa: the sponge groups,
ctenophores, placozoans, cnidarians, and bilaterians. The
phylogenomic approach [1] has recently provided a robust picture
for intrabilaterian relationships [2, 3] but not yet for more early
branching metazoan clades. We have assembled a comprehensive 128 gene
data set including newly generated sequence data from ctenophores,
cnidarians, and all four main sponge groups. The resulting phylogeny
yields two significant conclusions reviving old views that have been
challenged in the molecular era: (1) that the sponges (Porifera) are
monophyletic and not paraphyletic as repeatedly proposed [4-9], thus
undermining the idea that ancestral metazoans had a sponge-like body
plan; (2) that the most likely position for the ctenophores is together
with the cnidarians in a coelenterate clade. The Porifera
and the Placozoa branch basally with respect to a moderately supported
eumetazoan clade containing the three taxa with nervous
system and muscle cells (Cnidaria, Ctenophora, and Bilateria). This new
phylogeny provides a stimulating framework for exploring the important
changes that shaped the body plans.</ABSTRACT>

60601 <TITLE>Dickinsonia as a polypoid organism.</TITLE>

- 60602 <SOURCE>Paleobiology 18, 4: 378-382.</SOURCE>
- 60603 <ABSTRACT>Dickinsonia is reconstructed as a benthic polypoid of generally cnidarian design. The oral surface was without tentacles but contained a median oral slit that probably led through a pharynx into an enteron, which was divided into digestive diverticulae by radiating mesenteries; feeding may have been via ciliary tracts. The mesenteries and the body wall contained a stiff form of mesogloea. There seems to be no need to postulate a novel constructional grade for this organism, bringing the concept of the Vendozoa into question.</ABSTRACT>

- 60641 <SOURCE>Verh. naturwiss. Ver. Hamburg NF36: 5-32.</SOURCE>
- 60642 <ABSTRACT>The monophyly of the Porifera is well established. According to our hypothesis the Hexactinellida are the adelphotaxon of the Pinacophora (new taxon = Calcareia + Homoscleromorpha + Demospongiae). The Porifera are the adelphotaxon of the Eumetazoa / Placozoa. Sponge spicules are considered not to be a constituent character of the Porifera. Mineralized spicules developed independently within the three poriferan main taxa the Hexactinellida, Calcareia, and Demospongiae. Demospongian microscleres are not derived from megascleres in contrast to those of Hexactinellida. Accordingly, spicules probably developed several times within the Demospongiae. Remains of Porifera are known since the late Proterozoic.</ABSTRACT>

60667 <SOURCE>Munchener Geowissenschaftliche Abhandlungen, Reihe A, 37: 1-72.</SOURCE>
60668 <ABSTRACT>The taxon Porifera as the earliest definite Metazoan phylum is documented from ca. 543-549 Mio. Y. old sediments, e.g. of Ediacara lagerstaetten: Palaeophragmodictya, a hexactinellide-like early sponge from these strata may not have possessed any mineralized spicules at all. Tiny fossils from the ca. 580 Mio. Y. old Duoshantuo-phosphorite have been interpreted as juvenile sponges, in which case they belong to the Demospongiae. However, the clade Porifera most probably separated from the Eumetazoa at least 200 Mio. Y. earlier. During the earliest Cambrian the Hexactinellida were predominant, but already from the Atdabanian, the taxon Pinacophora has become highly diverse, e.g. the demospongide group Astrophora, including the ecologically flexible Geodiidae. 60718 <TITLE>Review on diagenetic microstructures in fossil corals - a controversial discussion.</TITLE>
60719 <SOURCE>Bulletin of the Tohoku University Museum 1 [Proceedings of the 8th International Symposium on Fossil Cnidaria and Porifera]: 193-209.</SOURCE>
60720 <ABSTRACT>Microstructures in Palaeozoic corals are discussed in a comprehensive survey resulting from current examinations. It is considered that diagenetic alterations are more common than hitherto assumed. This bears consequences for taxonomic purposes as well as for phylogenetic inferences. In principal, three fundamental types of diagenetical changes, concerning pseudoskeletal. i.e. diagenetic altered microstructures, have to be distinguished: (1) skeletogenic recrystallization, (2) aggrading neomorphism and (3) calcite twinning. * The latter includes zigzag patterns and pseudolamellar structures, both of which are due to the same mineralogical regularities of calcite. The occurrence of cyanobacteria in the coralla of Favosites specimens from the Eifel Hills, Germany, shows that the overprinting of the skeleton by aggrading neomorphism and formation of cleavages most probably succeeded cyanobacterial settlement. Therefore, "Stirnzonen ", zigzag patterns, and microlamellar structures cannot be primary in origin. [original abstract]</ABSTRACT>

60731 <TITLE>Corals, paleotemperature records, and the aragonite-calcite transformation.</TITLE>
60732 <SOURCE>Geology 23, 4: 333-336.</SOURCE>
60733 <ABSTRACT>Oxygen isotopic records from corals play an increasing role in paleoclimatic research and climatic modeling. Proxy records of sea-surface temperature are produced by isotopically analyzing samples drilled from aragonitic (CaCO₃) coral skeletons. However, drilling aragonite causes a polymorphic inversion to calcite accompanied by 180) enrichment. The isotopic enrichment may occur through atmospheric exchange, CO₂ degassing, or fractionation during digestion. Regardless of the mechanism, dry drilling produced isotopic shifts as large as 0.8‰, corresponding to an erroneous temperature decrease of 3°C. This error is larger than the global temperature rise since the Industrial Revolution, and a substantial part of the global temperature variation over the past 10 ka. Because the isotopic shift is inconsistent and can occur without the production of measurable calcite, detecting and correcting the isotopic shift may be difficult.</ABSTRACT>

61019 <ABSTRACT>The 10th meeting of the "International Association for the Study of Fossil Cnidaria and Porifera" was held in

Saint-Petersburg, Russia from August 12 to 16, 2007. Saint-Petersburg was elected to host the 10th International Symposium on Fossil Cnidaria and Porifera during the general assembly of the International Association in Graz, Austria in 2003. This 10th jubilee Symposium of the Fossil Cnidaria and Porifera Association was dedicated to the Academician of the Russian Academy of Science, Boris Sokolov, one of the founding fathers of the Association and the President of the First Symposium in Novosibirsk in 1971. A number of colleagues with the support of the Administration of The Karpinsky Research Geological Institute organized the scientific and social programme. About 120 participants from 24 countries attended the meeting. [taken from preface]

 61057 <SOURCE>Systema Porifera: A Guide to the Classification of Sponges [Hooper J. N. A. & Van Soest R. W. M. (eds); Kluwer Academic/Plenum

- Publishers, New York].</SOURCE>
- 61058 <ABSTRACT>Available evidence suggests that the first demosponges occur in the Late Proterozoic with forms characterized by bundles of long monaxonic spicules. In the Middle Devonian the first modern forms of Dendroceratida, 'axinellids' (mostly halichondrids), and first haplosclerida appeared. An important boundary for the demosponges is the late Devonian extinction event, which caused a complete overhaul of demosponge communities. The Late Permian and the Triassic, especially the Late Triassic, are the main eras for coralline sponge radiation and dominance, in which some modern taxa occur for the first time (Ceratoporella, Astrosclera, Vaceletia). In the Late Jurassic the freshwater environments were occupied by certain (marine) demosponges, mostly Haplosclerida. The importance of coralline demosponges as primary reef-builders decreases up to the Late Cretaceous.</ABSTRACT>

- 61070 <SOURCE>FC&P 20, 1.1: 46-49.</SOURCE>
- 61071 <ABSTRACT>Rauff (1893/94) was the first author to pay attention to the very special shape of nodes in some hexactinellid principal spicules. The principals concerned show the usual regular triaxial symmetry (a constituent character of the Hexactinellida), but in addition they are provided with 12 oblique cross-beams closely surrounding the axial cross. According to these lantern-like nodes Rauff (1893/94) invented the name lychnisk for this kind of spicules. Since the lychniscs are very common within the Mesozoic Hexactinellida, Schrammen (1902: 7) erected a taxon "Unterordnung Lychniskophora" to comprise all hexactinellids, whose principal supporting skeleton consists of lychniscs. - 61123 <ABSTRACT>Preparation of a review chapter on fossil Scyphozoa for Traite de Zoologie caused a new attempt to identify the structures in fossils attributed to (or likely to be) fossil scyphozoa. Their placement according to stratigraphic age and morphologic relations drew out very clearly how poor our understanding of the age of the coelenterates has been. It is certain that the Hydrozoa were strongly differentiated by the Vendian: some primitive characters in the Scyphozoa could relate to their later differentiation from a common ancestral class, rather than the Scyphozoa having an ancestral position themselves. - 61135 <SOURCE>Bulletins of American Paleontology 363: 1-560. ISBN 978-0-87710-450-6</SOURCE>
- 61136 <ABSTRACT>This is a listing of approximately 37.000 taxonomic genera of marine animals known from the fossil record, based on the late J. John Sepkoski, Jr's working database, which he last updated July 13 to November 13, 1998. These data are the basis of many analyses by Sepkoski and others, and are published here with minimal - and surely incomplete - clerical corrections to make this extraordinary compendium widely available. It covers invertebrates, and animal-like protists, gives time intervals of first and last known occurrence, and provides

- literature sources for these data. The time intervals are mostly the internationally recognized stratigraphic stages; many are resolved substage divisions. Genera are presented in a classification by order, class, phylum, and kingdom, reflecting current classifications in the published literature. [the volume has been edited by D. Jablonski & M. Foote]</ABSTRACT>

61160 <TITLE>Triassic Belemnoids (Cephalopoda, Coleoidea) formerly described as Corals versus Tertiary Corals described as Belemnites (or The Fairy Tale of Tertiary "Belemnites").</TITLE>
- 61161 <SOURCE>FC&P 20, 1.1: 40-45.</SOURCE>
61162 <ABSTRACT>In some genera of the coral order Pennatulacea Verrill 1865, spicules or sklerodermites and horny tissue form mesodermal solid calcareous axes or tubes with transverse tabulae. A well-preserved fossil example of Pennatulacea was described by Zittel (1924, p. 130, fig. 205) under the name Graphularia desertorum Zittel. Although clearly corals, such fossils could mislead palaeontologists into interpreting them as coleoid remains. Thus, carbonaceous Graphularia axes show some resemblance to internal structures of belemnite rostra, and unfortunately, certain Graphularia stems seem to have an orthoconic cavity at one end similar to the belemnite's alveolus. Conversely, the internal structures of some coleoids could lead to their interpretation as corals. [first fragment of a short note]</ABSTRACT>

61225 <TITLE>Early fossil Cnidarians.</TITLE>
61226 <SOURCE>The origin of major invertebrate groups [M.R. House (ed.)]: 161-207; Academic Press, London.</SOURCE>
61227 <ABSTRACT>The later Precambrian and early Phanerozoic record of cnidarian or supposed cnidarian fossils is reviewed. The first reliable records are considered to be among the Ediacaran fauna of Vendian age and most cnidarian groups with a significant fossil record had appeared by the Ordovician. The relationship of some important fossil groups of disputed or doubtful affinities are discussed. The Stromatopora and Chaetetida are considered to be closer to the Porifera than the Cnidaria, in agreement with most recent work. The Conulata are of uncertain relationship but may form a separate class of cnidarians. The Hydroconozoa are also accepted as a provisional cnidarian class. A suggestion that some or all tabulate corals may be more closely related to the Porifera is disputed. * Cambrian coral records are reviewed and some are regarded as very doubtful or not of cnidarian affinities. The relationship of the remainder to the Ordovician records are discussed and possible phylogenetic schemes for the early diversification of the tabulate and rugose corals are outlined. No post-Cambrian direct phyletic link between Tabulata and Rugosa is considered likely but a common ancestor for the two orders may have existed in the late Precambrian or early Cambrian. * Various opinions on the origin and phylogeny of the Cnidaria are briefly outlined. Doubts concerning the completeness of the fossil record and uncertainties over the interpretation of Precambrian material weakens the contribution of the palaeontological evidence to the debate on the nature of the earliest cnidarians. 61303 <TITLE>The fossil record of cnidarian medusae.</TITLE>
61304 <SOURCE>Palaeoworld 19, 3-4: 212-221.</SOURCE>
61305 <ABSTRACT>Fossils of cnidarian medusae are extremely rare, although reports of fossil medusoids, most of which do not represent medusae, are rather common. Our previous inability to distinguish these fossils has hampered attempts to investigate patterns and processes within the

medusozoan fossil record. Here we describe criteria for the recognition of bona fide fossil medusae and use them to assess the evolutionary, paleoenvironmental, and taphonomic history of the Medusozoa. Criteria include distinctive sedimentologic and taphonomic features that result from transport, stranding, and burial of hydrous clasts, as well as unequivocal body structures comparable to those of extant animals. Because the latter are uncommon, most fossil medusae remain in open nomenclature; many are assigned to stem-group scyphozoans. The majority of described medusae are associated with coastal depositional environments (such as tidal flats or lagoons). They rarely occur in oxygen-poor deeper-water facies. All medusan groups have long geologic histories. Scyphozoa are known from the Cambrian, but more derived scyphomedusae were not demonstrably present until the Carboniferous; Mesozoic scyphozoans are rather diverse. Hydromedusae are known from the Ordovician but may extend back to the Cambrian. The record of cubozoans is shorter and sparser; the oldest definite cubozoan is Carboniferous in age. [original abstract]

61357 <ABSTRACT>[...] the "VI. International Symposium on Fossil Cnidaria including Archaeocyatha and Porifera" took place in Germany, in Münster from September 9th to September 14th, 1991. The International Association for the Study of Fossil Cnidaria and Porifera was founded - almost exactly on the month - in Novosibirsk twenty years ago. The Symposium was organized by the Forschungsstelle für Korallenpaläozoologie in co-operation with the westfälische wilhelms-Universität Münster. 61526 <ABSTRACT>Coral reefs are amongst the most diverse ecosystems on our planet. Historical and ecological factors are discussed as potential causes of the extremely high species richness ranging to hundreds of thousands. The extreme depletion of nutrients, the spatial complexity and the common but moderate disturbances of the reef building is well documented in the fossil record but quantitative fluctuations of reef diversity are only roughly known. The best available diversity curves for the last 550 million years exhibit strong variations of both species richness within reefs and the global diversity of reef builders. These fluctuations are often related to mass extinctions but also occur independently of evolutionary crises. The most important

factor governing secular fluctuations of reef diversity is probably the nutrient concentration in the oceans. Climate change, while influencing the biological composition of reefs, had only limited effect on reef diversity.

61577 <SOURCE>Coral Research Bulletin 05: 151-160.</SOURCE>
61578 <ABSTRACT>Most fossil coral reefs are not readily comparable to modern reefs in terms of ecology and framework structure because both fossil and recent reefs formed in a wide range of particular environmental settings resulting in diverging aspects of individual bioherms. The most important environmental parameters are the type of substratum available for settlement of larvae and the influence of sea level fluctuations. Effects of both on reef formation are discussed. Reefs that formed with taxonomically divergent coral faunas and at different geological times under broadly comparable environmental settings may show surprising geomorphological and ecological similarities. Such reef formations are termed *analogous reefs*. Comparative studies of couplets of analogous reefs, one recent and one fossil may be an efficient tool for better understanding of both fossil and recent reef environments. A few selected examples of such analogous reefs, established on unstable substrata, are discussed from basinal and deltaic deposits and from turbiditic environments.</ABSTRACT>

61589 <TITLE>Ancient reef ecosystem expansion and collapse.</TITLE>
61590 <SOURCE>Coral Reefs 13, 1: 3-11.</SOURCE>
61591 <ABSTRACT>Platform carbonate and, particularly, reef ecosystem development (with reefs representing the acme of carbonate platform growth) were highly cyclical in early to mid Paleozoic time, especially in relation to known or postulated times of global warming or cooling. These cycles do not appear to correspond to postulated 26 Ma rhythms seen in diversity patterns, nor were they regular. There were major periods of worldwide reef expansion (e.g. mid-Silurian-Late Devonian), corresponding to global warming well above present day norms, and periods of complete global reef collapse (e.g., mid-Cambrian to mid-Ordovician, Late Devonian) corresponding to global perturbations. At times of major reef expansion in the Paleozoic, areas covered by equatorial reef and inter-reef carbonate platforms are conservatively estimated to have periodically exceeded 5 million sq. km, nearly ten times that in the modern ocean. At times of global reef collapse, e.g. the Famennian (Late Devonian), reef complexes were completely absent or, at best, covered *1000* sq. km. The chief factors relating to periodic collapse and mass extinction of reef biotas appear to be related to climatic change and possibly ocean anoxic events, in turn as a response to large scale, geologically disruptive factors such as plate collisions, plate movement across equatorial belts and volcanism. Stress *signals* in Cambrian through Cretaceous reef ecosystems appear to be comparable to those of today: whether these relate to physical versus biological stress is uncertain. Reef stress is evident in globally reduced areas and thicknesses of reef carbonate production, the absence of large scale barrier reef systems and reduction to smaller patch reef complexes (or, periodically, following mass

extinctions, no reefs at all), reduced species and genus diversity, small skeletons or colonies, limited or no biotic zonation along reef transects, and arrested succession and ecologic replacement of complex, more highly evolved taxa by simpler, stress-resistant disaster taxa at the genus to ordinal (or even phylum) level. 61602 <TITLE>Reefs under stress: the fossil record.</TITLE>

61603 <SOURCE>Courier Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, vol. 2]: 87-94.</SOURCE>

61604 <ABSTRACT>Reef ecosystems under stress are those which operate at much less than or below optimal environmental conditions. Stressed habitats are reflected in reduced reef thickness and diameters, absence of large scale barrier and atoll systems, general failure to develop clear biotic zonation, lowered diversity, stunted size of colonial corals, partial replacement by solitary corals and stress tolerant taxa, and arrested ecologic successions. Stressed reef communities typically occur today at the fringes of coral reef development in higher latitudes, where coral dominated faunas are replaced by bryozoan-foraminiferan-serpulid-sa-bellariid-mollusc dominated communities. In tropical belts, stress factors include high input of siliciclastics, especially clay minerals and laterites, unstable soft substrates, brackish environments in areas of high runoff around deltas, poorly lighted waters due to large amounts of fines in suspension, high surface plankton productivity (due to surplus nutrients) and increased water depth at the margins of the photosynthetic abilities of symbionts. Examples of Ordovician through Permian reefs under stress include especially the calcareous and siliceous sponge reef communities inhabiting slope environments, offshore mudmounds and lithoherms (including waulsortian mounds), and small reefs with impoverished and aberrant faunas. Though stressed reef communities are usually considered a response to less than optimal conditions at a local level, such conditions may also be a response to global deterioration of climates, especially at times of mass extinction. Reef recovery following mass extinction phases, such as the Late Ordovician and Late Devonian, apparently favoured re-invasion and repopulation of the reef habitat by Lazarus taxa which were preserved in deeper or colder (high latitude) water refugia: thus, these may represent offshore-onshore or onshore cold-onshore warm patterns. This contradicts the general pattern of onshore to offshore migration and evolution of benthic communities which set the style for the warmer Phanerozoic intervals. Similarly, deeper or cooler water reefs (mudmounds, lithoherms, etc.) emigrated to shallower water subequatorial habitats during mass extinction phases. Recovery periods for the reef ecosystem following mass extinction phases are measured in millions of years.</ABSTRACT>

61667 <TITLE>Another Internal Clock: Preliminary Estimates of Growth Rates Based on Cycles of Algal Boring Activity.</TITLE>
61668 <SOURCE>Palaios 1987, 2: 323-331.</SOURCE>
61669 <ABSTRACT>Modern corals from Lizard Island, in Australia's Great Barrier Reef, show pronounced dark gray zones parallel to growth surfaces. These color bands are caused by increased activity of boring algae during the dry sunny season, and hence are annual. Cyclicity in algal boring activity may therefore be used to determine growth rates and life spans of some fossil organisms, and possibly the seasons of spat settling and death. Samples of Devonian stromatoporoids from Bathurst Island in the Canadian Arctic show cycles in boring intensity which suggest growth rates of about 1 cm/yr. These results are questionable, however, because the borings cross through both the lamellae and calcite cement in the interlamellar spaces. This implies early infilling of the stromatoporoid skeleton, a process which is still in debate. Ordovician solitary rugose corals from Kentucky and southern Manitoba show marked cyclicity in intensity of algal borings preserved in the epitheca. Growth rates are estimated to have been about 2 cm/yr. Both the apices and distal portions of these corals are relatively unbored. Perhaps the larvae settled during the cloudy monsoon season, and the adults died (2-3 years later) as a result of overturning and transport by monsoonal storms. Both the stromatoporoid and rugosan growth rates are as high as those shown by modern hermatypic corals, reinforcing previous suggestions that some Early Paleozoic marine invertebrates possessed zooxanthellae.</ABSTRACT>

61695 <ABSTRACT>[This is a fascinating review and interpretation of the history of reefs, reef-building and reef faunas and floras through time. Starting with a synthesis of modern reef occurrences, physical and biological controls and processes, Fagerstrom proceeds to reef community description and analysis. This is followed by a discussion of the ecology and history (as related to reefs) of the major biologic groups involved, and finally by a history of the changing community structure of reefs through Phanerozoic time. There is much about corals in the book, but most interesting to me is the recognition of major units of time during which community structure was relatively constant, separated by short turnover episodes that permitted the development of quite different kinds of reefs. 61758 <TITLE>The plain man's guide to enigmatic coral reefs.</TITLE>
61759 <SOURCE>Mercian Geologist 9, 1: 1-30; Nottingham.</SOURCE>
61760 <ABSTRACT>Although by no means monomineralic, reefs are often enigmatic structures because the superficial homogeneity of their carbonate components renders their complex internal histories obscure to many forms of detection. This is particularly evident in the case of seismic studies of subsurface phenomena which tend to yield misleadingly uniform lensoid interpretations resulting from refraction at the shale:carbonate and sandstone:carbonate interfaces beyond the margins of the reef sensu stricto. But studies of random sections through reefs can be equally baffling in the field. The reasons for the ensuing confusion often results from attempting to compare different diagenetic grades of the same geological age. This account stresses the interdisciplinary nature of reef analysis irrespective of time by means of models and by analogy with present day tropical coral reefs. By drawing on case histories from Zanzibar and the Seychelles and comparing them with data from Bermuda, Bahamas, Florida and the Australian Great Barrier Reef, the oceanic provinciality of sediments is highlighted, and their local variability is related to their oceanographic and geomorphological setting and consequent settlement pattern which is often wind dominated. Then emphasis is placed on integrating ecosystem analysis of the biota and associated sediments with chemical predictions on the preservability of the fabric following burial in the vadose zone and subsequent loading. Intimate details of present day and vadose Pleistocene reef fabrics are illustrated by scanning electron micrographs which draw attention to the fact that quantitative data are only as good as the natural constraints put upon them. Thus one coral clast featuring no less than eleven adhesive dinoflagellates indicates that all the published sediment budgets are preferentially biased against the interstitial biota, the base of the

food chain and the role of organic matter so limiting their potential for ecosystem analysis and biasing their palaeoecological utility. Though more readily quantified, this limitation is no worse than the geochemical parameters encountered during burial diagenesis: hence reefs range from the obvious to the obscure. [original abstract]

61785 <SOURCE>Berliner geowissenschaftliche Abhandlungen A086: 87-125.</SOURCE>

61786 <ABSTRACT>Two different skeletal types occur within the Recent Calcarea. One type bears calcareous spicules only, and the other type shows rigid basal skeleton in addition to the spicular skeleton. Basal skeletons are characteristic of most fossil examples. Some of the observed basal skeletons are convergent with those of certain demosponges. Stromatoporoid, thalamid and adapted chaetetid skeleton types are observed besides other types not observed within the calcified demosponges. Basal skeletons are probably a plesiomorphic feature of the coralline Calcarea. Three phylogenetic models, based on phylogenetic systematics, are discussed. It is possible to distinguish two main phylogenetic lineages. The Minchinella-lineage and the closely related Barroisia-lineage are probably the stock of the Recent non-calcified Calcaronea. Most of the Recent species of coralline Calcarea are classified within this subclass. The second lineage (Murrayona-lineage) is probably the stock of the modern Calcinea. The new species Barroisia gandaraensis n.sp. is described. Verticillites extensus Lang is shown not to be a demosponge and a new genus name is created (Muellerithalamia).</ABSTRACT>

- 61864 <ABSTRACT>Dredging at the edge of the continental shelf at various stations between Eire and Morocco and again off the Natal coast of South Africa and Madagascar has revealed an interesting association between a polychaete and various cnidarians. The polychaete Lumbrineris flabellicola Fage (1936) is re-described, and its relationship to various species of ahermatypic corals is discussed. The worm forms grooves around the skeleton and the examination of fossil material shows that similar grooves occur on corals from the Miocene and later deposits in Italy. Surprisingly, dredging in the Mediterranean has revealed no living specimens. The worldwide distribution of the Lumbrineris-coral association is discussed.</ABSTRACT>

- 61890 <ABSTRACT>In connection with a study of the history of Mesozoic coral

research (Turnsek & Loser, in press) a data bank on coral genera cited in the literature (1940-1990) was compiled by D. Turnsek (Ljubljana). This data bank comprises over 4,000 items, each consisting of the source of the citation, the name of the genus as well as the higher taxa (subfamily, family, superfamily, suborder) to which the genus was assigned. * In order to obtain information on the current state of the systematics of Scleractinia the data bank was subjected to various transactions. For this purpose it was examined under two aspects: the classification of genera into families and of families into suborders (subfamilies and superfamilies were left out of consideration owing to their rare usage). * The following list shows the systematics as it emerges from the literature published between 1940 and 1990. The allocations given (of genera to families and of families to suborders) and the publications quoted are always the latest ones. * Two things become evident: for one, there seems to be little justification for certain suborders and families with hardly any subordinate taxa. Also, it is striking to note the large number of genera which were never cited again after their first description. As a product of data bank transactions, the systematics obtained presents an entirely objective picture. Although, of course, the literature evaluated lays no claim to completeness. * In conjunction with B. Lathuiliere (Nancy) the authors of the various families were verified on the basis of the International Rules of Zoological Nomenclature and were in part corrected (e.g. Thamnasteriidae Reuss not Vaughan, Latomeandriidae Fromentel not Alloiteau). * I thank my colleagues Dragica Turnsek and Bernard Lathuiliere for their assistance. [original introduction to the systematics]

61915 <SOURCE>Boletin de la Real Sociedad Espanola de Historia Natural, Seccion Geologica 91, 1/4: 005-033.</SOURCE>
61916 <ABSTRACT>The International Association for the study of Fossil Cnidaria and Porifera has played a leading role in the communication of cnidarian and poriferan research since its creation in 1971 at the First International Symposium in Novosibirsk, USSR, This paper presents

a review of the changes in and accomplishments of the Association during the past quarter century. Research reports published in symposium proceedings are based toward topics currently popular among the leaders of research and among the more affluent countries. As the Association approaches the 21st century, it faces new challenges posed by an aging and shrinking membership. Analysis of data on fossil Cnidaria and Porifera specialists reveals trends that are reshaping our science as we approach the next century: 1) a dramatic decline in the size of the workforce, 2) a shift away from government research institutions toward universities and museums as the main workplaces, 3) a shift away from the dominance of a few large countries toward a more equitable geographic distribution of the workforce, 4) a declining emphasis on Paleozoic zoantharia as the principal object of study within the Cnidaria, and 5) a declining relative emphasis on Stromatoporata and Archeocyatha as the principal objects of study within the Porifera. In this changing scene, the Association can be even more important than before in promoting, organizing and communicating the science of fossil Cnidaria and Porifera.</ABSTRACT>

61942 <ABSTRACT>Fossil and Recent Sponges contains articles on taxonomic, phylogenetic and ecological aspects of sponges of both biological and paleontological interest. They focus on three main topics: phylogeny and systematics, biology, and paleoecology of sponges. The reader is offered an overview over the most important aspects of current sponge research: 1) establishment of a new taxonomy based on monophyletic groups (phylogenetic systematics), including recent and fossil taxa; 2) new concepts of the biomineralisation of sponge skeletons; 3) palaeoenvironmental analysis of fossil sponge buildups.</ABSTRACT>

61992 <TITLE>Report on 4th International Porifera Congress.</TITLE>
61993 <SOURCE>FC&P 22, 1: 13-17.</SOURCE>
61994 <ABSTRACT>The International Porifera Symposia, which take place in
different countries every four to five years, are rare occasions for
spongiologists from all over the world to exchange and discuss
scientific results and to plan and coordinate future research programs.
This year's 4th International Porifera Congress was organized with
much devotion by zoological and paleontological colleagues in
Amsterdam, mainly from the Institute of Taxonomic Zoology and the
Foundation Pangea, Huizen. The title "Sponges in Time and Space"
indicates the combined effort of Poriferan scientists to investigate
this ancient group of organisms from all paleontological as well as
neontological aspects. Main emphasis of this congress was placed on the
side of recent biology with much attention paid to cell biology,

- biochemistry and the very promising exploration of sponges for medical and pharmacological purposes. [first part of extensive report] </ABSTRACT>

- 62007 <ABSTRACT>In spite of its considerable extension my first report on the Int. Congress "Sponges in time and Space" did not cover all important contributions. The total amount of information given during this meeting by far exceeded the extend of data that can be usefully recorded within one summary. Some of the topics, eg. session Biogeography and Natural Products Workshop, were touched only briefly without mentioning most of the contributions. Within this supplement, I intend to correct these omissions. For the poster sessions, I restrict myself to a simple list of contributions. [introductory part of the report]</ABSTRACT>

- 62033 <ABSTRACT>Research whilst compiling this book has uncovered a fauna about twice the size as that previously published in the literature and consequently Systema Porifera revises and stabilizes the systematics of the phylum to accommodate this new knowledge in a contemporary framework. Practical tools (key illustrations, descriptions of character) are provided to facilitate the assignment of approximately 680 extant and 100 fossil genera. * Systema Porifera is unique making sponge taxonomy widely available at the practical level of classification (genera, families, order). It is a taxonomic revision of sponges and spongiomorphs (such as sphinctozoans and archaeocyathans)

based on re-evaluation of type materials and evidence. It is also a practical guide to sponge identification providing descriptions and illustrations of characters and interpretation of their importance to systematics. Systema Porifera addresses many long standing nomenclatural problems and provides a sound baseline for future debate on sponges and their place in time and space. * Systema Porifera describes 3 classes, 7 subclasses, 24 orders, 127 families and 682 valid genera of extant sponges (with over 1600 nominal generic names and an additional 500 invalid names treated). Treatment of the fossil fauna is less comprehensive or critical, although 6 classes, 30 orders, 245 families and 998 fossil genera are mentioned. Keys to all recent and many fossil taxa are provided.

62044 <TITLE>Siliceous sponge-microbe biotic associations and their recurrence through the Phanerozoic as reef mound constructors.</TITLE>

62045 <SOURCE>Palaios 9: 370-387.</SOURCE>

62046 <ABSTRACT>The association between mound-building, benthic microbial communities and siliceous sponges is characteristic of some reef mounds of Early Cambrian, Early-Middle Ordovician, Late Silurian, Late Devonian, Late Mississippian, Late Permian, Late Triassic and Late Jurassic age. Significant episodes of siliceous sponge-microbe reef mound construction, each lasting 5-15 Ma, generally recurred at intervals of approximately 70-100 Ma. Each was a time when thrombolite-forming and/or stromatolite-forming calcimicrobes flourished as constructors, and associated demosponges and hexactinellid sponges diversified as bafflers and binders, and even constructors on the reef mounds. The siliceous sponge-microbe biotic association flourished in subtropical/tropical marine, generally low turbulent, nutrient-rich, deeper subtidal environments (largely below storm wave base). This biotic association shows a temporal change in paleoenvironmental preference through the Phanerozoic from generally inner- to mid-shelf Cambrian and Ordovician examples to both mid-shelf and foreslope environs in the Silurian, Devonian and Carboniferous to predominantly distal shelf and slope settings in Permian, Late Triassic and Late Jurassic examples. The occurrences of these episodes of reef mound construction near the culminations of substantial marine transgressions indicates that extrinsic controls associated with sea level change, such as their spatial association with stratified basin waters and fluctuating oxygen-minimum zones, may have been important in microbial reef mound establishment. During successive sea level highstands the deeper water siliceous sponge-microbe reef mound community appears to have flourished in proximal fore-slopes and extensive drowned shelves and ramps in areas where, at lowstand, reef-building metazoans such as stromatoporoids, corals and calcareous sponges usually predominated. The resurgence of the siliceous sponge-microbe community suggests the recurrence of similar conditions of depth, nutrient conditions, and other subtle physical and chemical controls. These were, in part, controlled by tectonic influences during the evolution of Paleozoic and early Mesozoic seas.</ABSTRACT>

62085 <ABSTRACT>A concept explaining biocalcification as a form of calcium detoxification is advanced using geochemical and paleontological criteria. The first appearance of calcareous skeletons at the turn of the Precambrian/Cambrian is interpreted as a biotic response to a gradual rise of Ca²⁺ in world ocean resulting in Ca²⁺ stress environments in shelf areas. Periodic appearance in the Phanerozoic record of heavily calcified marine biota, absent or relic in modern seas, suggests considerable temporal fluctuations of calcium concentrations in the ancient ocean. Temporal changes in Ca²⁺ and mineral nutrient contents in the environment can be seen as overriding factors in the evolution of organisms.</ABSTRACT>

62109 <TITLE>Paleoreef Maps: Evaluation of a Comprehensive Database on Phanerozoic Reefs.</TITLE>

62110 <SOURCE>American Association of Petroleum Geologists Bulletin 83, 10: 1552-1587.</SOURCE>

62111 <ABSTRACT>To get a better understanding of controls on reef development through time, we created a comprehensive database on Phanerozoic reefs. The database currently comprises 2470 reefs and contains information about geographic position / paleoposition, age, reef type, dimensions, environmental setting, paleontological and petrographical features, and reservoir quality of each buildup. Reef data were analyzed in two qualitatively different ways. The first type of analysis was by visualization of paleogeographic reef distribution maps. Five examples (Late Devonian, Early Permian, Late Triassic, Late Jurassic, middle Miocene) are presented to show the potential of paleoreef maps for paleogeographic and paleoclimatological reconstructions. The second type of analysis was a numerical processing of coded reef characteristics to realize major trends in reef evolution and properties of reef carbonates. The analysis of paleolatitudinal reef distributions through time shows pronounced asymmetries in some time slices, probably related to climatic asymmetries rather than controlled by plate tectonic evolution alone. The dominance of particular reef builders through time suggests that there are seven cycles of Phanerozoic reef development. First curves for the Phanerozoic distribution of bioerosion in reefs, bathymetric setting, and debris potential of reefs are presented. The observed pattern in the temporal and spatial distribution of reefs with reservoir quality may assist in hydrocarbon exploration. Statistical tests on the dependencies of reefal reservoir quality suggest that large size, high debris potential, low paleolatitude, high amount of marine aragonite cement, and a platform/shelf edge setting favor reservoir quality. Reefal reservoirs are significantly enhanced in times of high evaporite sedimentation, elevated burial of organic carbon, low oceanic crust production, low atmospheric CO₂ content, and cool paleoclimate, as well as when they are present in aragonite oceans.</ABSTRACT>

62122 <TITLE>Paleoclimatic significance of Phanerozoic reefs.</TITLE>

62123 <SOURCE>Geology 29, 8: 751-754.</SOURCE>

62124 <ABSTRACT>A database of pre-Quaternary Phanerozoic reefs is used to test the significance of ancient reefs as paleoclimatic tracers. The compilation of reef paleolatitudes through time and comparison with published paleoclimate curves shows that neither the width of the

tropical reef zone nor the total latitudinal range of reefs is correlated with published estimates of paleotemperature. However, reefs trace paleoclimatic indirectly: Algal reefs tend to prevail during icehouse climatic intervals, and distinct high-latitude reefs are only developed in the cold intervals, whereas during greenhouse episodes, the reef zone usually ended abruptly at a particular latitudinal boundary in the subtropics. Additionally, different biotic reef types tended to be concentrated in different latitudes. The lowest latitudes have usually been occupied by coralline sponge or microbial reefs, coral reefs tend to grow in intermediate latitudes, and bryozoan reefs constantly occupied the highest latitudinal position.</ABSTRACT>

62136 <SOURCE>Springer-Verlag Berlin Heidelberg New York: 455 pp., 187 figs, 18 tabs.</SOURCE>
62137 <ABSTRACT>Reef Diagenesis is a state-of-the-art survey demonstrating the importance of diagenesis in a series of case histories ranging from the Cambrian to the present. The individual contributions discuss topics such as the three-dimensional distribution of cements and other diagenetic fabrics, the vertical and lateral variations in porosity with respect to sedimentary and diagenetic conditions, as well as hydrodynamic systems leading to fabrics and their variations in time and space. Diagenetic models derived from these data will help elucidate similar processes going on in other types of carbonate rocks. In view of the petroleum reservoir potential of reefs, these models have direct application to the worldwide search for oil. - 62188 <SOURCE>Facies 26: 167-278.</SOURCE>
- 62189 <ABSTRACT>An updated data base is a matter of importance and urgency in order for encouraging a process-oriented approach to the study of reef evolution. The evolution of reefs is a major section of a Priority Program of the Deutsche Forschungsgemeinschaft devoted to 'Global and regional controls of biogenic sedimentation'. Biological, paleontological and geological approaches in the study of ancient and modern reefs are needed for providing a better understanding of the following basic questions: - Biological and non biological processes responsible for the construction and destruction of recent reefs. Studies should be focused on those processes which might also be regarded as important controls in the history of fossil reefs.- Paleontological data describing the changes in the biological controls of reef development over time. Studies should aim for a better understanding of major crises in the reef ecosystem during the Earth 's history.- Geological factors governing the short-term and long-term development of reefs. Studies should be concentrated on the controls of reef accretion by sea-level fluctuations, climatic changes and possible changes in early diagenetic factors. The Reef Bibliography presented includes more than 4000 references dealing with Cambrian to Pleistocene reefs and more than 750 references referring to processes relevant to the interpretation of ancient reefs. The constraints of reef evolution will become clearer through intensifying comparative studies of reefs of different ages. The new data base should encourage this comparative research approach.</ABSTRACT>

62200 <TITLE>Controls on modern carbonate sedimentation on warm-temperate to Arctic coasts, shelves and seamounts in the northern hemisphere: implications for fossil counterparts.</TITLE>
62201 <SOURCE>Facies 32: 71-108.</SOURCE>
62202 <ABSTRACT>In contrast to the well studied tropical carbonate environments, interest in non-tropical carbonate deposition was rather low until the basic ideas of the Foramol-concept were outlined by Lees & Buller (1972). In the following two decades studies on non-tropical carbonate settings evolved as a new and exciting branch of carbonate sedimentology (see Nelson 1988). This is achieved in a great number of publications dealing on temperate carbonate deposits from numerous coastal and open shelf settings on both hemispheres. The existence of wide extended carbonate depositional systems and even reefal frameworks in Subarctic and Arctic seas which are in focus by our research group made it possible to study modern non-tropical carbonate settings along a latitudinal transect from the warm-temperate Mediterranean Sea to the cold Nordic Seas. Because of increasing seasonality in environmental conditions towards high latitudes, the major controls in biogenic carbonate production can be more clearly addressed in these areas. After the initiation of the priority program & Global and regional controlling processes of biogenic sedimentation - evolution of reefs & by the German Science Foundation four years ago, a set of modern case studies were comparatively analysed specifically with regard to their principle controlling processes: (1) Modern and Holocene coralline algal reefs and rhodolith pavements formed in wave-protected shallow waters along the coast of the Brittany and northern Norway. Their fine-tuned interaction with herbivores resulted in the development of widespread but low-diverse, slowly growing coralline algal frameworks with high competitive value against the rapid-growing phaeophytic communities. (2) The Mediterranean Cladocora caespitosa banks provide an instructive example of non-tropical hermatypic coral framework construction out of the subtropical-tropical coral reef belt. (3) The geometry and environmental controls of several kilometer long coral reefs formed by the azooxanthellate Lophelia pertusa and Madrepora oculata are studied in more than 250m water depth in mid and northern Norway. (4) Modern Bryomol-sediments are widely distributed on non-tropical deeper shelf settings. The formational processes converting bryozoan-thickets into huge piles of sand and gravel dunes are recently studied on the outer shelves off northern Brittany and off northern Norway. (5) Arctic sponge-bryozoan buildups on the seamount Vesterisbank in the Greenland Sea and (6) balanid-dominated open shelf carbonates on the Spitsbergen Bank form the Arctic end members of modern Foramol-deposits. Seasonal ice-edge phytoplankton blooms and efficient mechanisms of pelagic-benthic food transfer characterize these depositional settings. Fossil counterparts of each of these modern case studies are discussed in context with their paleoceanographic and environmental settings.

- 62215 <ABSTRACT>Shifts in community structure and concomitant cavity formation may be rapidly effected by subtle environmental changes; as secretion rates vary from organism to organism. The experimental rates, placed in declining order are: encrusting worms, encrusting red algae, bivalve, coral. The worms, with their organic coatings, secreted a maximum extension of 12mm per month, and the red algae 3mm, whereas the bivalve and coral only achieved a matter of microns. Thus, in the aquarium, the coral would have been effectively smothered by the worms and algae in the foreseeable future. [end-fragment of extensive abstract]</ABSTRACT>

- 62239 <TITLE>The shapes of Paleozoic and modern reef-builders: a critical review.</TITLE>
- 62240 <SOURCE>Paleobiology 8, 3: 228-241.</SOURCE>
- 62241 <ABSTRACT>Paleoecologists studying Paleozoic reef-builders have interpreted their growth forms as responses to conditions of depth and turbulence in reef complexes. Comparison of the shapes of Paleozoic stromatoporoids and corals with the growth forms of modern scleractinians has been used to reconstruct Paleozoic conditions. A review of shape zonation on modern reefs indicates that no general pattern is applicable to all reefs and variations in shape are the result of the interaction of many environmental factors with the genetically dictated growth pattern of the coral. In most zones of a reef a wide range of shapes co-exist. The growth forms of corals on modern reefs are not a simple vegetative response to the many environmental parameters that have been shown to influence form, but are constrained by phylogenetic and developmental influences as well as functional ones. * Interpretations of the environments of western Canadian and other mid-Paleozoic reefs have been based on the growth forms of stromatoporoids. The environmental significance of the shapes has been deduced from comparison with the shapes of modern scleractinians, functional morphology, nature of the enclosing sediment, position of growth, position within the reef, and diversity gradients. The validity of these criteria is open to question and considerable doubt remains concerning the significance of the growth forms. The shapes of reef animals are not specific guides to environments of modern reefs and should not be expected to be guides for ancient ones. [original abstract]</ABSTRACT>

62252 <TITLE>Coralline algal reef framework.</TITLE>
62253 <SOURCE>J. geol. Soc. London 140: 365-376.</SOURCE>
62254 <ABSTRACT>Published and unpublished accounts of coralline algal reef frameworks are reviewed. The descriptions are divided into frameworks constructed from crustose coralline algae and those constructed from branching corallines. Crustose frameworks are briefly described and illustrated from the Miocene of Malta. Recent 'coralligene' from the Mediterranean, Eocene reefs from Spain, Recent algal reefs of St. Croix, U.S. Virgin Is. and algal reefs from Bermuda. Branching frameworks are briefly described and illustrated from the Recent nearl of the NE Atlantic. Recent mud mounds from Florida, Recent algal reefs from St. Croix and Recent algal ridges on Pacific reefs. Crustose and branching frameworks show an increase in strength of construction, early submarine cements and macro-borers and a decrease in erodibility from low to high energy environments. The occurrence of genera in coralline frameworks is primarily controlled by their geographic and water-depth ranges. The construction of coralline frameworks is seen as the result of competition for living space on shallow marine hard substrates. [original summary]</ABSTRACT>

62266 <SOURCE>Géologie et paléoécologie des récifs [J. Geister & R. Herb (eds)]: 16.1-16.15.</SOURCE>
62267 <ABSTRACT>In these brief course notes the analogy between ancient and recent stromatolites is stressed. Stromatolites are considered to represent mainly the response of algal and bacterial communities to environmental conditions. The fact that stromatolites may have evolved through time according to Russian authors, allowing a zonation of the Proterozoic, raises the question "Is the Present the (only) key to the Past?". Nonetheless, stromatolites considerably influenced sedimentation for hundreds of millions of years by their ability to form wave-resistant structures and, more importantly, to bind sedimentary material and prevent it from being displaced into the deeper parts of the seas. Thus, stromatolites were largely responsible for the construction of major carbonate platforms throughout much of the Proterozoic into the Lower Palaeozoic. [conclusions of the paper]</ABSTRACT>

62279 <SOURCE>Science 327, 5962: 196-198.</SOURCE>
62280 <ABSTRACT>Large-scale biodiversity gradients among environments and habitats are usually attributed to a complex array of ecological and evolutionary factors. We tested the evolutionary component of such gradients by compiling the environments of the geologically oldest occurrences of marine genera and using sampling standardization to assess if originations tended to be clustered in particular environments. Shallow, tropical environments and carbonate substrates all tend to have harbored high origination rates. Diversity within these environments tended to be preferentially generated in reefs, probably because of their habitat complexity. Reefs were also prolific at exporting diversity to other environments, which might be a consequence of low-diversity habitats being more susceptible to invasions.</ABSTRACT>

62291 <TITLE>Biological interactions among extant and fossil clonal organisms.</TITLE>
62292 <SOURCE>Facies 57: 351-374.</SOURCE>
62293 <ABSTRACT>Biological interactions among clonal marine organisms are an important aspect of their behavior and are important in the construction of biological reefs. The interactions addressed here are among crustose and erect coralline algae, sponges, corals, and bryozoans and may involve clones of the same species (conspecific), or different species (heterospecific). Conspecific interactions may be either between modules or clones that are produced asexually from one propagule, genetically identical, or between clones that are sexually produced from two or more propagules that may or may not be genetically identical. Juxtaposed genetically identical clones generally fuse whereas non-identical clones may or may not fuse, depending on their relatedness and histocompatibility. Most heterospecific clonal interactions are spatially competitive and result in overgrowths or stand-offs. Clone fission/fragmentation may occur as a result of biotic or abiotic processes that initially degrade but may eventually restore or even enhance ability to gain space and/or nutrients. Self-overgrowths also occur, usually over dead, diseased, or senescent parts of the same clone. [original abstract]</ABSTRACT>

62305 <SOURCE>Acta Palaeontologica Polonica 30, 3-4: 115-135. [imprint 1985]

- 62306 </SOURCE>
<ABSTRACT>Knowledge on transport and regulation of free calcium in the living cell is used in support of the theory (Kazmierczak et al. 1985) linking the onset of biocalcification at about the Precambrian / Cambrian boundary to a rise in Ca²⁺ concentrations in the shelf seas to levels toxic to biota. Following this event, fluctuating Ca²⁺ levels in the Phanerozoic seas are supposed to have challenged a variety of protists and invertebrates to respond by depositing no, thin, or thick skeletons respectively. Changes in type and extent of calcification, as observed in the stratigraphical record, are interpreted to reflect the pulsating flow of Ca²⁺ ions through crust, sea, and biota. Some implications of that theory to (i) the history of sea water, (ii) the global carbon cycle, (iii) stable carbon isotope geochemistry, and (iv) sedimentation of suspended clays, are briefly discussed.</ABSTRACT>

62344 <SOURCE>Bulletin de la Societe geologique de France 4: 609-619.</SOURCE>
62345 <ABSTRACT>The evolution of the genus concept in Archaeocyatha is proceeding by steps : 1861-1910, 1910-1955, 1955-1970, 1970-1974, 1974-1980. The place given to the Archaeocyatha in the living world might influence the adapted hierarchy of the generic characters. Methods used in establishing the characterization of the genera as follows : a) so-called ontogenic stages; b) bioseries; c) homological variability. Possibility of ecogenera. The results of the above investigations are displayed on tables. Lacking of any recent model, the terms genera; and species; only represent

our present concept of subordination of taxa, the real rank of which being not possible to determine. Nevertheless, genus in Archaeocyatha is the unit on which most of the specialists have come to an agreement.

62435 <SOURCE>CNRS Press, Paris, 256 pp.</SOURCE>
62436 <ABSTRACT>The Archaeocyaths (Archaeocyatha) are the first multicellular organisms with a calcified skeleton. They appear in Siberia at the beginning of the Palaeozoic. They also are the first reef-builder Metazoans. Archaeocyaths are subdivided into Regulars and Irregulars. Only the Regulars are studied here. * Their elegant porous skeleton is an ideal model for the application of Vavilov's laws, permitting the establishment of a classification based on the homological variability. * This book has been written as a treatise in which researchers and teachers will find the up-to-date results on morphology, ontogeny, systematics, as well as the last palaeogeographical maps and biozonations of the Lower Cambrian. The now well established relationships with sponges are exposed. [book presentation]</ABSTRACT>

62448 <SOURCE>Bolletino della Societa Paleontologica Italiana, Spec. vol. 3 [Cherchi A. (ed.): Autoecology of selected fossil organisms. Achievements and problems]: 7 pp., 1 pl., 3 figs.</SOURCE>
62449 <ABSTRACT>Archaeocyaths are Cambrian sponges with calcareous skeletons. They are stenothermal organisms, limited to the intertropical climatic conditions. They were stenohaline: when salinity increases they are represented only by their simplest forms. They were stenobathic, living anchored in soft substrata in intertidal to subtidal zones, but did not overpass the photic one. Turbidity and water movements influenced the morphological face of an archaeocyath community. Archaeocyaths are associated to the reefal environments. They were facultative reef-builders (mainly binders and bafflers) and associated with reefal buildups as a substratum for the calcified cyanobacteria and cements. Buildups were essentially microbially mediated mud mounds dominated by solitary or low modular soft-substrate dwelling filter-feeders (archaeocyaths).</ABSTRACT>

62462 <ABSTRACT>All archaeocyaths proceed through the following stages: conical with one wall and empty internal cavity; two-walled cup, with horizontal bars, corresponding to the first radial partition with one single pore per intervallum width. Since the third stage, two main groups are distinguishable: two-walled cup with septa characteristic of Regulares, two-walled cup with taeniae characteristic of the Irregulares, besides this radial structural plan, a thalamid growth pattern is realized among both groups. Despite their different types of

development, homologous architectonic characteristics are recognized in both groups and lead to the distinction of the following taxonomic categories: orders - growth pattern of the cup; superfamilies - outer wall structure; families - inner wall structure; genera - secondary order porosity features; species - additional elements and numeric discriminants.</ABSTRACT>

62474 <SOURCE>Bulletin de la Societe geologique de France 165, 5: 459-467.</SOURCE>

62475 <ABSTRACT>Since the end of Upper Proterozoic, carbonate platforms progressively settle down. At the beginning of the Lower Cambrian, calcimicrobes expanded, later accompanied by benthic filter-feeders as cobuilders, i.e. archaeocyaths, whose development is strictly controlled by salinity, turbidity, bathymetry and temperature, corresponding to intertropical climatic conditions. The reef mounds (sensu James) are placed on the most recent palaeogeographic maps, controlled by palaeomagnetic data on one hand and fossil (trilobites and archaeocyaths) and facies distribution on the other. The archaeocyaths reef mounds are distributed within a belt, extending on both sides to the Equator (latitude 0° to 30°). Even between these latitudes, when the environment is hypersaline (dolomites) or turbidic (siliciclastic sediments) the archaeocyaths did not develop. The extension of the intertropical zone at the Cambrian is comparable with the present one; this is confirmed by the presence of siliciclastic deposits of the same Lower Cambrian age in Avalonia which are, according to palaeomagnetic data, situated at 45°-50° latitude, and by the occurrence of some small bioclastic carbonate levels deposited in temperate conditions. The demise of archaeocyaths at the end of the Lower Cambrian is a consequence of the alteration of their environment, due to a generalized extensional phase, corresponding to gradual opening of the Iapetus Ocean, and to a displacement of continents towards the South Pole, disturbing all the previous global palaeogeographic, palaeoenvironmental and climatic conditions. Uniformitarianism principles, at least for intertropical and temperate zones, could be applied as far back as the Lower Cambrian time.</ABSTRACT>

62591 <SOURCE>Géologie et paléocéologie des récifs [J. Geister & R. Herb (eds)]: 5.1-5.15.</SOURCE>
62592 <ABSTRACT>A travers les temps géologiques, les biohermes peuvent être considérés comme de deux types, ceux formés par piégeage des sédiments par des filaments algaires et/ou édifiés par des algues calcaires, surtout bien développés au Précambrien et Paléozoïque inférieur et les récifs et bioconstructions récifales, structures principalement composées de squelettes de Métazoaires et d'Algues calcaires, qu

- 'on trouve dans tout le Phanérozoïque. * On a souvent lié l' apparition des récifs avec le développement des métazoaires à squelette comme les Coraux et les Stromatoporoides de l'Ordovicien moyen; mais dès le Cambrien inférieur on connaît des écosystèmes récifaux proches des structures plus récentes, coïncidant avec le développement des Archéocyathes, organismes parmi les premiers Métazoaires connus. - 62604 <SOURCE>Palaeoworld 19, 3-4: 222-241.</SOURCE>
- 62605 <ABSTRACT>The differences and variety of structural, depositional, and compositional features observed in the Early Cambrian microbial-archaeocyath buildups preserved in the present-day continents, suggest a direct correlation between the physico-chemical factors of deposition and the structural architecture of the buildups. This can be explained in terms of their palaeogeographic collocation on the shelves (depth, energy), and hence of the areal distribution of epeiric basins and perioceanic/pericontinental platforms. * Data on the analysis of biohermal communities and their architectures indicate that the relative development of the main reef-building components, as well as their evolution within the reef communities, reflects the dominant physico-chemical factors, mainly temperature and nutrient availability, and the physiography of the primary depositional setting. The bioaccumulations show different reef building styles, defined by the types of associated facies and by the early diagenetic features. They are represented by (i) mud-supported simple (Kalyptrae) to compound mounds locally with stromatactis-like cavities; (ii) dendrolitic bioherms and crustose buildups with large shelter cavities and low synoptic relief; (iii) cement-supported skeletal reefs with wave resistant frameworks often associated with oolitic shoals, and (iv) bioclastic sands, developed at photic and shallow sub-photoc depths on low-angle/low-energy ramps (i-ii) or on high-energy conditions on platforms distally rimmed (iii) or occasionally swept by storm currents (iv). The results of the analysis provide information on the spatial conditions of the primary depositional settings of the first metazoan involved in reef building in the history of the Earth, and suggest that the architecture of the bioconstructions was controlled not only by the physiography of the depositional setting and global/astronomic climate but also by local climatic conditions constrained by the latitudinal distribution of the Early Cambrian continental blocks. 62642 <TITLE>Early Cambrian microstructural diversification of Cnidaria.
</TITLE>
62643 <SOURCE>Courier Forschungsinstitut Senckenberg 164: 365-372. [P.
Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium
on Fossil Cnidaria and Porifera, Vol. 1] </SOURCE>
62644 <ABSTRACT>Radiation and diversification of early Cnidaria, at the
beginning of the Cambrian are documented here, with special attention
to the skeletal microstructures, investigated by means of electron
microscope and ultra-thin sections, each time on the same specimen for
direct comparison. Three centers are recognized: Siberia (Tommotian to
mid-Botomian), Australia (mid-Botomian to Toyonian), North America
(Upper Botomian to Toyonian), but without cosmopolitan forms.
Corallomorphs of the Cambrian were represented by slender irregular
polygonal tubes, mostly solitary in the Tommotian and Atdabanian and
mainly modular in the later stages (Botomian and Toyonian). They
acquired in their evolution multilayered walls and septum-like
structures which are absent in the oldest forms. Out of the 10 Early
Cambrian corallomorphs, 8 at least have different microstructures, none
of them fully identified with one of the post-Cambrian Corals. The
diversification of Early Cambrian corallomorphs, according to their
microstructure, had their acme in the Botomian and decreased during the
Toyonian; the Precambrian "medusoids", now thought plasmod
unicellulars, could not be considered the ancestor of Cambrian
corallomorphs. For cnidarians, the Early Cambrian represents an unique
stage in the development of the phylum with short-lived branches of
high taxonomic level among which it is not possible to recognize an
"ancestor" of true corals which will appear in the Ordovician.

62669 <SOURCE>Journal of Paleontology 73, 4: 598-607. <http://www.jstor.org/pss/1306759></SOURCE>
62670 <ABSTRACT>Palaeacmaea typica, the type species of the genus, and P. irvingi, the only other Late Cambrian taxon considered congeneric are redescribed herein. Their morphology suggests that they are neither Monoplacophora, where they are currently assigned, nor are they Mollusca. Specimens of P. irvingi demonstrate considerable variation in shape, interpreted as distortion of a flexible integument, of essentially no thickness. A neotype is designated for P. irvingi; it is interpreted as a medusiform fossil, possibly a cnidarian. Only the holotype of P. typica is known, but it shows comparable features. The genus and the family Palaeacmaeidae are placed in Phylum Incertae Sedis. Four Ordovician species previously assigned to Palaeacmaea, show none of the characteristics noted, and they are tentatively reassigned to other genera. [original abstract]</ABSTRACT>

62707 <TITLE>Reef ecosystem recovery after the Early Cambrian extinction.</TITLE>
- 62708 <SOURCE>Geological Society Special Publication 102 [Hart M.B. (ed.): Biotic Recovery after Mass Extinction Events]: 79-96.</SOURCE>
62709 <ABSTRACT>Revised and new stratigraphic data indicate a complex extinction event in the late Early Cambrian which consisted of two, temporally, separate, but related phases. The earliest phase (mid-Botomian, Sinsk Event) may be related to widespread anoxia due to eutrophication and phytoplankton blooms. The later event (early Toyonian, Hawke Bay Event), is connected to a world wide regression. This double extinction event severely injured the reefal biota which has undergone a further rejuvenation during the remainder of the Cambrian. As a result of the lowering of grazing pressure and unhealthy metazoan-calcimicrobial interactions, the remaining metazoan reef-builders were eliminated by the end of the Early Cambrian. Consequent reduction of space heterogeneity led to the decline of calcified microbes (Renalcis, etc.) in both diversity and abundance which gave the way to the thrombolite-stromatolite community. The recovery of the reefal biota occurred during the very end of the Late Cambrian-Early Ordovician and may be attributed to Elvis-taxa, with the exception of the spicular demosponges. These recovering biota intruded into the thrombolite-stromatolite community and created a space for the more successful encrusting reef dwellers of Middle-Late Ordovician time.</ABSTRACT>

62720 <TITLE>Lower Cambrian reefal cryptic communities.</TITLE>
62721 <SOURCE>Palaeontology 38, 2: 443-490.</SOURCE>
62722 <ABSTRACT>During the Lower Cambrian, cryptic communities were more abundant than previously thought. They offered a habitat of reduced environmental stress and housed a substantial proportion of the total biodiversity of early reefs. Cryptic communities were composed of solitary organisms with no evidence of succession compared with most modern reefal crypts. This may be a result of the small size and short-lived nature of both crypts and their occupants. The rapid growth of symsedimentary cements in crypts may have reduced the time available for both colonization and growth of the cryptos as they did not remain

open for long before partial or total occlusion. Solitary archaeocyathids, solitary chambered forms (coscinocyathids and kazachstanicyathids), calcified cyanobacteria and a microburrowing ? metazoan were the most ubiquitous and abundant elements; putative primitive cnidarian, spiculate sponges and various problematica were also present. Several species of archaeocyaths were obligate cryptobionts; infaunal deposit-feeding (?) worms and probable boring sponges have been noted only in crypts. On a sub-zonal scale, the vast majority of archaeocyath species appeared simultaneously in both open surface and cryptic niches suggesting that Lower Cambrian crypts were neither refuges for open surface inhabitants nor niches for evolutionary innovations.</ABSTRACT>

- 62800 <ABSTRACT>The Devonian collections comprise the nation's largest collection of Middle Devonian fossils from Wisconsin. The largest suite of fossils is a unique collection from the Taghanic Stage of Milwaukee County. The faunas are dominated by brachiopods with significant numbers of trilobites, bryozoans, corals, echinoderms and bivalves. Some of this material was described by Blodgett (1988), Cleland (1907, 1911), Griesemer (1965), and Pohl (1929a, 1929b). These localities are from quarries and temporary excavations that are now filled and cannot be recollected. There are 384 drawers of Devonian fossils from 797 localities represented by approximately 42,500 specimens. Of these localities, 360 are attributed either wholly or in part to Gilbert O. Raasch and share the same excellent documentation as his Cambrian collections. The Upper Devonian collections were made from tunnel projects under Lake Michigan in the early part of the century. These collections are especially significant since this unit is not represented by outcrop, and correlative strata in the subsurface of the

Michigan Basin are important gas producers. * Fossil preservation in these collections is very good, and the faunas, which are in need of revision, provide outstanding possibilities for taxonomic work. Interested professionals are encouraged to conduct research in these collections. Hard copies of data are available on request. [part of the paper]

62864 <SOURCE>Proceedings of the Estonian Academy of Sciences, Geology 52, 4: 199-212.</SOURCE>
62865 <ABSTRACT>The new genus Eurogrewingkia gen. nov. (type species selected here is Grewingkia bilateralis Neuman, 1969) is erected for streptelasmatic rugose corals with Grewingkia-like ontogeny lacking a cardinal fossula sensu stricto. In addition, the new genus Fosselasma gen. nov. (type species selected here is Streptelasma unicum Neuman, 1975) is erected for species with a Streptelasma-like ontogeny but provided with a cardinal septo-fossula. Species of Eurogrewingkia are currently recognized from the Upper Ordovician, Rawtheyan-Hirnantian strata in Europe and North America. Species of Fosselasma are found only in Hirnantian strata in Sweden and Norway. [original abstract]</ABSTRACT>

- 62903 <SOURCE>Geol. Palaeont. Mitt. Innsbruck 20: 335-347.</SOURCE>
- 62904 <ABSTRACT>Sponges are primitive metazoan organisms which occur since the late Proterozoic. The oldest sponge remains (hexactinellids) are from a shallow marine carbonate facies of the late Sinian Shibantan Member (China). From the Tommotian (Sansha, China) protospongiid and rossellimorph hexactinellids were discovered in shallow marine silicified rocks. The middle part of this section consists of silty shales with entirely preserved hexactinellid sponges: Sanshadictya, Hyalosinica, Solactinella, Triticispongia, Hunanospongia. The hexactinellids typically are soft bottom dwellers, which sometimes grow on and form in situ spiculites (spicule mats). The sponges from the Chengjiang deposits of Atdabanian age, which show a rossellimorph spicule organization typical of the conservative hexactinellid groups, which inhabited the deep sea during most of the Phanerozoic, were also typical soft bottom dwellers. All sponge taxa (Leptomitella, Leptomitus, Paraleptomitella etc.) described from this locality we consider to be hexactinellids and not demosponges, as originally classified. The sponge communities of carbonate-dominated archaeocyathid mounds are completely different from the above described sponge mounds. The sponges from the archaeocyath mounds of the Flinders Ranges (S Australia) are characterized by Calcareia and demosponges (≠ modern type of the pharetronid Calcareia Gravestockia pharetroniensis., and many tetractinellid demosponges, Geodiida). Questionable is the origin of four-rayed demosponge spicules found in some archaeocyaths. The oldest ceractinomorph demosponges are documented from the middle Cambrian (Vauxia - an aspicular sponge with keratose affinities, and isolated sigmata microscleres). Sponge communities of the Early Cambrian were highly developed, and already then they were taxonomically strongly dependent on substrates and trophic conditions.</ABSTRACT>

</TITLE>
62929 <SOURCE>Proceedings 8th International Coral Reef Symposium 2: 1623-1630.
</SOURCE>
62930 <ABSTRACT>Late Precambrian reefs, at a time of stromatolite and carbonate productivity decline, were marked by calcimicrobial encrusters and cementers: soft bodied metazoans played no identifiable role. This was largely continued in the earliest Cambrian stage (Nemakit-Daldynian), a period of radiation of many skeletal protostomes and deuterostomes, but a period of restricted carbonate shelf production. Metazoan archaeocyath reefs dominated the Tomotian-Toyonian, but vanished after only 10 Ma: their demise is speculative but focuses on anoxia, cooling, phosphate deposition, and regressions. The 65 Ma long Mid-Cambrian to late Middle Ordovician (Llanvirn) is marked by sparse but increasing chlorophyte, lithistid-pulchraminid, and bryozoan content, but most reefs were calcimicrobial, especially in distal ramp and slope settings. Tabulate and rugose corals, stromatoporoids, chlorophytes, rhodophytes (assisted by calcimicrobes), and bryozoans of the late Llanvirn-Caradoc initiated the expansion of mid-Paleozoic reefs, largest of the Phanerozoic. This reef ecosystem collapsed in the late Devonian (Frasnian), never to recover fully in the remaining Paleozoic: extended F/F mass extinction over 10 Ma is related to anoxia, nutrient increase, cooling (steep CO₂ decline, rising O₂ with the arrival of vascular plants) and sea-level drawdown as ocean shifted to an icehouse mode.</ABSTRACT>

63020 <SOURCE>Postilla 223: 1-49; New Haven.</SOURCE>
63021 <ABSTRACT>Type material for 182 nominal species of fossil anthozoans is in the Invertebrate Paleontology collections of Yale University's Peabody Museum of Natural History. Primary types for 77 nominal species include 64 holotypes, 74 syntypes (representing 11 nominal species), 1 lectotype and 2 neotypes. Secondary types for 39 nominal species include 124 paratypes (representing 38 nominal species) and 16 paralectotypes (representing 1 nominal species). Tertiary types of 114 nominal species include 488 hypotypes. Most types are from new York State, Ohio, Quebec and Tennessee and have been described by T.W. Amsden, C.E. Beecher, E.J.Buehler, CO. Dunbar, G.H. Girty, E.C. Stumm and W.H.Twenhofel. [original abstract]</ABSTRACT>

63032 <TITLE>Automobility in Tabulata, Rugosa, and extant Scleractinian analogues: Stratigraphic and paleogeographic distribution of Paleozoic mobile corals.</TITLE>
63033 <SOURCE>Journal of Paleontology 73, 6: 985-1001.</SOURCE>
63034 <ABSTRACT>Freeliving corals capable of automobility (e.g., lateral migration) were rare during Paleozoic time, but some species within the tabulate genera Procterodictyum, Procteria (Granulodictyum), P. (Pachyprocteria), Palaeacis and Smythina, and the rugose genera Combophyllum, and Baryphyllum, have morphologic characters that suggest they were capable of such self-directed movement. The rugose corals Gymnophyllum and Hadrophyllum, sensu stricto may have exhumed and righted themselves. No single morphological character is diagnostic for an automobile habit, but the following characters appear to be important indicators: 1) lack of an external attachment surface; 2) concentric skeletal accretion; 3) discoid corallum shape; 4) concavo-convex, plano-convex, and, less commonly, biconvex corallum profile; and 5) small, lightweight corallum. Additionally, the occurrence of corallites on the base of the corallum (hypocorallites) is a good indicator of automobility in freeliving corals, but the character is so far known only in Procterodictyum. All known fossil automobile taxa appear to have inhabited relatively quiet environments

on muddy or silty, soft substrates. The earliest known automobile corals were early Emsian (Devonian) Procterodictyum. Paleozoic automobile corals were most abundant during Devonian time, with Procterodictyum, Procteria (Granulodictyum), and Combophyllum distributed in a narrow longitudinal band in the southern hemisphere on both sides of the Rheic Ocean. Carboniferous and Permian automobile taxa (Palaeacis partim, Smythina and Baryphyllum) were less diverse, but more cosmopolitan. Throughout Paleozoic time, the vast majority of automobile corals was confined to within 40 degrees of the paleoequator. However, additional research will be required before coral automobility can be used to constrain paleolatitude independently. </ABSTRACT>

63046 <SOURCE>Lethaia 35, 4: 328-344.</SOURCE>
63047 <ABSTRACT>The soft bodies and individual development sequences of the polyps of Palaeozoic corals are reconstructed on the basis of the functional, engineering and constructional morphology of recent Anthozoa. Four types of body reconstruction can be distinguished by the arrangement of mesenteries, the number of mesentery insertion zones and characteristic septal insertion patterns: (1) serial insertion of single mesenteries in four sectors, which has resulted in the serial insertion of septa, (2) symmetrical insertion of single mesenteries in four sectors, which has resulted in a symmetrical septal pattern or pseudo radial patterns, (3) exponential insertion of paired mesenteries in four sectors, which has resulted in septal bifurcation, and (4) exponential insertion of paired mesenteries in six sectors, which has resulted in a radial pattern. Suggestions for a constructional taxonomy are given on the basis of the arrangement of mesenteries and on individual development of reconstructed polyps. Accordingly, new superorders are introduced: 'Seriales' for the first body constructions and 'Symmetricales' for the second. The third body construction is that of the Heterocorallia and the fourth that of the Hexacorallia. Following a constructional taxonomy, new and stricter definitions are given for the new and already known taxonomic categories of Rugosa, Heterocorallia and Hexacorallia. A byproduct of this re-definition is that several Palaeozoic corals represent the body reconstruction of the Hexacorallia and should therefore be revised as Hexacorallia; consequently, Hexacorallia must already have been present in the Palaeozoic.</ABSTRACT>

63071 <TITLE>Patterns of extinction and survival in Palaeozoic corals.</TITLE>
63072 <SOURCE>Spec. Vol. Syst. Ass. 34 [Larwood G. P. (ed.): Extinction and survival in the fossil record]: 65-88.</SOURCE>
63073 <ABSTRACT>The two major subclasses of Palaeozoic corals, the Tabulata and the Rugosa, appear respectively in the Lower and Middle Ordovician. Analyzed at the generic level, both show similar patterns of peaks of extinction close to successive system boundaries accompanied or followed by enhanced rates of diversification. Prior to the final disappearance of both groups at the end of the Permian, the most important extinction event occurs in the late Givetian, followed by the loss of most remaining genera about the Frasnian-Famennian boundary. Both subclasses survive into the Carboniferous through a very small number of long ranging genera together with the continued evolution of distinctive Rugosa, mainly adapted to deeper water fine clastic environments. Although the Rugosa eventually rediversify vigorously in the Lower Carboniferous the Tabulata never regain their early-mid Palaeozoic prominence. Coloniality and colonial integration appear to have little value to overall in enhanced survivorship among Rugosa. Tabulate faunas are dominated successively by massive coenenchymal, massive perforate cerioid, and communicate fasciculate colony forms. A detailed analysis of generic ranges from the late Frasnian to the early Tournaisian reveals three extinction events among the rugose corals which can be matched to those in other groups. Environmental perturbations of eustatic and/or climatic origin are favoured as the principal causal factors.</ABSTRACT>

63085 <SOURCE>Mem. Ass. Australas. Palaeontols 8 [Jell P. A. & Pickett J. W. (eds): Fossil Cnidaria 5 (Proceedings of the Fifth International Symposium on Fossil Cnidaria including Archaeocyatha and Spongiomorphs)]: 157-168.</SOURCE>
63086 <ABSTRACT>Primary or secondary origin of the microlamellar microstructures of many Palaeozoic corals, is an object of controversy. They are especially frequent in Carboniferous corals (rugosans, tabulates, and all known Heterocorallia). Architecture and relationships of the microlamellar elements with fibrous microstructures seem to demonstrate that they are primary and not diagenetic. Furthermore some petrographic criteria indicate that they are not secondary. Since it is probably primary, the lamellar microstructure could be used in taxonomy. Nevertheless our knowledge of the microstructure of rugose corals is too slight. Many studies on microstructure must be done before using it broadly in the systematics of Rugosa. Such studies should be done with the appropriate techniques, scanning and ultrathin sections, and not with conventional thin

- sections.</ABSTRACT>

63137 <SOURCE>Courier Forschungsinstitut senckenberg 164: 017-019. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 1] </SOURCE>
63138 <ABSTRACT>Paleozoic corals of Russia are first mentioned at the beginning of the 19th century in the papers of G. Fischer von Waldheim

and E. Eichwald. Their systematic study was started by A. Stuckenberg (Carboniferous and Permian of the European Russia and Urals); these works are classical ones. A new stage began in the thirties with the papers of E.D. Soshkina, T.A. Dobrolyubova (Rugosa) and a little bit later with the papers of B.B. Chernyshev and B.S. Sokolov (Tabulata). The works of these paleontologists stimulated the study of Paleozoic corals in various aspects: that especially became evident in the late fifties, when dozens of paleontologists worked on this topic. At that time progress was achieved especially in systematics and stratigraphy. Later on the number of specialists and their quality decreased which had nothing to do with falling interest in corals, but can be explained by a general decrease in the USSR for research on paleontology and stratigraphy. That led to the fact that only a few specialists now work on Paleozoic corals and this tendency does not promise any positive changes in this respect.</ABSTRACT>

63149 <TITLE>Phylogeny reconstruction: problems posed by Paleozoic corals.</TITLE>

63150 <SOURCE>Courier Forschungsinstitut Senckenberg 164: 71-074. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 1]</SOURCE>

63151 <ABSTRACT>Cladistic theory provides a sound basis for phylogeny reconstruction of Paleozoic corals because it: 1, forces evaluation of every morphologic character; 2, bases relationship on shared morphologic "novelties" rather than gross morphologic similarity; and 3, rejects a priori conclusions on the taxonomic value of characters (i.e., "specific level" and "generic level" characters). Despite the value of cladistic theory, standard cladistic methodology is not an effective technique for phylogeny reconstruction of Paleozoic corals. To operate properly, cladistic methodology requires limited amounts of convergence and large numbers of non-convergent morphologic characters. Paleozoic corals are notable for convergence and parallel evolutionary trends and, in many cases, offer few characters for analysis owing to simplicity of morphology and phenotypic plasticity. These problems may be overcome in the future by developing: 1, better taxonomic descriptions; 2, new, untested morphologic characters; 3, better understanding of Paleozoic coral biology; and 4, new cladistic techniques that make use of both morphologic data and non-morphologic data, such as stratigraphic and geographic distribution.</ABSTRACT>

63162 <TITLE>The Palaeozoic corals I: origins and relationships.</TITLE>

63163 <SOURCE>Proc. Yorkshire Geol. Soc. 51, 3:177-208.</SOURCE>

63164 <ABSTRACT>The status, origins and relationships of the various groups of Palaeozoic corals are reviewed. Five orders are currently

recognized: Rugosa, Tabulata, Heterocorallia, Cothoniida and Kilbuchophyllida, to which I add the Tabulaconida and Numidiaphyllida. The Rugosa and Tabulata are considered to be broadly monophyletic clades, and the Tabulata are confirmed as zoantharian corals. Morphological features, particularly aspects of septal insertion in both groups, are discussed as clues to their likely origins and relationships. They are not considered to have had a skeletonized common ancestor, but they may have arisen as separate skeletonization events from the same broad group of anemones, represented by the living Zoanthiniaria. The Rugosa are not considered to be ancestral to the Scleractinia. The latter, together with the Permian Numidiaphyllida, are considered to have evolved through skeletonization events among a group of anemones derived from the Actiniaria / Corallimorpharia, a member of which also gave rise to the Kilbuchophyllida in the Ordovician. The pattern of septal insertion in the Heterocorallia is controversial and the relationship of these corals to contemporary coral groups remains uncertain. The increasingly important record of Cambrian coralomorphs is assessed, and considered to include several genera of zoantharian corals. However, although similarities are apparent, none is regarded as directly ancestral to the post-Cambrian coral clades. The history of diversification and extinction of corals through the Palaeozoic is briefly reviewed. </ABSTRACT>

63175 <TITLE>The Palaeozoic corals II: structure, variation and palaeoecology.</TITLE>

63176 <SOURCE>Proc. Yorkshire Geol. Soc. 52, 1: 1-57.</SOURCE>

63177 <ABSTRACT>Palaeozoic corals faunas were dominated by two orders of Zoantharian corals, the Rugosa and the Tabulata. Almost all rugose and tabulate corals developed an epitheca or holotheca around the corallum and possessed small to minute attachment scars. A limited number had an encrusting life style and many others could facultatively encrust to some extent when settling by chance on a hard substrate. However, most were effectively free living on a soft substrate as mature coralla. A high percentage of rugose corals were solitary and of the colonial genera few exhibited physical integration of modules within the colony. In contrast, most of the exclusively modular tabulate corals possessed some degree of integration. Colony formation in tabulate corals was, with doubtful exceptions, solely of non-parricidal increase, whereas both non-parricidal and parricidal increase, the latter in a minor role, occur in the Rugosa. The sources of variation in solitary and colonial Palaeozoic corals are reviewed and data on growth rates, measured on the basis of cyclomorphic variation expressed as density band couplets, are assessed. Growth-form variation in solitary corals and its relationship to stability on the substrate are explored. Growth strategies in colonial corals are described and their adaptive success under different environmental conditions is discussed. Colonial growth-forms were a function of the interaction between growth strategy and prevailing conditions during astogeny, although some species had genetically constrained, relatively invariable growth-forms. Factors controlling the distribution of Palaeozoic corals in the environment - substrate and turbidity, water energy, depth, light, temperature and variations in salinity and oxygenation - are reviewed. Palaeozoic coral diversity was much lower than that of Recent hermatypic scleractinian corals in comparable environments. Most Palaeozoic corals were adapted

to soft substrates in warm, shelf seas, and made a limited contribution to reef frameworks. It is concluded that none of them developed a symbiosis with algae in contrast to zooxanthellate scleractinian corals.

- 63332 <SOURCE>Geol. Palaeont. Mitt. Innsbruck special volume 4: 1-55.</SOURCE>
- 63333 <ABSTRACT>The Hexactinellida, first appearing in the Late Proterozoic of China, are the earliest animals in Earth's history, which can be definitely attributed to an extant metazoan group. Already in the Middle Cambrian the hexactinellids show remarkably high diversity. Beside many specialized extinct groups, such as the Protospongiidae, the main groups of the recent Hexactinellida, the sister groups Amphidiscophora and Hexasterophora, are known since the Early Paleozoic. The large Paleozoic taxa, Reticulosa and Brachiospongiidae, known since the Cambrian and Ordovician, respectively, may have given rise to the recent Hexasterophora and Amphidiscophora. First representatives of the Hexactinosa, important sponges of the widely distributed Mesozoic spongiolithic facies and common also in recent deep sea environments, are known since the Devonian. A probably paraphyletic grouping, the Rossellimorpha, stayed conservative in its skeletal architecture from the Early Cambrian until today, most of the time apparently restricted to deep-sea habitats, similar to those of most recent hexactinellids. During some periods of Earth's history, specialized groups of the Reticulosa, e.g. the Dictyospongiidae, developed the ability to live in shallow water under higher-energetic conditions. The Late Palaeozoic, especially Permian, was a time of highly diversified spicular skeletal types within the Hexactinellida, including lithistid-like frameworks with zygosis and also groups with demospongioid spicule tracts. During the history of the Hexactinellida, the main faunal extinction occurred at the end of the Permian. However, no major extinction event is recorded at the Frasnian / Famennian boundary. The distribution of sponges and assemblages of isolated sponge spicules, especially for Early Palaeozoic sediments, gives important paleocological indications. An evolutionary-ecological evaluation of organismic groups expands the method of paleocology. The value of this concept for our understanding of e.g. taphonomic and sedimentary processes is demonstrated by some examples on account of Palaeozoic Porifera.</ABSTRACT>

- 63344 <TITLE>Directional orientations of solitary rugose corals.</TITLE>
- 63345 <SOURCE>Canadian Journal of Earth Sciences 24, 4: 806-812.</SOURCE>
- 63346 <ABSTRACT>Unattached solitary rugose corals lying parallel to bedding are common in many Ordovician and younger Paleozoic units, but their directional orientations have seldom been examined. Interpretations based on occurrences in North American Upper Ordovician and Lower

Silurian strata provide a foundation for such studies. Distinct directional patterns resulted from preferred orientation with respect to water motion. They indicate transportation rather than biologic orientation, if it can be shown that the corals were not preserved in life position or were abraded to a significant degree before burial. Transported, slightly curved specimens having trochoid to ceratoid form were aligned parallel to currents, with the apex pointing upstream, and (or) were rolled nearly perpendicular to currents or almost parallel to crests of advancing waves, with the apex facing either way but directed slightly upstream. Therefore, unimodal orientation patterns, bimodal patterns with equal peaks that are opposite one another but slightly skewed, and trimodal patterns that are a combination of these can be used to determine flow directions. An apparently bimodal pattern with nearly equal and directly opposite peaks has been observed in a case involving mostly subcalceoloid corals. These individuals may have been aligned parallel to currents or to the direction of wave progression, with the apex facing either way. Random directional distributions do not necessarily indicate low-energy environments. They could have resulted from changes in flow direction during the time in which the sampled stratigraphic interval was deposited or from the effects of bioturbation on corals that were initially preferentially oriented. Directional patterns of solitary rugose corals are of value in paleoecology (recognition of transported assemblages) and basin analysis (determination of paleocurrent directions). They may also prove to be useful in making paleoenvironmental reconstructions (type of water motion, nature of substrate) if the reasons for different types of orientation patterns can be established with experimental work and additional data from the geologic record. </ABSTRACT>

63372 <ABSTRACT>The Rugosa have long posed problems for those seeking to classify their various taxonomic categories. To be convinced of this, one need look no farther than a comparison of the classifications offered in the original and recently revised coral sections of the Treatise on Invertebrate Paleontology (Hill, 1956 and 1981 respectively) and in Osnovy paleontologii (Sokolov, 1962). The differences between the various systems are significant. [first

63396 <TITLE>Paleozoic Scleractinia: Progenitors or extinct experiments? </TITLE>
63397 <SOURCE>Paleobiology 24, 2: 227-234.</SOURCE>
63398 <ABSTRACT>The scleractinia, which are one of the most important builders of modern reefs, have been considered to have first appeared in the Middle Triassic. Recently, Paleozoic scleractiniamorphs have been reported from both the Ordovician and the Permian, suggesting that the scleractinian-like body plan was already established in the Paleozoic. Those Paleozoic scleractiniamorphs are considered either unsuccessful skeletonized offshoots (extinct experiments) or Paleozoic progenitors of the post-Paleozoic Scleractinia. Permian scleractiniamorphs are characterized by "ancestral" features and have no specific morphologies that deny scleractinian affinities. Molecular phylogenetics also indicate that extant scleractinians are monophyletic and originated long before their Triassic appearance. A Paleozoic origin for the Scleractinia is supported by morphological and molecular phylogenetic data. On the other hand, there is no positive evidence to show that different groups of scleractinians had separate soft-bodied precursors. The Paleozoic scleractinians evolved within the framework of their basic body plan, and a direct derivation of the Scleractinia from the Rugosa is not probable. The Anthozoa are characterized by a bilaterally symmetrical body plan, which is traditionally considered to have been derived from other radially symmetrical Cnidaria. The problem of the origin of scleractinian body plan may provide a key for deciphering the early anthozoan radiation within the Bilateria. Other examples of Paleozoic Scleractinia and scleractiniamorphs will be found, probably in shallow-water reefal facies or deeper-water communities, bridging the stratigraphic gaps in occurrence and elucidating the origin of the Scleractinia and their

- body plan.</ABSTRACT>

63592 <SOURCE>Journal of Paleontology 65: 611-622.</SOURCE>
63593 <ABSTRACT>Anostylostroma is limited to species with complex upwardly branching pillars and simple planar laminae. Species with V- or Y-shaped pillars are removed to Schistodictyon. Simplexodictyon is limited to species with double laminae formerly referred to Diplostroma and a new genus, Petrostroma. is proposed for species with simple planar laminae are rod-like pillars. The scope of Atelodictyon is limited to species with planar, simple laminae and species with collicular laminae are assigned to Aculatostroma. Several genera are placed in synonymy.</ABSTRACT>

63604 <TITLE>Revised classification and terminology of Palaeozoic stromatoporoids.</TITLE>
63605 <SOURCE>Acta Palaeontologica Polonica 44, 1: 1-70. <http://www.a.pp.pan.pl/article/item/app44-001.html></SOURCE>
63606 <ABSTRACT>Paleozoic stromatoporoids comprise a distinct class of non-spiculate poriferans that are represented as fossils by their basal skeleton. A revised terminology for the description of these fossils is presented. Seven orders (Labechiida, Clathrodictyida, Actinostromatida, Stromatoporellida, Stromatoporida, Syringostromatida, Amphiporida) are recognized. The following are recorded for each genus: (1) type species, catalogue number and depository of the primary holotype; (2) synonyms and their type species, (3) diagnosis; (4) stratigraphic range; (5) estimate of the number of species assigned to the genus; (6) stratigraphic and geographic distribution of the genus. Problems in definition and recognition of the genus are briefly discussed in annotations. One hundred and nine genera are considered valid, or doubtfully valid. Fifty-three genera are placed in synonymy. An additional 14 genera are considered to be of uncertain placement in the classification.</ABSTRACT>

63617 <TITLE>Palaeozoic Stromatoporoid taphonomy: ecologic and environmental significance.</TITLE>
63618 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 149: 313-328.</SOURCE>
63619 <ABSTRACT>Epibenthic marine organisms, such as the aspiculate stromatoporoids, show a wide range of growth forms in different settings across Palaeozoic carbonate banks and reefs making them useful taphonomic tools in palaeoenvironment analysis. Three main postmortem taphosignatures are discussed: (1) physical breakage and bioerosion prior to burial are the main processes; (2) loss of morphologic and taxonomic information due to postburial diagenesis; and (3) minor localized reorientation during karstification. Hydrodynamic behaviour of stromatoporoid clasts was similar to that of other carbonate skeletal clasts in their rounding and sorting characteristics. Although bioerosion and bioturbation did not play an important role in Palaeozoic stromatoporoid taphofacies characterization, a marked increase in bioerosion of stromatoporoids is evident, beginning in certain silurian (wenlock) morphotypes and in some Devonian morphotypes. Stromatoporoids offer various profiles to shelf currents and seasonal storm surges, and apparently have different skeletal strength (durability) depending on skeletal architecture. Cyst-dominated skeletal architecture appears to have been resistant to fragmentation. Latilaminae represent inherent zones of weakness that appear to have enhanced equidimensional (breakage away from latilaminae) to oblate (breakage along latilaminar surfaces) breakage. Construction of lamina-pillar architecture, gives the visual impression of varying robustness but this is supported by few data. Stromatoporoid

response to increasing hydrodynamic energies varies greatly from no movement or simple overturning to severe fragmentation and size sorting. Although such variation broadly reflects palaeogeographic setting and thus periodic disturbance by tropical storms, familial and generic skeletal traits greatly influenced taphofacies characterization. These differences in modularity and ontogeny in the stromatoporoid groups have hampered the development of generalized taphofacies models. Taphofacies are not comparable between modern coralgal reefs and Palaeozoic stromatoporoid-bearing reefs for the following reasons: significant differences exist in the diversity of observable growth strategies; probable significant differences in life modes between these groups; and Palaeozoic microborers were fewer than modern representatives and apparently less effective in stromatoporoid taphofacies characterization than modern reef macrobioeroders are for coral taphofacies development.</ABSTRACT>

63630 <TITLE>Skeletal density: implications for development and extinction of Palaeozoic Stromatoporoids.</TITLE>

63631 <SOURCE>Courier Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, vol. 2]: 319-327.</SOURCE>

63632 <ABSTRACT>Palaeozoic Stromatoporoids present a large diversity of skeletal density (S.D.). A computer process is used to calculate this S.D.; the method is detailed. The first (Early Ordovician) and the last (topmost Devonian) Palaeozoic Stromatoporoids have the lowest S.D.; the Givetian and Frasnian ones present the highest S.D. The variations in the S.D. correspond to differences in the amount of calcium carbonate used by the Stromatoporoids to build their skeleton. These are correlated with variations in paleoenvironments (differences in water temperature and variation of PCO₂). Palaeozoic Stromatoporoids may be derived from pre-Ordovician non-calcified soft-bodied organisms (Webby, 1979). During the Early Ordovician, they develop a thin cystose skeleton. From the Ordovician to the Frasnian, they progressively erect a thicker and thicker skeleton. From Famennian to topmost Devonian they develop again a thin cystose skeleton. During and after the Carboniferous they may have again been living as non-calcified soft-bodied organisms.</ABSTRACT>

63643 <TITLE>Classification of the Paleozoic stromatoporoids.</TITLE>

63644 <SOURCE>Journal of Paleontology 54, 5: 881-902.</SOURCE>

63645 <ABSTRACT>A classification of Paleozoic stromatoporoids is proposed that is based on similarities in structural elements. Because microstructures are subject to extensive diagenetic alteration, and classifications that have been based on them are difficult to apply, they have not been used as diagnostic criteria in the classification.

The stromatoporoids are recognized as a class within the phylum Porifera and divided into five orders. Within the Labechiida, the families Labechiidae, Rosenellidae, Aulaceridae, and Cliefdenellidae are recognized. The Lophiostromatidae are the only family in the order Lophiostromatida. The Actinostromatida include the Pseudolabechiidae, Actinostromatidae, and the Densastromatidae. Within the Clathrodictyidae, the families Clathrodictyidae, Ecclimadictyidae, Tienodictyidae, Diplostromatidae, and Amphiporidae are recognized. The Stromatoporida includes the families Stromatoporidae, Syringostromellidae, and Syringostromatidae. Eighty-seven genera are recognized as valid and are distributed to the various families. Forty genera are placed in synonymy. [original abstract; five orders, sixteen families and eighty seven genera are recognized and briefly discussed; forty genera are placed in synonymy]

 63671 <ABSTRACT>[The author provides two figures illustrating the diversity of stromatoporoids, using Ordovician and Silurian series and Devonian stages. The first figure combines all stromatoporoid genera. Maximum genus diversity occurs in the Eifelian Stage of the Middle Devonian. For the Silurian, the Ludlow Series has maximum diversity, and for the Ordovician, it is the Upper Ordovician. The second figure treats the generic abundance on an order-by-order basis. The abundances are not calibrated on the length of a particular increment, so short intervals (e.g., Silurian Pridoli Series) tend to have low diversities.]</ABSTRACT>

- 63710 <ABSTRACT>The past 30 years [1960-1990] have witnessed a major increase in the number of stromatoporoïd genera named from Ordovician through Devonian rocks. Nearly two-thirds the 187 genera listed below were named between 1960 and 1986. Unfortunately, many of these genera have proven to be useless. At least 19 of these newer genera have been shown to be junior synonyms of other genera, most likely due to poor communication among stromatoporoïd workers. Some workers have not had access to all of the pertinent literature, especially from foreign countries, or are unable to read certain foreign languages. In some cases descriptions of genera or type species do not provide the information necessary for the full characterization of the taxon. Many authors do not adequately compare their new genera to other similar genera. In addition, at least 14 of the genera named in the last 30 years are invalid, having been proposed in violation of the International Code of Zoological Nomenclature. 63748 <SOURCE>Paleontologicheskii Zhurnal 1978, 2: 23-35.</SOURCE>
63749 <ABSTRACT>Es wird der Beweis gefuhrt, dass die heteromorphe Komponente bei der Mehrzahl der tabulatomorphen Korallen durch die Veranderlichkeit der Polypen bedingt ist. Bei den alten Heliolitoidea kongruiert so die Ausgestaltung der Koralliten, der Siphonoliten und der Cystoliten. * Betrachtet wird die allgemeine Gesetzmassigkeit der Entwicklung des innerkolonialen Polymorphismus. Es zeigt sich, dass bei den tabulatomorphen Korallen dimorphe (genetischer Polymorphismus), tri- und tetramorphe Kolonien (genetischer und funktionaler Typ des Polymorphismus) auftreten. Die Polymorphie der Kolonien erscheint unabhingig in verschiedenen Stammen der Heliolitoidea und Tabulata (heterochron parallel). Trimorphe Kolonien entstehen als neue Komponente aus dimorphen als Resultat der Umgestaltung der Koralliten. Tetramorphe entwickeln sich aus trimorphen Kolonien als Resultat der Modifizierung der Cystoliten und Siphonoliten. Bei tetramorphen Kolonien fuhrt die weitraumige Regelung in der Anordnung der Komponenten zur Entstehung von Bildungen, analog den Kormidien der

63761 <SOURCE>C.R. Acad. Sci. Paris 302 (II, 11): 761-763.</SOURCE>
63762 <ABSTRACT>Ultra-thin sections (polished slides), whose thickness is
some microns, allow measurement of diameter and length of sclerenchyma
fibers of Tabulate Corals, as well as height and density of their
surface embossements. Study of forms distributed from the Ordovician to
Permian makes obvious a variability of these characters; on the other
hand, invariability of them is a strict rule in all of the skeletons
for each considered species. An accurate determination of fibers
morphology appears henceforth as an indispensable component for the
generic definition of Tabulate Corals. Its part at a higher level in
their sytematics cannot be presently estimated.</ABSTRACT>

Michelinimorphes (Tabulata paleozoiques).</TITLE>
63787 <SOURCE>Bulletin du Museum national d'histoire naturelle, Paris,
ser. 4, 7, C, 1: 13-63.</SOURCE>
63788 <ABSTRACT>The present study deals with the group of michelinioid
Tabulate corals having in common convex incomplete tabulae, they are
namely: Michelinia, Praemichelinia, Eumichelinia, Michelinopora,
Protomichelinia, Cystimichelinia, Holacanthopora, Beaumontia, Rhizopora
and Turnacipora nov. gen. Except for the lamellae in Praemichelinia
their microstructure has been poorly known with only few illustrations
given of the lamellar sclerenchyme within Michelinia and
Holacanthopora. Ultra-thin sections bring new light on the wall
structure of most of these Devonian to Late Permian genera. Michelinia
shows parallel undulating lamellae; Praemichelinia has its lamellae

diverging upwards; in *Turnacipora* the wall is composed of domed micro-lamellae as is the case in *Beaumontia*. The presence of a fibrous stereozone in *Protomichelinia* seems probable. The microstructure of *Michelinopora* and *Cystimichelinia* remains unknown. A genus close to *Praemichelinia* shows a lamellar wall still with the formation of fibres in its median part. Finally a totally fibrous composition is recorded in a Late Permian form. Concerning stratigraphy, forms having parallel lamellae are not found beyond the Middle Carboniferous; forms showing divergence are present up to the Late Permian whereas the microlamellar michelinoids are good indicators of the Early Carboniferous. For the research of evolutionary trends, such characters as inclination of tabulae or presence of epitheca are revealed to be insignificant whereas microstructural patterns suggest phylogenetic relations between the principal michelinoid genera. The interest of microstructure in generic definition of michelinoid Corals is underlined. At the same time attention is drawn to problems arising by its introduction into family definition and the profound eventual changes to be expected in Tabulate corals; systematic.

63826 <SOURCE>Acta Palaeontologica Sinica 41, 3: 464-468.</SOURCE>
63827 <ABSTRACT>Recently, Oliver, Jr. W.A. (1996) and Scrutton, C.T. (1997)

published their important papers on the classification of the Cnidaria as well as the origins and relationships of Palaeozoic corals respectively. These papers have great value to us in the systematics of Cnidaria and the origins and relationships of various coral groups although these themes have been discussed for over 100 years. Integration of newly available global data of Cnidaria and Palaeozoic corals makes possible biologically significant advances in our understanding. The classification of Phylum Cnidaria recognizes three classes: Hydrozoa, Scyphozoa, and Anthozoa. Corals and true anemones are anthozoans. They are referred to zoantharians. The Phylum Cnidaria is represented in the geological record principally by the corals. The two major Palaeozoic groups of corals have records from the Early Ordovician (Tabulata) and Middle Ordovician (Rugosa) to the end of Permian. The third major group (Scleractinia) ranges from Middle Triassic to Holocene. The Rugosa and Tabulata may have arisen as separate skeletonization events from some groups of anemones. None of Cambrian coralomorphs is regarded as directly ancestral to the post Cambrian coral clades. Scleractinia are considered to have evolved through skeletonization events among a group of anemones. The Rugosa are not considered to be ancestral to the Scleractinia. Some of the Cambrian coralomorphs can be dismissed as cnidarians, others may be non zoantharian, or even non anthozoan cnidarians. Some have been reassigned to other phyla, such as algae, bryozoan or sponges. Among them only a small number of genera are accepted as true zoantharian corals. The scleractiniamorph corals were found in the Ordovician from Scotland and northern Ireland as well as in the Permian from North Africa and South China respectively. It is likely that these Palaeozoic scleractiniamorph corals represent another small independent skeletonized clades. They disappeared at the end Permian extinction. The Palaeozoic corals were strongly affected by the mass extinction events. The end Ordovician (O/S) event and the Late Devonian (F/F) event distinctly reduced the diversity of Rugosa and Tabulata. Finally, these two groups became extinct at the end of Permian. [original abstract]

63851 <TITLE>Spatial competition among clonal organisms in extant and selected Paleozoic reef communities.</TITLE>
63852 <SOURCE>Facies 42, 1: 1-24.</SOURCE>
63853 <ABSTRACT>Occurrences of densely packed benthic organisms in extant

reefs are of two types: (1) live-live interactions, where two living organisms interact, and (2) live-dead associations, where only one is alive and uses the other as a substrate. The latter are common in reef deposits due to biostratigraphic feedback, i.e. dense skeletal accumulations provide hard substrates for clonal recruitment, thus facilitating greater frequency of live-dead encounters than in lower biomass level-bottom communities dominated by solitary organisms. Differentiating between these two types in ancient reefs is difficult, often impossible. * Most live-live interactions among clones in extant reef communities involve competition for space. Clonal spatial competition is divisible into four types: (1) direct-aggressive: encrusting overgrowth; (2) indirect-passive: depriving neighbors of resources, chiefly sunlight, by growth above them; (3) stand-off: avoidance of competition by organisms adopting positions that avoid or minimize direct polyp / zooid contact; and (4) overwhelming: one clone / species volumetrically or numerically overwhelms the other, meeting minimal resistance. Despite class-order level differences in taxa, our results indicate that extant analogs, based on the arrangement and distortion of skeletons, are valuable for recognizing live-live interactions in Silurian and Carboniferous reefs and interpreting the types of spatial competition represented. * Comparison of overhead (plan) views of live-live coral competition in Polynesian reefs with vertical sections of Silurian and Carboniferous sponge-dominated reefs and biostromes suggests that direct-aggressive competition is more common among extant than among Paleozoic reef-builders. Stand-offs showing clone margin distortion and overwhelming with minor skeletal distortion are most common in our fossil examples and probably relate to the dominance of these reefs by sponges. Success by extant sponges in spatial competition is largely due to allelochemical deterrence which may explain the predominance of stand-off and overwhelming confrontations in fossil sponges rather than tentacle-mesentery based direct aggression among extant corals and bryozoans. [original abstract]

63865 <SOURCE>Geological Society, London, Special Publications 275 [Alvaro J.J., Aretz M., Boulvain F., Munnecke A., Vachard D. & Vennin E. (eds): Palaeozoic Reefs and Bioaccumulations: Climatic and Evolutionary Controls]: 1-16.</SOURCE>

63866 <ABSTRACT>One unresolved conceptual problem in some Palaeozoic sedimentary strata is the boundary between the concepts of 'shell concentration' and 'reef'. In fact, numerous bioclastic strata are transitional coquina-reef deposits, because either distinct frame-building skeletons are not commonly preserved in growth position, or skeletal remains are episodically encrusted by 'stabilizer' (reef-like) organisms, such as calcareous and problematic algae, encrusting microbes, bryozoans, foraminifers and sponges. The term 'parabiostrome', coined by Kershaw, can be used to describe some stratiform bioclastic deposits formed through the growth and destruction, by fair-weather wave and storm wave action, of meadows and carpets bearing frame-building (archaeocyaths, bryozoans, corals, stromatoporoids, etc.) and/or epibenthic, non-frame-building (e.g.

pelmatozoan echinoderms, spiculate sponges and many brachiopods) organisms. This paper documents six Palaeozoic examples of stabilized coquinas leading to (pseudo)reef frameworks. Some of them formed by storm processes (generating reef soles, aborted reefs or being part of mounds) on ramps and shelves and were consolidated by either encrusting organisms or early diagenetic processes, whereas others, bioclastic-dominated shoals in barrier shelves, were episodically stabilized by encrusting organisms, indicating distinct episodes in which shoals ceased their lateral migration.

Fanerozoic of Tajikistan 1: 10-20. Donish, Dushanbe.</SOURCE>
63879 <ABSTRACT>Uralo-Tien-Shan paleozoogeographical province appeared at the
beginning of Devonian and disappeared at the beginning of Permian. In
early Permian on the most part of this area land was formed. To the
north of it there were the seas of the Arctic realm and to the south of
it there was the ocean Tethys. The most resemblance between the Urals
and the Tien-Shan faunas was in Devonian and in early Carboniferous,
and the most difference was in Cambrian, Ordovician, Artinskian,
Kungurian and late Permian.</ABSTRACT>

- 63983 <ABSTRACT>The second part of this paper is an analysis of the variations in the reefs of the Onandaga unit of SW Ontario and New York State and comparison with those of the Java Seas. The distribution of stromatoporoid shapes are measured in several of the Devonian reefs. Stromatoporoids are distinguished as tabular or laminar but not identified taxonomically. The scarcity of tabular stromatoporoids and the dominance of phacelloid corals and dendritic branching corals in the Onandaga Formation (Appalachian Basin) are here explained by localized high productivity conditions driven by quasi-estuarine circulation.</ABSTRACT>

64007 <TITLE>Solenopora is a chaetetid sponge, not an alga.</TITLE>
64008 <SOURCE>Palaeontology 47, 1: 117-122.</SOURCE>
64009 <ABSTRACT>For over 100 years the Ordovician fossil Solenopora (Dybowski) has been widely considered to be a calcified red alga. The type species Solenopora spongoides consists of tubes with longitudinally flexuous walls, lobate-petalloid cross sections 30-175µm across with septal projections and sporadic cross partitions. This internal morphology is not characteristic of calcified red algae but is consistent with the original interpretations of Solenopora as a chaetetid and with subsequent recognition of chaetetids as sponges. Solenopora is widely misidentified in Silurian and younger rocks. Removal of Solenopora from the algae underscores the need to comprehensively reassess the palaeoecological and phylogenetic significance of numerous disparate Ordovician to Miocene fossils currently classed as Solenoporaceans. 64020 <TITLE>Ellisites, an upper Ordovician heliolitid coral intermediate between coccoserids and proporids.</TITLE>
64021 <SOURCE>Palaeontology 29, 2: 391-413.</SOURCE>
64022 <ABSTRACT>The upper Ordovician heliolitid corals Ellisites labechioides gen. et sp.nov. and E. astomata (Flower) combine vesicular skeletal plates with zones of strongly dilated vertical trabeculae. In these characters they provide the first evidence of a phylogenetic link between the Coccoseridicae and Proporicae. They are referred to a new family, the Ellisitidae, and included in the Coccoseridicae, which necessitates taxonomic modification of the latter to include genera with vesicular skeletal plates. They show features most related to Coccoseris Eichwald 1855, and two of three species considered to have been erroneously referred to the stromatoporoid Dermatostroma Parks 1910. Their substantially vesicular skeletal development can lead them to be mistaken for strongly cystose labechiid stromatoporoids.</ABSTRACT>

64112 <SOURCE>Journal of Paleontology 60, 1: 14-25.</SOURCE>
64113 <ABSTRACT>Neotryplasma floweri n.sp. is an epizoic solitary rugose coral characterized by two orders of perforate, monacanthine, carinate septa, a complex axial structure of septal lobes and lamellae, and a well developed broad dissepimentarium. It occurs in the Late Ordovician (late Edenian to earliest Maysvillian; late Caradoc) Upham Dolomite Member of the Second Value Dolomite, Montoya Group, at El Paso, Texas, U.S.A. Neotryplasma kaljo, 1957, also includes two Late Ordovician species from the Estonian S.S.R. and one from the late Middle and Late Ordovician of the northern and middle Ural region, U.S.S.R. This genus is assigned to the Neotryplasmataidae n.fam., which is placed in the Suborder Monacanthina Neuman, 1984.</ABSTRACT>

64163 <TITLE>The scleractiniamorph coral kilbuchophyllia clarksoni at
Kilbucho.</TITLE>
64164 <SOURCE>Scottish Journal of Geology 32, 1: 91.</SOURCE>
64165 <ABSTRACT>The first well authenticated Palaeozoic examples of a
scleractiniamorph coral were described by Scrutton & Clarkson
(1991). The material was collected from fossiliferous mid-Ordovician
(Caradoc) silt-grade greywackes of the Kirkcolm Formation in Tract 2
(of the accretionary prism model) of the Northern Belt of the Southern
Uplands at Kilbucho, near Biggar. Subsequently, further material became
available (Scrutton 1993), including a new, small specimen from the
greywackes at Kilbucho which demonstrated hexamerall cyclic septal
insertion with much greater clarity than any of the original material.
The range of the type species, Kilbuchophyllia discoidea, was extended
to further localities along strike to the southwest and a new species,
K. clarksoni, was described. The new material from these additional
localities, Wallace's Cast, Glenkip Burn, Snar water and
Duntercleuch, was all found in a poorly sorted, matrix-supported,
quartz pebble conglomerate facies. However, despite extensive
collecting no kilbuchophyllids had been found in the fossiliferous

conglomerates underlying greywackes at Kilbucho. This note is to record the finding of a single specimen of *K. clarksoni* from the conglomerate facies at Kilbucho during a visit in August 1995, the first record of this species from any facies at that locality. This find provides further evidence to support the likelihood that throughout Tract 2, the kilbuchophyllids are occurring in fossiliferous conglomerate and greywacke obrution deposits at a single level in the Kirkcolm Formation (Clarkson et al. 1992). One further additional observation since the publication of Scrutton (1993) has been the rediscovery of the fossiliferous conglomerate localities in Glenkip Burn [NS 869174] and Snar Water [NS 859169]. Additional material of both species of Kilbuchophyllia was recovered from these localities, the original material having been collected in the last century during the survey by Peach and Horne (1899). The correlation of this level in the succession has contributed to a reassessment of the structure and history of the Northern Belt of the Southern Uplands shortly to be published (Armstrong et al. 1996).

 64176 <TITLE>Evolutionary trends in Ordovician stromatoporoids.</TITLE>
 64177 <SOURCE>Courier Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, vol. 2]: 373-380.</SOURCE>
 64178 <ABSTRACT>An attempt is made to assess the early (that is, Ordovician) history of stromatoporoid genera using both cladistic and stratigraphical data. Only two relatively independent and homogeneous stromatoporoid groups have been recorded. The order Labechiida is the most diversified, with elements first appearing in the Middle Ordovician. The group is divided into four families based on differing morphological features and growth form: the rosenellids with their simple (?more primitive), small to large cysts, denticles, and encrusting, laminar to domical form; the labechiids with rounded pillars formed by superposition of denticles, and a trend in some to flatter, lamina-like cysts; the stylostromatids (fam. nov.) with mamelon columns and development of composite, blade-like pillars within columns; and the aulacerids with extended, mamelon-like, cylindrical to branching forms. The massively thickened, encrusting lophiostromatids may comprise a fifth group. The order Clathrodictyida has only a few members, and these make their first appearances in the Upper Ordovician; they differ from representatives of the Labechiida in showing downwardly inflected pillars and common astrorhizae. Given the distinctively different morphologies of the two groups, it may be suggested that they represent separate lines of descent from uncalcified sponge-like organisms.</ABSTRACT>

- 64217 <ABSTRACT>Some old (Ordovician) stromatoporoids are revised and their first appearance in different regions of the globe is shown. A new system for the genera beginning with Priscastroma is proposed. The oldest stromatoporoids were found in the Middle Ordovician strata of the Siberian platform (Moriero River), North America (Champlain Lake), Australia (Tasmania), and probably the Urals. It is suggested that stromatoporoids in these regions originated synchronously at the beginning of the Middle Ordovician when a new major sedimentary cycle in Earth history began. [original abstract; the paper contains discussions and diagnoses of the following genera: Priscastroma, Dermatostroma, Pseudostylodictyon, Cystostroma, Stromatocarium, Labechia, Pachystylostroma; the type species of Priscastroma is P. gemina Khromykh, 1999; the early genera are placed in a phylogenetic sequence]</ABSTRACT>

- 64230 <ABSTRACT>The orders Labechiida (6 families, 22 genera) and Clathrodictyida (2 families, 4 genera) represent the class Stromatoporoidea of calcified sponges in the Ordovician. One stromatoporoidea community is associated with the reef facies; another is characterized by genera of columnar growth and is presumed to have lived in deeper water on carbonate ramps. All Ordovician stromatoporoidea communities plot into paleolatitudes between 30 degrees north and thirty degrees south. The pulchrilaminids comprise a family of doubtful affinity of large framebuilders that occur in the late Early Ordovician of North and South America. The rest of the labechiids first diversified in late Middle Ordovician and secondly in Caradoc time. The initial radiation of the clathrodictyids occurred in mid to late Caradoc with the appearance of Ecclimadictyon. Ordovician stromatoporoidea diversity peaked in early to mid Ashgill and fell abruptly with the Hirnantian glaciations. Diversity curves for genera and species are presented as "normalized" and "range through" versions. The latter shows a steady increase in generic diversity from late Middle Ordovician to mid Late Ordovician and a sharp decline in the Hirnantian. The sensitivity of labechiids to oceanic cooling is discussed in the light of the hypotheses of Stearn (1987) and Nestor and Stock (2001). The relationship of the diversity trends to sea level changes is also considered.</ABSTRACT>

- 64242 <SOURCE>Journal of Paleontology 50, 3: 380-391.</SOURCE>
- 64243 <ABSTRACT>Middle and Upper Ordovician specimens of Foerstephyllum from a number of localities in eastern North America were studied to determine the details of hysteroontogeny and most particularly the nature of sepal development in the genus. The increase is exclusively lateral in nature, most common in cericoid rugose corals and in tabulate genera. The dividing wall appears adjacent to the intercorallite wall or it appears to be formed by splitting of the intercorallite wall. The holotypes of F. halli (Nicholson), type species of the genus, and of F. magnificum (Okulitch) are illustrated and commented upon. Closely spaced serial acetate peels show that F. halli and forms comparable to F. magnificum lack an ordered sequence of sepal development such as is characteristic of rugose and scleractinian corals. Septa emerge in an apparently random manner around the corallite. Corallites of a specimen of F. vacuum (Foerste), however, show an early stage of development in which septa possibly equivalent to the cardinal and alar septa are present. Subsequent development in this specimen is more typical of other representatives of the genus. Remarks: The used term "intercorallite wall" does not coincide with the definition of a corallite. According to Hill (1956: 247; in Moore R.C., Treatise on Invertebrate Paleontology, Part F) a corallite means "exoskeleton formed by an individual coral polyp". Therefore, it is proposed to use "corallite wall" only.</ABSTRACT>

64280 <TITLE>Mode of growth and life-history strategies of a late Ordovician halysitid coral.</TITLE>
64281 <SOURCE>Journal of Paleontology 65, 2: 191-199.
<http://www.jstor.org/pss/1305754></SOURCE>
64282 <ABSTRACT>The upper surface of the corallum of Catenipora rubra was often at or just above the sediment-water interface during life. The vertical growth rate was barely sufficient to keep pace with background sedimentation and possible subsidence of the corallum. Therefore, the colonies were in constant danger of being covered by influxes of sediment, especially during storms. This was compensated by the ability of polyps to respond to sedimentation events and by certain aspects of colony growth. Rapid regeneration following partial mortality involved budding of uninjured polyps and rejuvenation of damaged individuals, in some cases accompanied by a type of axial increase not previously known in tabulate corals. Rapid lateral expansion was possible because small, "immature" polyps could bud and grow in a reptant manner. Interconnected ranks of the cateniform corallum served to dam shifting sediment at the periphery of the colony. Lacunae within the colony were reservoirs for material that breached peripheral ranks and for sediment that settled on the ranks and was rejected by polyps or removed by passive flow. Polyps comprising the colony were distributed over a large area of the substrate surface, thereby decreasing the probability of complete mortality during sedimentation events and increasing the probability that a sufficient number of individuals would survive to ensure the optimum regeneration. The corallum, anchored in the

substrate and with sediment filling the lacunae, provided a broad, stable base during high-energy events. It remains to be established how widespread these growth patterns and strategies were among other corals with cateniform colonies, a form that appeared in many unrelated stocks. Most previous workers emphasized physical strength when considering functional morphology, following a tacit assumption that the corallum rose high above the substrate and was therefore susceptible to breakage during high-energy events. An understanding of the origin of cateniform patterns and the phylogeny of these corals requires knowledge of their modes of growth and life-history strategies, which were genetically as well as environmentally controlled.</ABSTRACT>

64293 <TITLE>Microborings and growth in Late Ordovician halysitids and other corals.</TITLE>

64294 <SOURCE>Journal of Paleontology 67, 6: 922-934.</SOURCE>

64295 <ABSTRACT>Microborings in the Late Ordovician tabulate corals *Catenipora rubra* (a halysitid) and *Manipora amicarum* (a cateniform nonhalysitid) and in an epizoid solitary rugose coral differ from nearly all of those previously reported in Paleozoic corals. These microborings were formed within the coralla by endolithic algae and fungi located beneath living polyps. Comparable structures in the Late Ordovician tabulate *Quepora lagglomeratiformis* (a halysitid) represent algal microborings, not spicules, and halysitids are corals, not sponges as suggested by Kazmierczak (1989). Endolithic algae in cateniform tabulates relied primarily on light entering through the outer walls of the ranks rather than through the polyps; lacunae within coralla permitted appropriate levels of light to reach many corallites. The direction of boring was determined by corallum microstructure and possibly also by the distribution of organic matter within the skeleton. There is an apparent inverse correlation between boring activity and coral growth rate. The location and relative abundance of pyritized microborings within calcareous coralla can be established quantitatively and objectively from electron microprobe determinations of weight percent sulfur along appropriate traverse of the coral skeleton. The distribution of such microborings in *Catenipora rubra* and *Manipora amicarum* is comparable to algal banding in modern corals; this is the first report of such banding in the interiors of Paleozoic corals. Change in the intensity of boring within each corallum was evidently a response to variation in the linear growth rate of the coral, or to fluctuation in an environmental factor (perhaps light intensity) that could control both algal activity and growth rate in these corals. Change in the algal boring intensity and linear growth rate of the coral was generally but not always seasonal and usually but not invariably associated with changes in the density of coral skeleton deposition. Cyclic bands of boring abundance maxima within fossil colonial corals provide a measure of annual linear growth comparable to the widely accepted method based on skeletal density bands. Algal bands are more sporadically developed than density bands within and among coralla, thus increasing in difficulty of interpretation. Fluctuations in the abundance of algal microborings apparently provide a detailed record of changes in the linear growth rate of colonies and individuals within colonies. Combined analyses of microboring abundance and skeletal density will contribute significantly to our understanding of

- the biological and environmental factors involved in endolithic activity and coral growth.</ABSTRACT>

- 64320 <SOURCE>Geology 23, 4: 305-308.</SOURCE>
- 64321 <ABSTRACT>The Ordovician radiation of marine life was among the most substantial pulses of diversification in Earth history and coincided in time with a major increase in the global level of orogenic activity. To investigate a possible causal link between these two patterns, the geographic distributions of 6576 individual appearances of Ordovician genera around the world were evaluated with respect to their proximity to probable centers of orogeny (foreland basins). Results indicate that these genera, which belonged to an array of higher taxa that diversified in the Middle and Late Ordovician (trilobites, brachiopods, bivalves, gastropods, monoplacophorans), were far more diverse in, and adjacent to, foreland basins than they were in areas farther removed from orogenic activity (carbonate platforms). This suggests an association of orogeny with diversification at that time.</ABSTRACT>

- 64333 <SOURCE>Journal of Paleontology 73, 1: 26-37.</SOURCE>
- 64334 <ABSTRACT>Sponges have an unrealized potential importance in biogeographic analysis. Biogeographic patterns determined from our analysis of all published data on distribution of Ordovician genera

indicate Early Ordovician sponge faunas have relatively low diversity and are completely dominated by demosponges. Early Ordovician (Ibexian) faunas are characterized by the widespread co-occurrence of Archaeoscyphia and the problematic Calathium. This association is commonly found in biohermal structures, Middle Ordovician faunas show an increase in diversity, and two broad associations are differentiated: Appalachian faunas (including Southern China and the Argentine Precordillera) and Great Basin faunas. Late Ordovician faunas show important changes in diversity and provincialism. Hexactinellid and calcareous sponges became important and new demosponge families appeared. Four Mohawkian-Cincinnatian associations are recognized here, including: 1) Mid-continent faunas; 2) Baltic faunas; 3) New South Wales faunas; and 4) western North American (California and Alaska) faunas. However, two separate biogeographic associations are differentiated based on faunal differences. These are a Pacific association (western North American and New South Wales) and an Atlantic association (Midcontinent Laurentia and Baltica). Distribution of sponge genera and migration patterns are utilized to consider paleogeographic dispositions of the different continental plates, climatic features, and oceanic currents. Such an analysis points to close paleogeographic affinities between the Argentine Precordillera and Laurentian Appalachian faunas. However, significant endemism and the occurrence of extra-Laurentian genera suggest a relative isolation of the Precordillera terrane during the Late Ibexian-whiterockian. The study also shows a faunal migration from the Appalachian region to South China during the Middle Ordovician and the migration of faunas from Baltica to Laurentia in the Late Ordovician. The occurrence of Laurentian migrants in New South Wales during the Late Ordovician could be related to inferred oceanic current circulation between these two areas, although other paleogeographic features may be involved.

64345 <TITLE>Patterns of Ordovician reef development.</TITLE>

64346 <SOURCE>SEPM Special Publications 72 (Phanerozoic Reef Patterns): 129-179.</SOURCE>

64347 <ABSTRACT>A review of factors that may have influenced the major changes in Ordovician reef development is presented against an earth-system background of profound global and biotal change that includes a greenhouse climate, a sluggish, saline oceanic state, high sea levels, progressive ventilation of surface waters, intense episodes of volcanicity and orogeny, massive diversification of biotas, and an apparently short, sharp, end-Ordovician glaciation with accompanying extinction. Major controls on reef growth are inferred to include: (1) under the existing high levels of atmospheric carbon dioxide of the Early Ordovician, higher-than-normal temperatures promoting microbial reefal communities and cyanobacterial calcification processes - high temperatures may have exceeded adaptive ranges of many metazoans (excepting sponges), delaying their proliferation as reef builders; (2) sea-level fluctuations and elevated sea-level highstands of the Early Ordovician caused episodic drowning and influx of anoxic waters from an expanded oxygen-minimum zone over platforms and archipelagos, limiting reefal diversification to more rudimentary phases involving mainly microbial growth; (3) lower sea-level highstands during the Middle Ordovician restricted flooding to outer shelves, and consequently reef

building occurred only in peripheral parts of platform areas, hence the lower abundances (only 18% of all preserved Ordovician reefs); (4) apparent rise in levels of oxygenation of tropical surface waters to a peak near the Middle-Late Ordovician boundary aided significantly the colonization of the reef habitat by sessile, respiring metazoans; and (5) elevated Late Ordovician sea-level highstands again causing episodic drowning over platforms, but this time influxes of oceanic waters had a limited, mainly regional, impact on reef development. Diversification and spread of reefs continued through the Ashgillian but, in the lead up to the end-Ordovician glaciation, late Ashgillian (Hirnantian) reefs developed in only a few sites, though they retained diverse biotas. [end-fragment of extensive summary] </ABSTRACT>

64384 <TITLE>Late Ordovician and Early Silurian rugose coral biogeography and world reconstruction of palaeocontinents.</TITLE>
64385 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 86: 3-21.</SOURCE>
64386 <ABSTRACT>Two epochs of Early Palaeozoic rugose coral diversification, Caradocian-Ashgillian and Middle Llandoveryian-Early Wenlockian, are chosen for biogeographical analysis at the generic level, following an overall revised classification of the Rugosa (Wang et al. 1989). World reconstruction maps are based on palaeomagnetic, palaeotectonic and palaeobiogeographic data, and were constructed through an autograph programme on an IBM PC-AT microcomputer. The Caradocian and Ashgillian rugose corals are in 16 families and 71 genera, including 15%

Cystiphyllida, 40% Streptelasmata and 44% Columnariida, in addition to the zaphrentoidid genus Protozaphrentis. Two biogeographical realms, the West Prototethyan and the East Prototethyan, may be discerned. The West Prototethyan Realm includes three provinces, the Siberian, the North American and the Kazakhstan-Hinganian. The East Prototethyan Realm also includes three provinces, the Southeast Asian (Yangtzean), the East Australian and the North European. The third area, the Gondwanan, is devoid of corals. In Middle and Late Llandoveryan and Early Wenlockian, the rugose corals have 27 families and 130 genera, of which 26% are Cystiphyllida, 32% are Streptelasmata and 41% are Columnariida, in addition to the zaphrentoidid genus Duncanella. The West Prototethyan Realm contains three provinces, the Siberia-Mongolian, the North European and the North American. The East Prototethyan Realm consists of two provinces, the Southeast Asian (Yangtzean) and the Kazakhstan-Sinokorean, both bearing Ceriaster and Amplexoides.

64436 <TITLE>Recovery of stromatoporoid fauna after the Late Ordovician extinction.</TITLE>
64437 <SOURCE>Bulletin of the Tohoku University Museum 1 [Proceedings of the 8th International Symposium on Fossil Cnidaria and Porifera]: 333-341.</SOURCE>
64438 <ABSTRACT>The Late Ordovician extinction of stromatoporoids was a gradual rather than an abrupt process of decrease in diversity through the Late Ordovician to Early Silurian transition. A transformation of a labechiid-dominated Ordovician stromatoporoid fauna into a clathrodictyid-dominated Early Silurian fauna embraced a wide time interval, from beginning of the late Caradoc to the end of the middle Llandovery (Aeronian). It roughly coincided with a supposed global cooling, or 'ice-house' period in Earth history. During this period the earliest labechiids with poorly calcified (probably aragonitic) skeletons were replaced by more advanced labechiids and clathrodictyids with well-calcified skeletons. The generic diversity of stromatoporoids reached its lowest value in the early Rhuddanian with representatives of only four genera, Clathrodictyon, Ecclimadictyon, Pachystylostroma and Forolina. During the late Rhuddanian and early Aeronian the earliest representatives of the families Actinostromatidae (Plectostroma) and Atelodictyidae (Intexodictyon) were added, respectively. Generic diversity abruptly increased in the late Aeronian (reaching at least 12 genera) when the first representatives of the Geronostromatidae (Petridiostroma), Pseudolabechiidae (Pachystroma), Stromatoporidae (Lineastroma) and Syringostromellidae (Syringostromella) appeared. During the Telychain the generic diversity of actinostromatids and stromatoporoids increased further and the first densastromatids (Densastroma) appeared. A comparatively long duration of Late Ordovician extinction and Early Silurian recovery of the stromatoporoid fauna is probably best explained by general global cooling, including several glacial episodes in addition to the well-known end-Ordovician (Hirnantian) ice age, unfavourable for stromatoporoids as thermophilic organisms.</ABSTRACT>

64462 <TITLE>Classification and controls of internal banding in Palaeozoic stromatoporoids and colonial corals.</TITLE>
64463 <SOURCE>Palaeontology 48, 3: 623-651.</SOURCE>
64464 <ABSTRACT>Palaeozoic corals and stromatoporoids exhibit a variety of internal banding phenomena, many of which have been commonly interpreted as annual growth bands. We evaluate bands through analysis of colonial corals and stromatoporoids from three stratigraphic intervals: Upper Ordovician of Manitoba, Canada, and Llandovery - Wenlock and Ludlow of Gotland, Sweden. Banding features are divided into four categories: (1) absence of banding; (2) density banding formed by variation in density or form of elements; (3) growth-interruptions banding including growth cessation and regeneration; and (4) postmortem banding caused by compaction or diagenesis. For discrimination of band types, it is essential to examine internal structures and skeletal margins in thin sections or acetate peels. Species vary considerably in degree and type of banding; each has a distinct pattern of variation. We propose criteria to determine if banding is consistent with seasonally induced growth variation: (1) consistency in band character and thickness; (2) continuity of skeletal growth; (3) marginal features; and (4) evidence of diagenetic alteration. Density bands in tabulate and rugose corals probably represent annual variations, but results for stromatoporoids are more ambiguous; although stromatoporoids commonly show banding, unequivocal density banding is poorly developed and growth interruption generated most stromatoporoid banding. Cerioid rugose and tabulate corals possess the thickest density bands; the thinnest bands are in stromatoporoids and heliolitid tabulates.</ABSTRACT>

64475 <TITLE>Patterns of variation in Late Ordovician and Early Silurian tabulate corals.</TITLE>
64476 <SOURCE>Boletín de la Real Sociedad Española de Historia Natural, Sección Geológica 91, 1/4: 193-204.</SOURCE>
64477 <ABSTRACT>A large data set on latest Ordovician and earliest Silurian tabulate corals from the East-central United States permits recognition and explanation of trends in intracolony and intraspecific variation. All common colonial coral species from this region were analyzed; these represent the orders Heliolitida, Halysitida, and Favositida. Comparison of patterns of intraspecific variation indicates that the inherent variabilities of the orders are different, and that certain types of variation tend to recur between species and orders. The variation pattern of each species was produced by the combination of structural and growth factors, working in concert with the coral's

response to a particular set of environmental conditions. The development of external growth form was affected by environmental factors such as sedimentation rate and substrate stability. Interlocality variation within some species indicates that internal morphology was also strongly linked to environment. Correlation of internal characters with paleoenvironment probably reflects the control exerted on their development by space constraints determined by external corallum form. Assessment of the control of variation by structural factors can permit a more valid definition of coral species.

64488 <TITLE>Structure of the corallite wall of the Upper Ordovician and Silurian Favositidae (Tabulata) and its possible use in stratigraphic correlation.</TITLE>

64489 <SOURCE>Palaeoworld 19, 3-4: 256-267.</SOURCE>

64490 <ABSTRACT>Based on an analysis of the significant collections of Favositidae (tabulate corals) from the Upper Ordovician-Lower Devonian of the Taimyr Peninsula, western slope of the North Urals and the Tchernychev Uplift, this paper focuses on the macro- and micro-structure of the corallite wall. Seven structural types of the corallite wall have been recognized; some of them seem to have a definite stratigraphic range. The results contribute to the long-time discussion on the applicability of skeletal structure for systematics of the Favositidae, its evolutionary implications, and stratigraphic correlation. It has been held that the skeletal structure of the fossilized remains of Favositidae is inapplicable for such purposes because diagenetically, it is secondary, being a product of mineral replacement of the primary structure. In contrast, an assumption is made here that the "secondary" skeletal macro- and micro-structure may reflect in some way the "primary" skeleton. As a result, it is proposed that some evidence of evolution of the Favositidae may be obtained by evaluating the stratigraphic range of favositid representatives possessing different types of structure of the corallite wall. 64579 <TITLE>Growth form in silurian heliolitid corals: the influence of genetics and environment.</TITLE>
64580 <SOURCE>Paleobiology 17, 4: 369-387. <http://www.jstor.org/pss/2400751>
</SOURCE>
64581 <ABSTRACT>Colony growth form in some Silurian heliolitid corals is analyzed by the measurement of their shape in profile. Data are presented for seven species, *Stelliporella parvistella*, *Heliolites interstinctus*, *H. megastoma*, *H. daintreei*, *H. spongodes*, *Propora tubulata*, and *Plasmopora scita* from three localities in Gotland, Sweden, and three localities in England. Intraspecific growth-form variation is presented on triangle diagrams. These plots allow variation to be compared between species present at each locality and between localities for each species. Results indicate that the overall potential for growth-form variation is genetically controlled and that levels of response to environmental stimuli may differ markedly between species. *Stelliporella parvistella* is a very plastic species, the only one developing branching growth in addition to other growth forms. *Heliolites interstinctus* is much less variable, dominantly tabular, domal, and low bulbous in form, but demonstrates a similar response. *Propora tubulata* has a tightly constrained bulbous growth form that shows little variation between localities. The other species are represented by few specimens, most of which parallel *H. interstinctus*. The likely moderating influences of light levels, substrate type, sedimentation rate, energy levels, and other variables on growth-form variation and species range are considered. The main environmental factor including ecophenotypic response is concluded to be sedimentation rate. A close correlation between this factor and growth form in *S. parvistella* indicates that form in this species is a particularly sensitive indicator of sedimentation rate and substrate conditions. No simple equations can be made between specific environments and one particular growth form in these corals. [original abstract]</ABSTRACT>

64592 <TITLE>A symbiotic relationship between Lingula and the coral Heliolites in the silurian.</TITLE>
64593 <SOURCE>Trace fossils [T.P. Crimes & I.C. Harper (eds)]: 335-343; Liverpool.</SOURCE>
64594 <ABSTRACT>Many specimens of Heliolites interstinctus from the Aymestry Limestone (Ludlovian) of the Welsh Borderlands contain borings: the most commonly associated coral, Favosites gothlandicus, does not. The only fossil preserved intact in the now sediment filled borings is Lingula sp., which occurs in life position in some 28 borings. It is concluded that in some cases the corals were still alive when the borings were occupied. It is inferred that Lingula was unlikely to have made the borings and from the morphology of the borings themselves, annelids, bivalves or cirripeds were the most likely borers. It is concluded that Lingula occupied preformed sediment filled borings, in some cases living symbiotically with the live Heliolites. It is suggested that the structure of Heliolites was less resistant to boring attack than that of Favosites. [original abstract.]</ABSTRACT>

64646 <ABSTRACT>A description is given on the topotypical material of
Anisophyllum agassizi E. & H., 1850, from Upper Silurian deposits
(Brownsport formation) of North America. Primary investigations on the
inner structure and the trabecular microstructure of the septa, based
on thin sections and peels, show that the genus Anisophyllum belongs to
the family Plerophyllidae. The genus Anisophyllum is revised.

64657 <TITLE>Regular and flexible modes of division and hystero-ontogenetic
growth in the Silurian rugose coral Stauria favosa.</TITLE>
64658 <SOURCE>Palaeontology 47, 5: 1075-1091.</SOURCE>
64659 <ABSTRACT>New modules arise in colonial corals as the result of asexual
reproduction. The Silurian rugosan Stauria favosa ordinarily exhibits
cerioid coralla with a characteristic cross-shaped axial structure and a
typical pattern of parricidal increase. Quadripartite increase at the
sites of the four protosepta is most common, whereas cases of tripartite
increase are rare. Parental protosepta are transformed into dividing
walls, where the four protosepta first appear with a definitive
polarity in offset corallites. Daughter corallites inherit metasepta as
metasepta, and catasepta as catasepta, within the same quadrants as
those of the parents. Metasepta are inserted serially, following Kunth
's rule, as is characteristic of rugosan protoallites. As each
daughter corallite derived immediately from the same parent is arranged
with identical polarity, it grows equally and evenly both individually
and as a group. Daughters thus form protosepta and metasepta under
strict phylogenetic and developmental constraints. However, individual
corallites grow and reproduce autonomously, by using all
available skeleton and space of the parent. Although each module cannot
modify essential modes of division, flexibility of the system was via
changes in the density and arrangement of corallites, and
regulating modes of growth, in tandem with adjacent corallites within
the corallum. It is probable that regularity, due to constraints of

several origins, as well as flexibility are typical of other rugosan colonies and played an important role in growth dynamics between corallites and corallum.

64683 <TITLE>Ecophenotypic variation in the early silurian rugose coral Palaeocyclus porpita.</TITLE>
64684 <SOURCE>Proceedings of the Yorkshire Geological Society 05, 1: 1-8.</SOURCE>
64685 <ABSTRACT>Palaeocyclus porpita (Linnaeus) is a highly distinctive and biostratigraphically important early Silurian rugose coral, widespread in north-west Europe and with scattered records in North America. In eastern North America, Palaeocyclus rotuloides (Hall) occupies a similar biostratigraphical position, but differs from P. porpita in possessing a thin or imperfectly developed epitheca with septal ridges or exposed septal plates and a distinct profile to the undersurface. The calicular surfaces of P. rotuloides and P. porpita are essentially indistinguishable. The relationship between P. porpita and P. rotuloides is resolved by material from the Coralliferous Group of Dyfed, south-west Wales. Collections from siliciclastic horizons have P. porpita type epitheca, whereas material from thin bioclastic limestone beds has P. rotuloides type epitheca. P. rotuloides from eastern North America also appears to be associated with thin bioclastic limestones. It is suggested that these two forms were ecomorphs of the same species, P. porpita, in which epithecal development was influenced by the character of the substrate. The stratigraphical and palaeoecological distribution of the species is briefly reviewed.</ABSTRACT>

</TITLE>
64697 <SOURCE>GFF 115, 2: 119-143.</SOURCE>
64698 <ABSTRACT>The taxonomic relationship between all operculate genera of rugose corals is thoroughly discussed. The family Goniophyllidae includes the subfamilies Araeopomatinae and Goniophyllinae. Araeopomatinae is characterized by having only one type of opercular septa and includes Araeopoma and Rhytidophyllum. Calceola, Goniophyllum and Rhytidophyllum with two types of opercular septa are brought to the subfamily Goniophyllinae. The morphology, ontogeny and taxonomy of the species of Goniophyllum from Upper Llandovery and Wenlock are described and illustrated. The ontogeny of this genus is represented by an early calceoloid and a late pyramidal stage. Goniophyllum pyramidale is separated into two subspecies, viz. G. pyramidale pyramidale and G. pyramidale primigena. The septal microstructure in Goniophyllum is multitrabecular.</ABSTRACT>

64710 <SOURCE>GFF 117: 31-41.</SOURCE>
64711 <ABSTRACT>The operculate rugose coral genera Araeopoma Lindstroem and Rhytidophyllum Lindstroem, represented in Silurian sequences on Gotland, are here revised and redescribed. These genera belong to the subfamily Araeopomatinae which is characterized by undifferentiated opercular septa. The affinities between Araeopoma and other operculate genera including Goniophyllum is discussed. The species treated in this paper are Araeopoma prismaticum (type species), Araeopoma elongatum and Rhytidophyllum pusillum, all of which appear to be endemic on Gotland. Araeopoma has a rhabdacanthine septal microstructure, while that of Rhytidophyllum is unknown.</ABSTRACT>

64802 <ABSTRACT>Interactions between stromatoporoids and syringoporines, rugose corals and trepostomes are described. It is demonstrated that the stromatoporoid-syringoporine intergrowth cannot be interpreted as commensalism. The stromatoporoid-rugose coral intergrowth is interpreted as neutralism, whereas space competition is demonstrated in the stromatoporoid-trepostome intergrowth. Six types of borings were found in Silurian stromatoporoids from Gotland; three could be ascribed to bivalve borings, the other three to worms. [original summary]

64826 <TITLE>Autecology of Stromatoporoids in Silurian cratonic seas.</TITLE>
64827 <SOURCE>Spec. Pap. Palaeont. 32: 265-280.</SOURCE>
64828 <ABSTRACT>Stromatoporoids are fossils of problematical affinity that were probably colonial, benthic sessile, or liberossessile marine organisms with a basal ectodermal skeleton. They were most common on carbonate shelves bordering peneplaned continents in low palaeolatitudes. They were rare in shelve seas with a high influx of coarse elastics. Stromatoporoids were absent from seas of the Malvinokaffric Realm and late Silurian evaporitic epicontinental basins (Michigan basin, Tunguska basin). High-energy carbonate shoal environments were optimal for Stromatoporoids, and there they often

formed parts of organic buildups (bioherms, biostromes, banks). Their role in reef building increased during the Silurian. Near-shore low-energy environments (lagoons, mud flats, restricted shelf) were less favourable for Stromatoporoids, especially when their hydrochemical regime declined from normal marine. Stromatoporoids were typical of low-energy open shelf environment, but their taxonomic diversity and frequency decreased offshore. They lived in normal marine conditions in warm water, at depth up to 70 m. They preferred agitated water and a hard or semi-soft, stable bottom. Ecological differentiation of Silurian stromatoporoid faunas was quite low.

64840 <SOURCE>Journal of Paleontology 72: 190-201.</SOURCE>

64841 <ABSTRACT>Two new genera of Upper Silurian stromatoporoids in order Actinostromatida are described. Genus Bicolumnostratum Stock, with type species, *B. micum* (Bogoyavlenskaya), is characterized by two kinds of pillars and nonaligned colliculi, and is assigned to the family Actinostromatidae. Genus Acosmostroma Stock, with type species *A. ataxium* Stock n.sp., contains irregular micropillars and microcolliculi, and is assigned to the family Densastromatidae. Two additional new species are *Acosmostroma glascoense* Stock and *A. ? cobleskillense* Stock. A fourth species is *A. tenuissimum* (Parks). *Bicolumnostratum* is known from Ludlow- and Pridoli-age strata, whereas the occurrences of *Acosmostroma* are strictly Pridoli in age.</ABSTRACT>

64852 <TITLE>Main trends in stromatoporoid evolution during the Silurian.</TITLE>

64853 <SOURCE>Courier Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, vol. 2]: 329-339.</SOURCE>

64854 <ABSTRACT>The Silurian was a period of the most intensive diversification of the Palaeozoic stromatoporoid fauna. By the end of this period all the main phylogenetic branches of the Palaeozoic Stromatoporoids were formed. Half of the orders (Stromatoporellida, Actinostromatida, Stromatoporida) and most of the families originated in the Silurian. The most rapid expansion in diversity took place in Wenlock time. Progressive folding of the basal surface of the soft body, increasing the skeleton secreting ability of the basal pinacoderm, was the most general tendency in stromatoporoid evolution. The role of Labechiids decreased and that of Clathrodictyids increased rapidly. Stromatoporoids with regular continuous laminae (order Stromatoporellida), with a loose skeleton lattice (order Actinostromatida) and irregularly amalgamated structure (order

- Stromatoporida) appeared in the early Silurian. Parallel evolution of Stromatoporoids with different kinds of microreticulate microstructure (ortho-, clino- and akosmoreticulate) was characteristic of the Silurian.

64865 <TITLE>Morphology of the Silurian Demosponges Desmidopora Nicholson and Nodulipora Lindstrom: affinities of Favositids.</TITLE>
64866 <SOURCE>Munster. Forsch. Geol. Palaont. 52 [Kl. Oekentorp (ed.): A. von Schoupe jubilee commemorative volume]: ... pp ... </SOURCE>
64867 <ABSTRACT>Skeletal morphology and its variation are described in Desmidopora alveolaris Nicholson and in Nodulipora acuminata Lindstrom. The features of these Silurian fossils suggest sclerosponge affinities. Pores are present in both species and the surface of Nodulipora carries astrorhizae. A comparison is made between skeletons of sclerosponges and tabulates: favositids are interpreted as the basal skeletons of demosponges.</ABSTRACT>

64956 <TITLE>Variation in the Silurian tabulate coral Paleofavosites, and the status of Mesofavosites.</TITLE>
64957 <SOURCE>Palaeontology 21, 2: 307-319.</SOURCE>
64958 <ABSTRACT>Paleofavosites asper (d'Orbigny) is redescribed on the basis of the holotype and additional material from its type area of the Welsh Borderland. The species shows considerable variation, particularly in the form and location of intercorallite pores, from colonies with pores, including a high proportion of solenia, almost exclusively located in corallite angles to those with up to 40% of pores within corallite walls. This species, the type species of Paleofavosites Twenhofel 1914, includes variants with the structural features considered characteristic of Mesofavosites Sokolov 1951. We, therefore, regard Mesofavosites as a junior subjective synonym of Paleofavosites. [original summary]</ABSTRACT>

64969 <TITLE>Palaeoecology and taxonomy of some Wenlock tabulate corals and stromatoporoids.</TITLE>
64970 <SOURCE>Leeds Inst. of Geol. Sciences, unpublished Ph.D. thesis.</SOURCE>
64971 <ABSTRACT>The stratigraphy of the Wenlock Series of the Welsh Borderlands is briefly reviewed and the application of the standard East European coral biozones discussed. * The taxonomy of some Wenlock tabulate and heliolitid corals from the Welsh Borderlands and South Wales is revised. The taxa comprise 13 genera and 28 species including new species of Favosites (2), Thamnopora (1), and Halysites (1), as well as species of Paleofavosites, Thecia, Angopora, Coenites, Cladopora, Alveolites, Cystihalysites, Heliolites, Plasmopora, and Propora. Observations are made on the concepts of some genera particularly Paleofavosites, Angopora and Halysites. Some Wenlock stromatoporoids are briefly described along with commensal associations of Diplostroma yayorski and calcareous algae, Cornulites and heliolitids, and chimney shaped burrows in Thecia. * Periodic zones of skeletal thickening in favositids are shown to be related to levels of

increase in colonies, and the seasonal nature of periodic thickening is discussed. Serial sections of Favosites have revealed pits at three corallite junctions and confirm lateral increase in favositids. Wall structure and septal spine development in the Halysitidae is revised and their taxonomic significance outlined. * Poorly defined tabulate - heliolitid coral associations have been established in the reef and inter-reef facies of the Much Wenlock Limestone. The associations are related to phases of reef development and location on or off-reef. Growth rates and longevity in favositids are comparable with Scleractinian corals. * Analysis of reefs within the sequentially developed (inter-reef) facies of the Much Wenlock Limestone of Wenlock Edge has shown that the reefs of the stratigraphically lower, clay-rich facies are dominated by heliolitids, whereas the reefs of the uppermost grainstone facies show a decrease in heliolitids with a marked increase in favositids and stromatoporoids. This pattern is attributed to a gradual shallowing through the deposition of the Limestone, but with only the uppermost facies deposited within wave base. * Regional faunal - facies variations in the Wenlock of the Welsh Borderlands and South Wales indicate a high diversity focus in the Wenlock-Dudley area with a decreasing diversity gradient towards deeper water and non-reef facies. Local variations are apparent, such as the bryozoa dominated reef at Usk. Comparison of Wenlock coral faunas between the Welsh Borderlands and the Baltic province indicates few palaeogeographical links between these areas.</ABSTRACT>

65021 <TITLE>Silurian reef episodes, changing seascapes and paleobiogeography.</TITLE>
65022 <SOURCE>In: Landing E. and Johnson M. E. (eds): Silurian Cycles [James Hall Centennial Volume]. New York State Museum Bulletin 491: 265-282.</SOURCE>
65023 <ABSTRACT>Eight global Silurian reef-building episodes coincide with climatic and oceanic conditions characterized by inferred warmer, high-latitude climates; salinity-dense bottom waters; and accompanying low diversity, planktic and nektonic faunas. Periodic removal of reef and bottom-level community habitats by tectophases and relative sea-level falls appears to have stimulated reorganization and evolution of invertebrate communities during subsequent transgressive intervals. Latest Ordovician and early-middle Llandovery metazoans-parazoans gradually reestablished shallow- and deeper-water reef ecosystems. Evolutionary radiations of coral and stromatoporoid faunas are evident in the upper Llandovery and lower Wenlock. Although corals and stromatoporoids reached their Silurian acmes in the Wenlock, stromatoporoids maintained similar diversities in the Ludlow. Numerous coral species disappeared by the early Ludlow, in part coinciding with the end-Wenlock extinctions of different planktic and benthic faunas. Calcimicrobial communities and calcareous algae were important constructors in many early-middle Llandovery reefs, are less conspicuous in many late Llandovery-early Wenlock reefs, and were volumetrically important reef constructors in many Late Silurian reefs. Morphological innovations of selected Ludlow benthos and associated lithofacies show a "Devonian carbonate bank archetype", with distinguishable forereef, reef, backreef, and lagoonal facies. Partially reef-rimmed, late Ludlow, distally-steepened, carbonate banks reflect a change in reef patterns from the patchiness that characterized most Early Silurian flat-topped carbonate bank seascapes. Wenlock and late Ludlow reef tracts were larger in areal extent than modern reef tracts and were concentrated in subtropical and equatorial climatic belts [See also: Brunton F. R., Copper P. & Dixon O. A., 1997, Silurian reef-building episodes. Proceedings 8th International Coral Reef Symposium 2: 1643-1650].</ABSTRACT>

65034 <TITLE>James Hall and Fossil Corals.</TITLE>
65035 <SOURCE>Earth Sci. History 6, 1: 99-105</SOURCE>
65036 <ABSTRACT>During his long career, James Hall named and described over 250 species and several genera of fossil corals, mostly of Middle Silurian to Middle Devonian age. Hall's principal coral works were published in 1843, 1877, 1882-84, and (with G. B. Simpson) 1887. Sporadic work on corals continued to 1898, the year of his death. In spite of shortcomings, his four main contributions provided the taxonomic base for much of the later work on Helderberg, Onondaga and Hamilton corals in New York and adjacent areas. Beginning in 1868, George B. Simpson was one of Hall's many assistants. He began as illustrator, became a describer of corals and bryozoans, and ultimately co-author of the 1887 work. His own study of Paleozoic coral genera, based on thin section analyses, began the post-Hall era of coral work in eastern North America.</ABSTRACT>

65047 <TITLE>Das Rugosa-Genus *Duncanella* Nicholson 1874 (Anthozoa, Silur-Devon).</TITLE>
65048 <SOURCE>Abhandlungen und Berichte für Naturkunde und Vorgeschichte 12, 5: 29-52.</SOURCE>
65049 <ABSTRACT>Studies on the morphology of the type species *Duncanella borealis* Nicholson 1874, from the Waldron shale (upper Wenlockian) of Waldron (Indiana), result in a redefinition of the genus, which is classified because of its aulos as a member of Laccophyllinae, with probable synonym *Petronella* Birenheide 1965. Distribution of *Duncanella* reaches from lower Wenlockian to upper Eifelian throughout Europe, Asia, and North America. Additionally described species are *Duncanella*? n.sp. A from the Kitaigorod horizon (early Wenlockian) of Podolia, and *Duncanella* n.sp. B from the Haragan formation (Lochkovian) of Oklahoma. *Duncanella borealis* occurs in Wenlock limestones/shales near Dudley (England). * Missing apical wall structures in *Duncanella* and some few similar genera (of Laccophyllidae, Hapsiphyllidae, Plerophyllidae, Polycoeliidae) may be explained by a special mode of asexual reproduction, well known from several Scleractinian corals as gemmation by transverse fission. Comparative materials of European Miocene *Kionotrochus* (*Cylindrophyllia*) Yabe & Eguchi 1937 are figured, with signs of transverse fission. There was no proof for the adradosiid growth model proposed by Plusquellec (1981). Records of a wall-free apex run from Lower Silurian to Upper Permian (Wenlockian-Dzhulfian). The curious feature obviously is of no taxonomic use at the generic level, and some taxa perhaps might become synonyms of identical parallel genera provided with normally developed archaeothecate corallum tips (*Gymnaxon* Birenheide & Soto 1977 = *Laccophyllum* Simpson 1900; *Hapsizaphrentis* Kong 1981 = *Adradosia* Birenheide & Soto 1977; *Barbarella* Flügel 1972 = *Pentaphyllum* de Koninck 1872; *Groenlandophyllum* Flügel 1973 = *Calophyllum* Dana 1846). 65061 <SOURCE>Mitteilungen des Museum für Naturkunde Berlin, Geowissenschaftliche Reihe, 4: 71-82. </SOURCE>
65062 <ABSTRACT>The new taxon, one of the most ancient members of the ahermatypic suborder Cyathaxoniina, includes the type species Muenstraia franconica n.sp. (Ludlovian, Elbersreuth, Orthoceratites Limestone Formation, Upper Franconia, Germany) and three further species: Muenstraia squarrosa (Sutherland 1965) (lower Ludlovian, Henryhouse Formation, Oklahoma, USA), Muenstraia sp. (upper Lochkovian, Yukon Territories, Canada), Muenstraia thuringica n.sp. (middle/upper Pragian, Tentaculitid Limestone Formation, Thuringian Mountains, Germany, and middle Pragian, Tafilalet, Morocco). The genus descends from the isolated Upper Middle Ordovician Protozaphrentis Yu 1957, only known from Xinjiang in China; it is the ancestor of two new phylogenetic lines starting in the Ludlovian with Laccophyllum Simpson 1900 and Sutherlandia Weyer 1972. </ABSTRACT>

65073 <TITLE>Das silurisch-devonische Rugosa-Genus Petraia Muenster 1839. </TITLE>
65074 <SOURCE>Freiberger Forsch.-Hft C357: 25-42. </SOURCE>
65075 <ABSTRACT>Morphology and systematic position of Petraia Muenster 1839 are unknown, not one of the five genosyntypes being sufficiently studied for generic determination. The revision proposed by Schindewolf in 1931 must be rejected because of serious errors concerning morphological observation and nomenclature. * The type species Petraia decussata Muenster 1839 is probably of Upper Devonian rather than of Upper Silurian age. A series of 14 syntypes (Berlin museum) has been found in Famennian clymenioid limestones at the locality Schubelhammer. Up to a future revision based on a lectotype to be selected and perhaps offering basic taxonomical alterations, the best way will be to retain the traditional idea of Petraia in the sense of Schindewolf, using one of his specimens (1931, text-figs. 5-9) as a provisional standard. * The coral fauna of the Upper Silurian "orthoceratite limestone" at the locality Elbersreuth includes species of several genera: Palaeocyathus Foerste 1888, Petraia Muenster 1839 (sensu Schindewolf 1931), Sutherlandia Weyer 1972, Laccophyllum Simpson 1900. The lectotype of Petraia radiata Muenster 1839, used by Schindewolf to define the genus Petraia, is a coral without contrasting minor septa, most probably belonging to Palaeocyathus. 65087 <SOURCE>C. R. Acad. Sci., Paris 96: 1749-1752.</SOURCE>
65088 <ABSTRACT>Le sclerenchyme de Goniophyllum, est compose de microlamelles cupulaires du type connu chez les Celenteres paleozoiques. Les microlamelles de Calceola sont plus minces, plus larges et presentent parfois une morphologie "en tenaille". II est propose de considerer Calceola comme un genre incertae sedis, rattache toutefois a la famille des Goniophyllidae. The sclerenchyme of Goniophyllum is made of cupular microlamellae, of the kind encountered in Paleozoic corals. The microlamellae of Calceola are thinner, broader and sometimes exhibit a pincers-shape morphology. It is proposed that Calceola be considered as a genus incertae sedis, which nevertheless bears some resemblance with the Goniophyllidae family.</ABSTRACT>

65100 <SOURCE>Senckenbergiana lethaea 54, 5/6: 453-473.</SOURCE>
65101 <ABSTRACT>Examples of the Silurian Cystiphyllinae Araeopoma and Hedstroemophyllum as well as of the Goniophyllinae Goniophyllum and Calceola demonstrate that the minor septa between the counter septum and its neighbouring major septa are absent. This peculiarity probably also occurs in Cystiphyllum and Rhizophyllum. Together with the similar architecture shown in longitudinal sections this character reveals strong relations between all these genera and the Devonian Digonophyllinae (= Plasmophyllinae sensu Birenheide 1964). The systematics of the "Cystimorpha", outlined in Birenheide 1964, are completed. By subsequent designation (Stumm 1949: 44) the lectotype of Mesophyllum defectum is the colony figured in Goldfuss 1826: pl. 17 fig. 5e, being at the same time the lectotype of Cyathophyllum vesiculosum Goldfuss 1826. The subsequent change of the lectotype by Tsien 1970 is invalid.</ABSTRACT>

65112 <TITLE>Stauromatidium and Stauromatidiidae, new genus and family of Upper Silurian and Lower Devonian rugose corals.</TITLE>
65113 <SOURCE>Bulletin geol. Surv. Can. 352; 43 pp.</SOURCE>
65114 <ABSTRACT>The Stauromatidiidae [fam.nov.] include seven named and at least two unnamed species assigned to two genera, Stauromatidium [gen.nov.] and Farabophyllum. In earlier works, species of the family

were referred, either firmly or tentatively, to no less than nine genera, representing seven families. Although stauromatidiid species range from upper Ludlow or early Pridolian to late Dalejan or early Eifelian and are found in both the Eastern Americas and Old world Devonian faunal realms, the family, on the whole, is rare and as currently known is confined to just four of twelve Early Devonian coral provinces. The stauromatidiidae probably evolved from the Tryplasmataceae and possibly gave rise to the Stringophyllidae. New species are *S. strigosum* from the upper Ludlow or early Pridolian part of the Road River Formation, Yukon Territory; *S. sentum* from the Pragian part of the same formation and region; and *S. montjolicum* from the Lochkovian Mont Joli Formation, Quebec. </ABSTRACT>

65151 <TITLE>Orientation of corals and stromatoporoids in some Pleistocene, Devonian, and silurian reef facies.</TITLE>
65152 <SOURCE>Journal of Paleontology 60, 6: 1147-1158.</SOURCE>
65153 <ABSTRACT>A quantitative study was made of the orientation of corals and stromatoporoids in reef core, flank, and interreef rocks representig three geological periods at eight sites, including the Florida Keys (Pleistocene), Ridgemount, Ontario (Devonian), and Pekin,

New York, Maumee and Rockford, Ohio, and Bluffton and Delphi, Indiana (Silurian). Orientation, width, and height were measured for each fossil as seen in outcrop. Fossils in Pleistocene and Silurian reef core facies have pronounced upward orientation, suggesting that most fossils are in growth location, or that the reefs were moved to their present location without appreciable tilting. Silurian distal flank facies have approximately random coral orientations with some upward bias. Coral width is greater than or equal to coral height (on outcrop) for 79% of the corals at all flank sites, and for 80% of the corals at the interreef site, an indicator of transport when taken with orientation data. This study permits reef facies differentiation and illustrates that fossil orientation is a useful technique for studying reefs.</ABSTRACT>

65165 <SOURCE>Boletin de la Real Sociedad Espanola de Historia Natural, Seccion Geologica 92, 1/4: 187-195.</SOURCE>
65166 <ABSTRACT>The "Cyathaxonia faunas" consist in general of small solitary corals without dissepiments; they have a small number of septa and tabulae. They belong mainly to the suborders Metriophyllina, Plerophyllina and Stereolasmatina and are widespread from Silurian up to late Permian times. The "Cyathaxonia faunas" settled exclusively in non-reef environments and are frequently associated with ammonoids. The ecological range comprises mainly basinal facies in moderately deep to shallow environments with poorly circulating waters.</ABSTRACT>

65218 <ABSTRACT>The reconstruction of the distal cone in the Famennian heterocoral Oligophylloides pachytheucus Rozkowska from the Holy Cross Mts., Poland, is based on the widely accepted assumption that heterothecae increase in thickness by successive overgrowth of the conical tabulae. The calculations based on 50 corallites with 39 thin sections prove apical angles from 1 to 7, commonly 1.5 to 2.5 degrees; the calculated height of the distal cone varies from 4 to almost 200mm. Preliminary calculations for the Carboniferous genera Heterophyllia and Hexaphyllia prove similar values of apical angles; on the other hand in Longlinophyllia Lin & Wu this angle attains 40°.</ABSTRACT>

65229 <TITLE>Symbioses of Devonian rugose corals.</TITLE>
65230 <SOURCE>Memoirs Association Australasian Palaeontologists 01 [J. Roberts & P.A. Jell (eds): Dorothy Hill Jubilee Memoir]: 261-274.</SOURCE>
65231 <ABSTRACT>Calcareous tubes, apparently the dwelling places of commensal

or parasitic animals ('worms') have been described from fossil and living corals, where they tend to occur in the wall separating adjacent corallites or on the outer sides of the coralla. Here, tubes are reported centrally located within the skeletons and parallel to the axes of individual corals. These tubes were apparently deposited by the coral polyps to protect themselves from a parasitic wormlike animal. The tubes open into the calice of the coral in such a way as to indicate that the parasite prob-ably projected through the basal disc and into the polyp's gastric cavity, where presumably it fed upon organic matter taken in or discarded by the polyp. A long vermiform groove on the theca of a solitary coral is interpreted as the dwelling place of a tube worm, possibly a polychaete, by analogy with living examples. Other known examples of metazoan/ rugose coral symbioses are briefly reviewed.</ABSTRACT>

 65243 <SOURCE>Current Research A, Geological Survey of Canada 84-1A: 449-452.</SOURCE>
 65244 <ABSTRACT>Although corals have negligible value in worldwide or intercontinental correlation, they have been successfully used for correlation within basins or biogeographic provinces. The factors responsible for their limited value in correlation make them excellent indices of environment and provinciality. Analyses of the distribution of over 300 genera of Devonian rugose corals in 20 regions of the world and in six stages shows a maximum of endemicy and provinciality in the late Early Devonian. Because of this, corals are of least value in Devonian correlations near the Lower-Middle boundary. They are more useful in the Lochkovian, Givetian and Frasnian than in the intervening Pragian to Couvinian stages.</ABSTRACT>

- 65295 <SOURCE>Acta Palaeontologica Sinica 40, 1: 44-50.</SOURCE>
- 65296 <ABSTRACT>In this paper the morphology, ontogenesis and systematic description of the genus Hebukophyllum Liao and Cai, 1987 are reviewed and compared with those of its related genera Circellia Ye and Wang, 1983, Conilophyllum Poty and Boland, 1996 and Siphonophyllia Scouler MS in McCoy, 1844. In the youngest stages, axial ends of the major septa in the specimens of Hebukophyllum are united each other to form an aulos, which is never present in the related genera. For this reason, Hebukophyllum is certainly assigned to the Family Laccophyllidae Grabau, 1928. Conilophyllum and Siphonophyllia seem to show typical characters of caninoid rugose corals; and Circellia, in consequence of their rudimentary or degenerated septa along the ontogeny, could be assigned to the family Amplexidae Chapman, 1893.</ABSTRACT>

- 65308 <SOURCE>Acta Palaeontologica Polonica 47, 2: 397-404.</SOURCE>
- 65309 <ABSTRACT>Literature data indicate above average diversity of the Cyathaxonia fauna in the Devonian period, both in absolute numbers of (sub)families and genera per age and also with respect to taxonomic

diversities as calculated per Ma (106 years). The Emsian and Famennian faunas, although represented by most numerous (sub)families and genera have less than average diversities, due to their more than average durations, whereas the shorter intervals of the Pragian and Givetian have the highest values for diversity per Ma, and the Frasnian faunas the lowest diversities, for both (sub)families and genera. The post-Givetian crisis may have been responsible for the Frasnian minimum, although limited temporal resolution of the analysis does not allow for a more precise description of the Givetian/Frasnian transition. However, "silent taxa" are extremely numerous in the Frasnian, i.e. taxa which are present both prior to and after the Frasnian, but missing from the Frasnian record itself indicating that the Famennian Cyathaxonia fauna contains significant numbers of Lazarus and/or Elvis taxa.</ABSTRACT>

65322 <ABSTRACT>Development in this genus is distinct from most rugosans (adradosid). During an apical stage, the protosepta and several metasepta are inserted with typical rugosan pattern whilst the skeleton is completely enveloped in soft tissue. In a post-apical stage, septal insertion continues but the edge zone of the polyp withdraws to the calicular margin to deposit an epitheca.</ABSTRACT>

65346 <TITLE>A revision of the Devonian rugosan phillipsastreid genus Smithicyathus.</TITLE>
65347 <SOURCE>Acta Palaeontologica Polonica 52, 3: 609-632.www.a
pp.pan.pl/article/item/app52-609.html</SOURCE>
65348 <ABSTRACT>The rugose coral genus Smithicyathus is diagnosed in this paper as massive to phaceloid phillipsastreid, with common horseshoe

dissepiments and major septa that are very short in the tabularium. Revised taxonomy of this genus is based on analysis of over 20 numerical characters measured in sections and/or extracted from the literature data. Species are distinguished either by morphometric non-overlap in at least one, key feature or by geographic-stratigraphic isolation. The earliest possible representatives of the genus are known from the Eifelian of Angara (*S. ? emendatus* and *S. ? russakovi*). In the Upper Frasnian *Smithicyathus* is represented by seven species; in western Euramerica occur *S. cinctus* and *S. mcleani* sp.nov.; south-eastern Euramerican shelf area is with *S. lacunosus*, *S. cf. lacunosus*, *S. smithi*, *S. cf. smithi*, and *S. lubliniensis*, one probable species is recorded in Angara: *S. ? belkovskiense*. The genus did not survive the Frasnian-Famennian crisis. *Smithicyathus* lived in tropical and sub-tropical shallow-marine carbonate environments, with the possible exception of the northern mid-latitudes species from Siberia. In the Holy Cross Mountains, *S. lacunosus* and *S. smithi* show a preference for restricted-marine facies. They may make up over 90% of all rugosan colonies collected in such locations, whereas in the more open-marine settings they are rare both in numbers and in proportion to other rugosan species.

65372 <TITLE>Rugose coral distribution as a test of Devonian palaeogeographic models.</TITLE>
65373 <SOURCE>Geological Society Memoir 12 [McKerrow W. S. & Scotese C. R. (eds): Palaeozoic palaeogeography and biogeography]: 267-275.</SOURCE>
65374 <ABSTRACT>A data bank, based on stage by stage distributions of 420 rugose coral genera in 25 regions of the world is analysed, mostly by means of Otsuka coefficients, to test an Emsian reconstruction of the world proposed by Scotese. Devonian rugose corals inhabited a narrower range of facies than some other benthic groups, and even without regard to facies, provide a tool for testing geographic reconstructions. Basin dwelling coral genera typically have longer temporal and broader geographic ranges than corals living in shallower environments, and are less suitable for palaeogeographic studies. They are treated separately in this work. For the most part, conclusions drawn from the analysis are either consistent with, or positively supportive of, the Scotese reconstruction. However, large but poorly known rugose coral faunas

from Mongolia and the Amur Basin are at about 60° N in the reconstruction, and other well known coral faunas, from Altai-Sayan, are at 45-50° N. In the light of known distributions of both modern corals and Devonian southern hemisphere corals, in all recently proposed palaeogeographic reconstructions, it is questionable that the original latitude of any large northern hemisphere Devonian coral fauna would have exceeded 45.</ABSTRACT>

65385 <TITLE>The Devonian Rugose Coral Genus *Tabulophyllum* Fenton and Fenton 1924.</TITLE>

65386 <SOURCE>Dept. of Geol. Sci., S.U.N.Y., 397-412.</SOURCE>

65387 <ABSTRACT>The predominantly Middle Devonian and Frasnian coral genus *Tabulophyllum* is highly characteristic of the cosmopolitan faunas of the latter part of the Devonian System and approximately 99 species have been described from all major areas of marine Devonian outcrop. At least 20 of these are wrongly assigned and should be placed in Carboniferous or other Devonian genera, and in addition the status of some of the remainder must be regarded as possible synonyms due to the highly variable nature of those species that are thoroughly known. In this study all post-Frasnian corals are excluded from the genus, with the questionable exception of one species from Czechoslovakia. * The genus has a characteristic diagenetic lamellar wall structure in thin-section; its septal structure is of very fine monacanthine trabeculae and fibro-normal flanks in well preserved specimens. Long, complete tabulae are typically marked by peripheral gutters, gracefully downcurved (as seen in longitudinal section), while the characteristic lonsdaleoid dissepimentarium is marked by large presepiments which interrupt the septa in peripheral areas. Some Frasnian species show the development of large individuals with a cardinal fossula and marked bilaterality. This is most marked in species of the latest Frasnian, preceeding the Frasnian-Famennian extinction event. Adaptation to substrate played an important role in the success of *Tabulophyllum* species. Those inhabiting soft, muddy substrates are commonly characterized by thin, leaf-like expansions of the corallite through large presepiments, along with a sharply pointed apex positioned within the substrate. Several species were apparently adapted for a sandy (shifting?) substrate, with the apical part of the skeleton filled by biogenic calcite. Species living on a firm substrate have well developed talons and normal growth above, forming a large base.</ABSTRACT>

65398 <TITLE>Crises in the Devonian history of rugose corals.</TITLE>

65399 <SOURCE>Paleobiology 20, 2: 178-190.</SOURCE>

65400 <ABSTRACT>Detailed analysis of the stratigraphic ranges of Devonian rugose coral genera within the Old World and Eastern Americas Realms

gives new information on faunal extinctions and other bioevents in both realms. Various origination and extinction metrics are calculated from tabulations of occurrences in each stage. The most significant faunal changes were near or at the ends of the Lochkovian and Frasnian stages. The former marks the gradual transition from dominance by Silurian families and genera to the characteristic Devonian coral assemblages; the latter marks the virtual extinction of the Devonian families and genera. Other coral events are related to the two major changes. The data provide new bases for comparing the histories of the two realms. Most of the events are recorded in both, giving support to previous suggestions that the causes were worldwide. The coral record shows an increase (probably episodic) in environmental deterioration persisting through the Middle Devonian and culminating in extinction at the end of the Frasnian. Eustatic sea level fluctuations may have caused the precursor events and a bolide impact may have caused the end-Frasnian extinction.

65412 <SOURCE>In Boardman, Cheetham, and Oliver (eds): Animal Colonies (Dowden, Hutchinson & Ross, Inc., Stroudsburg, Pa.): 59-68.</SOURCE>
65413 <ABSTRACT>Protocorallite and hystero-corallite development in colonies of Hexagonaria anna are described in detail. The specimens originate from the Givetian Bell Shale and Ferron Point Formation in Michigan. Comparison of the characters of growth between the two types of corallites shows that the very early stage of protocorallite development when it is initially infilled with sclerenchyme, followed by an aseptate phase, is lacking in the hystero-corallite. Otherwise details of development in both types of corallites compare closely, especially with regard to the inobvious nature of protosepta throughout development and the lack of typical patterns of rugosan septal insertion.</ABSTRACT>

</TITLE>
65438 <SOURCE>Journal of Paleontology 49, 1: 153-159.</SOURCE>
65439 <ABSTRACT>A bellerophontid gastropod shell was found completely
surrounded by primary skeletal calcite in a Devonian cystimorph coral.
The shell is sediment-filled, and similar sediment fills the former
calice of the coral around the shell. The coral polyp survived the
introduction of shell and sediment, "roofed over" the shell
with its own skeletal deposits, and continued upward growth. Comparison
with a previously described occurrence leads to the interpretation that
the shell entered the coral calice between the polyp and the side of
the calice at a time when the polyp was injured and occupied only part
of its normal space.</ABSTRACT>

65581 <SOURCE>Abhandlungen und Berichte für Naturkunde 21: 75-107.</SOURCE>
65582 <ABSTRACT>Czamockia is known by three specimens from the Upper Famennian Clymenia and wocklumeria genozones of the Holy Cross Mountains in Poland and of the Tafelalt in Morocco. The redescription (based on additional sectioning of both holotype and paratype) leads to a classification within the phyletic line Neaxon > Petraia > Famennelasma > Czarnockia of the ahermatypic family Petraiidae

Koninck, 1872 (synonym Neaxoninae Hill, 1981). The more common ancestor Famennelasma Weyer, 1973, which is found in the same Upper Famennian time span from Poland through Germany and France to Morocco, differs in the lack of dissepiments occurring only in the mature calice of Czarnockia. * A redefinition (quite different from that proposed by Schindewolf, 1931) for Petraia Munster, 1839 is included in order to attain taxonomic stability of its family taxon by selection and illustration of a lectotype of the true type species Petraia decussata Munster, 1839 from the Upper Famennian (Clymenia genozone) of Upper Franconia in Germany (anticipating a future more detailed revision of that genus). * Another pleonophorous descendant from Neaxon is Nicholsoniella Soshkina, 1952, with type species Nicholsoniella baschkirica Soshkina, 1952, from the Upper Frasnian of the western slope of the southern Ural Mountains in Russia. After reillustration of its type series, this genus is grouped into a phyletic line Neaxon > Neosyringaxon > Nicholsoniella. [original summary] </ABSTRACT>

65593 <TITLE>'Engineering morphology" of the rugosan Argutastrea quadrigemina: new views on the reconstruction of soft body behaviour during parricidal budding.</TITLE>

65594 <SOURCE>Bulletin of the Tohoku University Museum 1 [Proceedings of the 8th International Symposium on Fossil Cnidaria and Porifera]: 041-049.</SOURCE>

65595 <ABSTRACT>Two general types of budding can be distinguished in massive colonies of Rugosa, Tabulata or Scleractinia: extratentacular and intratentacular budding. A remarkable variation of intratentacular budding, so called "parricidal increase", is studied in the rugose coral Argutastrea quadrigemina. Instead of creating a new corallite, an existing one is divided into four new ones by "killing" the mother corallite. * To understand the character of this special kind of reproduction we reconstruct the process by which fleshy soft parts divide into four new individuals. On the basis of considerations of engineering morphology (i.e., constructional morphology) we present a model to explain the generation of structures observable in skeletal tomography of Argutastrea quadrigemina during the budding process. Our hypothetical soft body is a polyp with distinct engineering and structural functional constraints: it is supplied with single mesenteries (in contrast to scleractinian corals!) which are added symmetrically in four sectors. Due to the remarkably deep calyces and quite short septa our polyp has rather short mesenteries. * Arrangements of mesenteries and positions of their insertion imply that from each growth sector, the body wall of the polyp increases until enough body mass is present to divide the existing polyp into four new ones. Thus the new body walls are arranged in a definite way as proposed by D'Arcy Thompson for four bubbles in close contact. [original abstract] </ABSTRACT>

65619 <TITLE>Septal architecture and palaeoecology of Calceola (Cnidaria, Calceolidae), with comments on the phylogeny of Devonian operculate tetracorals.</TITLE>
65620 <SOURCE>Memoirs of the Association of Australasian Palaeontologists 39: 159-176.ISSN 810-8889</SOURCE>
65621 <ABSTRACT>In Calceola sandalina the full complement of counter major septa was established very low in the calyx, extending from the counter septum across to the edge of the counter face. At about mid-height of the calyx, a counter-lateral major septum was generated on either side of and from the counter septum. Serial minor septal insertion was initiated adjacent to the counter-lateral septa at a slightly later stage and continued throughout the subsequent ontogeny of the corallite, with minor septa (schizosepta?) arising on the median side of major septa and bifurcating from them. Alar fossulae are seen in the calyx of mature corallites, on the counter side of a low ridge near the lateral extremity of the inner surface of the counter face. Insertion of major septa in the alar fossula has been observed rarely on the external counter face of worn corallites. The median septum in the operculum of C. sandalina is a compound structure which incorporates adjacent minor septa. * In an Emsian(?) corallite of ?Chakeola sp. minor septa are derived from major septa, new-minor septa being generated on the outer side of major septa. This corallite also exhibits minor septa adjacent to the K septum, thus casting doubt on Birenheide's generalisation that the counter-lateral septa of C. sandalina are not separated from the counter septum by minor septa. In the Emsian Chakeola whitehousei minor septa are present adjacent to the counter septum of the operculum. * The distal, anteriorly facing, projecting peg of the K septum of the corallite articulated within the large socket in the opercular K septum, and subsidiary grooves and plates on the socket and septum further facilitated interlocking. Knobs and/or small lists are developed along the posterior edge of the operculum, in the shelf inside the counter edge; septal pegs developed by septa in the corallite were accommodated within this shelf. The opercular septal blades interlocked loosely between the anteriorly facing, distal parts of septa of the corallite. * Rare opercula show one or more (abortive?) attempts to overcome damage which led to displacement of the operculum relative to the corallite, and rejuvenescence is exhibited to various degrees in many opercula. One operculum was apparently broken (bitten?) in half as a juvenile, but was reconstructed to reach a mature form. Other specimens show epifauna, borings and bioerosion either on the external surface of the operculum or on the external cardinal surface of the corallite. '

Galls' on the inner opercular surface are interpreted as stereome deposited to seal off some type of internal parasite. In *C. sandalina*, tubules containing tabulae are located just inside the counter face, and may have served to house soft parts associated with the operculum. Changes of opercular septal morphology suggest that the phylogeny of Devonian genera of the Calceolidae is *Rhizophyllum* > *Savageola* > *Chakeola* > *Richtereola* and ultimately, > *Calceola*. 65645 <TITLE>Die weichkorperkonstruktion von *Calceola sandalina* (Rugosa, Anthozoa) - Konstruktionszusammenhänge, Ontogenese, Evolution und Funktionsweisen.</TITLE>

65646 <SOURCE>Paläontologische Zeitschrift 74, 1/2: 37-49.</SOURCE>

65647 <ABSTRACT>The slipper-like corallum of *Calceola sandalina* comprises the calyx and the lid. It was generated by an anthozoan-like coral. Anthozoan polyps have a barrel-like shape that is produced and maintained by the activity of internal tethering elements and muscular structures in the body wall. All these structures counteract the hydrodynamics of the gastrovascular cavity* In this reconstruction of the soft parts of *Calceola* the functional aspects pointed out by Richter (1929) will be reviewed and revised and partially corrected. *Calceola* was reconstructed on the basis of the model of rugose polyps. Consequently it consisted of single mesenteries which were added in four sectors in a serial manner. The lid was formed on the counter side and is explained as a bulge of the basal parts of the soft body. The lid was connected coherently by the mesenteries to the whole construction. It could be closed by contraction of the mesenteries and opened by regeneration of the hydraulic volume in the gastric cavity. As a mechanical consequence of moving the lid a straight hinge was developed between the calyx and the lid. The soft body of *Calceola* developed by quite simple structural modifications of a rugose coral. The most important modification was the bulging of the basal parts of the soft body on the counter side which formed the lid. This bulge enlarged the surface for adhesion to the substrate and might have been an advantage in survival as well. The soft body generated its own substrate giving it the specific slipper shape. This shape prevented *Calceola* from sinking into the soft or muddy substrate by the principle of a snowshoe which enabled *Calceola* to conquer new territories. The lid meant protection where enemies and pollution were concerned. The slipper shape and the lid of *Calceola* indicated a complex evolutionary pathway, but they evolved by simple modifications of an ancestor with a

- round diameter. The slipper shape is just a mechanical consequence of a flappable lid. [original English summary] </ABSTRACT>

- 65658 <TITLE>The Devonian rugose coral family Charactophyllidae Pedder.</TITLE>
- 65659 <SOURCE>Courier Forschungsinstitut Senckenberg 164: 109-118. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 1] </SOURCE>
- 65660 <ABSTRACT>The rugosan family Charactophyllidae Pedder is primarily composed of small, solitary forms and its representatives are common in strata of Eifelian to Frasnian age. Diagnostic morphological features include coarse, monacanthine trabeculae, commonly flexed to varying degrees in a vertical plane, small, globose dissepiments, and a broad, clearly defined tabularium. The high degree of intraspecific variability evident in large populations of many North American charactophyllid species indicates that only the genera Charactophyllum Simpson, Spinophyllum wedekind, Temnophyllum walther, Sinodisphyllum Sun, Hunanophrentis Sun, Alaiophyllum Goryanov, Piceaphyllum Rozkowska, Chostophyllum Pedder and Ceciliaphyllum McLean can be recognized within the family, at least provisionally. It is clearly important for such variability to be assessed in species from other regions, especially many relevant type species. Mictophyllum Lang & Smith has commonly been regarded as a member of the Charactophyllidae, but restudy of the type species, M. nobile Lang & Smith, indicates it is unrelated to that family. Its affinities lie with the kyphophyllid genus Tabulophyllum Fenton & Fenton.</ABSTRACT>

- 65685 <SOURCE>Coral Research Bulletin 05: 229-238.</SOURCE>

- 65686 <ABSTRACT>The Family Kyphophyllidae Wedekind (McLean & Pedder 1984) contains the widespread Devonian genera Tabulophyllum, Smithiphyllum and Tarphyphyllum. These, and presumably the whole family, have species with an outer wall composed of laterally expanded septal bases coated by epitheca. The biogenic structure of this septotheca is shown in several best preserved individuals of Tabulophyllum traversensis collected from Givetian rocks in Michigan. The structure is fibrous, with calcitic fibers directed towards those of neighboring septa to form septotheca by lateral coalescence, with banding of magnesium providing a geochemical indicator of growth pattern. Diagenetic change of this structure progressively alters in to a septotheca with lamellar structure within septal bases, but with boundaries of remaining distinct. In T. traversensis., the lamellar wall structure thus is demonstrably diagenetic in origin. Similar lamellar structures occur in other species of Tabulophyllum, and in Smithiphyllum and Tarphyphyllum from Frasnian strata of Iowa. As yet, pristine biogenic structure is known in this family only in T. traversensis. A uniform style of diagenetic modification is envisaged for all genera of the Kyphophyllidae, although only the three have been studied to date. Additional data is needed prior to generalizing microstructure in other families and higher taxa of the Rugosa and Tabulata.</ABSTRACT>

65842 <ABSTRACT>After an historical review of the genus Pennastroma Dong De-Yuan 1964, the relationships between this genus and some similar labechiid genera are studied. The generic features proposed by Dong De-Yuan 1964, for the establishment of Pennastroma are then investigated; they concern the shape of primary and secondary pillars arranged penniformly and their V-shaped aspect in tangential section. These features seem to be inadequate to validate the genus Pennastroma which is a junior synonym of Stylostroma Gorskiy 1938.</ABSTRACT>

65854 <SOURCE>Palaeontology 40: 833-854.</SOURCE>
65855 <ABSTRACT>Understanding of the morphological variation and defining characters of the abundant and ubiquitous dendroid stromatoporoid genus Amphipora has been hindered by the loss of the holotype specimen of the type species, *A. ramosa* (Phillips). In the absence of the type, the boundaries of the genus could only be defined vaguely, yet 12 genera of Amphipora-like fossils have been named to constitute the family Amphiporidae Rukhin and about 175 species of these genera have been described. Assemblages of amphiporids in a single bed show a wide range

of variation but are considered to be the remains of a monospecific stand because a comparable range of variation can be demonstrated along the length of single stems. Some highly variable characters have been used to distinguish genera and species. In particular, the expression of the axial canal, nature and presence of peripheral membranes., thickness of skeletal elements, and density of the skeletal network are shown to be of dubious value as criteria for characterizing genera or species. A neotype for *A. ramosa* is selected from collections made from the Chercombe Bridge Limestone at Broadridge wood quarry, Newton Abbot, Devon, and revised diagnoses of the species and genus are formulated. The presence of distinct pillars in the neotype and all examined specimens from Devon, shows that the four genera whose distinctness from *Amphipora* was based on the presence of this character, should be regarded as junior synonyms. Four other genera are also placed in synonymy with *Amphipora*. The amphiporid animal is reconstructed as a small cylindrical, branching, calcified sponge in which the dermal membranes covering the vestibules were locally calcified to form the peripheral membranes and vesicles.

65972 <ABSTRACT>The annual increments in skeletons of Devonian stromatoporoids are 1-8 (3-6) mm thick. The primary elements calcified during several days were thin and/or minute and correspond to immediate CaCO3 accretion rates 0.05-0.12 g/cm2/yr. Such accretion is one order of magnitude less than for present scleractinians but up to several orders of magnitude more than for present calcareous sponges. According to thousands of specimens assessed worldwide, there are no doubts that more than 90% of backreef Givetian and Frasnian stromatoporoids display a conspicuously developed seasonal bandings. 65983 <TITLE>Stromatoporoid shape and burial ratio changes during growth history and their methodological consequences in morphometrical analyses.</TITLE>
65984 <SOURCE>Lethaia 39, 4: 339-358.</SOURCE>
65985 <ABSTRACT>Eight Devonian stromatoporoids with clearly exposed arrangements of latilaminae were subjected to detailed morphometrical analyses. Distinctive sets of latilaminae were marked on photographs taken from polished specimens, which allowed reconstruction of their individual growth histories by presenting consecutive stages of their growth. The growth forms measured above the sediment surface and the overall shapes of the skeleton at a given time have proved to differ distinctly between each other throughout the growth history of these stromatoporoids. The morphometrical features of individual specimens (both of their growth forms and of their whole skeletons) distinctly changed throughout their development. Changing environmental factors directly influenced the growth form above the sea floor, and each specimen shows its own specific history of growth form changes. Instead, overall shapes of the skeleton of most of the studied specimens changed in a similar general manner resulting from growth during sediment accumulation. Basing the palaeoenvironmental considerations only on the stromatoporoids' final shapes may thus be very misleading. It is therefore suggested that the ascription of a specimen to a particular morphometrical category should be based on the mode of its growth history represented by a curve recording the V/B changes (vertical height versus basal length) during consecutive growth stages. Certain sedimentary processes have their direct reflection in the mode of stromatoporoid growth, and are recorded by the attributes of the shape profile (V/B), and burial ratio (BR) curves, which allows deciphering such features as, for example, periodicity of sediment supply, substrate consistency and tempo of sediment cementation. This is particularly valuable when the deposits are recrystallized and the sedimentary structures are not visible. The paper also tests the applicability of the new definitions of the parameters describing the stromatoporoid shape introduced recently by the author. [original abstract]</ABSTRACT>

65996 <TITLE>Biogeography of the Devonian stromatoporoids.</TITLE>
65997 <SOURCE>The Geological Society Memoir 12 [W.S. Mckerrow & C.R. Scotese (eds): Palaeozoic Palaeogeography and Biogeography]: 257-265.</SOURCE>
65998 <ABSTRACT>Stromatoporoids were a common component of shallow carbonate environments of North America, Eurasia, and Australia during the Devonian. They were least abundant during the Early Devonian. After that time abundance increased, and remained high steadily through the Frasnian. At the Frasnian-Famennian boundary the number of stromatoporoids was greatly diminished, but they did not become extinct until the end of the Devonian (at the end of the Strunian). The geographic extent of stromatoporoids expanded and contracted concurrently with increases and decreases in total population size.

Provincialism at the genus level prevailed during the Early Devonian, with stromatoporoids inhabiting the Old World and Eastern Americas Realms; none are known from the Eastern Americas during the Siegenian. For the remainder of the Devonian stromatoporoids were cosmopolitan at the genus level. The abundance of stromatoporoids varied directly with eustatic sea level during the Devonian. Variations in depositional conditions apparently controlled the local distribution of genera.

Roemeria Milne-Edwards et Haime 1851 (Tabulata, Devonien moyen d'
Allemagne et de Belgique).</TITLE>
66062 <SOURCE>Paläontologische Zeitschrift 62, 1-2: 11-48.</SOURCE>
66063 <ABSTRACT>Three Middle Devonian tabulate coral species assigned to the
genus Roemeria Milne-Edwards et Haime 1851 are described. R.
infundibulifera (Goldfuss 1829) the type species of the genus and R.
minor Schlueter 1885, both from the Rheinisches Schiefergebirge and a
new species, R. cubiniensis from the Couvin area of Belgium. Their
external and internal characters and microstructures are described in
detail. The dominant morphological features they have in common are
cerioid and locally fasciculate corallites and tabulae with an
infundibuliform profile. The microstructure of the corallite walls is
characterized by an hitherto undescribed association of an internal
fibrous zone and a peripheral lamellar zone flanking a median plate
made of small granules and larger elements of stellate form. The only
microstructural variation between the three species lies in the
proportions of these components.</ABSTRACT>

1851 (Tabulata, Devonien).</TITLE>
66075 <SOURCE>Annales de la Societe geologique de Belgique 110: 297-308.
</SOURCE>
66076 <ABSTRACT>The genus Trachypora Milne-Edwards et Haime 1851 was
originally established for the species T. davidsoni Milne-Edwards et
Haime 1851, which is insufficiently known; therefore the use of this
generic name should be avoided. Most of the Devonian species of the Old
world assigned to this genus by subsequent authors belong very probably
to the genus Hillaepora Mironova 1960. The American Devonian species
are either members of the family Dendroporidae de Fromentel 1861, or
species of the genus Thamnoptychia Hall 1877. Consequently, the use of
the family name Trachyporidae Waagen et Wentzel 1886 should be avoided.

66088 <SOURCE>Annales de Paleontologie 77, 1: 3-20.</SOURCE>
66089 <ABSTRACT>In the axial part of Thamnopora corallum, the wall is composed of a median lamina in large vertical elements flanked by perpendicular fibers; in the middle part of the corallum, the median lamina broadens out and becomes made of pennate rods; in the cortical part of the corallum, the skeleton is entirely fibrous. Biocrystals of the median lamina enclose dark granulae whose dimensions and location are not hazardous. Interfaces of biocrystals are strongly underlined (by organic matter ?) between the median lamina and the fibers, but considerably less pronounced between rods and fibers themselves. Microstructure of Tabulate corals must be studied in various parts of the corallum. Thamnopora is a good example of fibrization, a tendency which is a general feature of Tabulata. In its axial part, the skeleton of Thamnopora is analogous to that of Pachyfavosites . Problems of relations between Pachyporidae-Thamnoporidae (with peripherically thickened skeleton) and Favostidae (with walls of uniform thickness) are evocated.</ABSTRACT>

66100 <TITLE>Biological fabric and the study of growth in the Devonian tabulate coral genera Lecfedites and Favosites.</TITLE>
66101 <SOURCE>Courier Forschungsinstitut Senckenberg 164: 159-168. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 1]</SOURCE>
66102 <ABSTRACT>Study of tabulate corals has been plagued by a lack of consistently definable anatomical features. Conspicuously absent are homologous point-for point correspondences between corallites. Corallite size, growth patterns, colony form and polymorphism comprise much of the basis for current systematics, but these commonly are only informally descriptive. This study approaches corallite pattern and growth from a numerical standpoint by means of biological fabric . Biological fabric is defined as a morphological pattern in which there are multiple subunits displaying complex relationships between individuals and also between neighborhoods. In these patterns, variability and position of subunits are parameters as important as overall pattern means, or central tendencies. Measurements of corallite sizes, shapes, relative locations, and orientations in colonies of the genera Lecfedites and Favosites have been collected from transverse sections using a microcomputer based videometric system. Methods have been developed for consistent characterization of corallite fabric: these are interpreted as variations in rates of skeletal growth and budding. Regions of faster and slower growth and a dynamic hummock-hollow behavior of the colony surface are seen in Lecfedites.

Measurable variability in corallite size and shape are interpreted in terms of intracolony population structure. In contrast, species of the genus Favosites studied tend to be homogeneous both at the level of individuals and in larger regions of colonies. However, some areas of more patterned budding are present and these are easily distinguished. Further success in using the morpho-metric characterization of biological fabric in the study of the Tabulata will lead to more accurate definition of species and genera. </ABSTRACT>

66113 <TITLE>Statistics on Thamnopora (Tabulata, Devonian).</TITLE>

66114 <SOURCE>Boletín de la Real Sociedad Española de Historia Natural, Sección Geológica 91, 1/4: 217-230.</SOURCE>

66115 <ABSTRACT>Thamnopora is a ramose tabulate coral that was abundant world-wide in the Devonian (Lochkovian to Frasnian). Its simple morphology allows the testing of statistical methods. 312 descriptions of 148 species and subspecies of Thamnopora and Gracilopora were assembled from 73 publications. Every description has been entered into a data bank with the following morphological data: growth of the corallites in the branches, septal elements, diameter of branches, diameter of corallites in the central (resp. peripheral) part of the branch, thickness of the walls in the central (resp. peripheral) part of the branch, diameter and spacing of mural pores, and distance between tabulae. Some morphological characters show interdependent positive correlations, and peripheral corallite diameter is a good indicator for the size of the polyp, which is at least partly genetically controlled. It is not possible to discriminate between Gracilopora and Thamnopora: therefore Gracilopora Tchudinova 1964 is a junior synonym of Thamnopora Steining 1831. Thamnopora shows a phylogenetic increase in size. A cluster analysis performed with the aim discriminating true species from synonyms failed.</ABSTRACT>

66126 <TITLE>Morphogenesis, taxonomy and microstructures of Beiliupora Yu & Deng 1974 (Devonian, Tabulata), with bearing on Devonian stratigraphy in Beiliu, Guangxi (South China).</TITLE>

66127 <SOURCE>Boletín de la Real Sociedad Española de Historia Natural, Sección Geológica 91, 1/4: 245-260.</SOURCE>

66128 <ABSTRACT>Beiliupora Yu & Deng is a tabulate coral genus erected in 1974 with the monotypic species Beiliupora beiliuensis Yu & Deng in Wang, Yu & Wu 1974 from the Lower Devonian, Emsian, Beiliu Formation in Beiliu, Guangxi, South China. The present restudy based on the topotypic material collected by Kl. Oekentorp during his visit to the type locality in 1982 reveals that the coral is mainly characterized by its peculiar colonial growth form, which is named here the lattice-framework form. The branches grow to a certain level and extend horizontally almost in all directions (never downwards).

Subsequently, they grow further in the vertical direction, either isolated or in combination with another branch extending from the opposite direction. The corallites radiate from the axial part of the cylindrical branch extending upward to the surface of the branch at a sharp to rectangular angle. All branches show continuous growth. The walls are recrystallized, e.g. the thickening of the walls at the calical portions with fibrous structures are secondary caused by reorganization of the crystals. Because of the peculiar colonial form, the genus is best placed under a distinct family, regarding the well developed polygonal to subrounded corallite walls, the mural pores, the more or less complete tabulae and the transition from anormal type of septal spines to squamulae. It is believed that family and genus are reasonably placed in the Favositina. Forms of Beiliupora have a wide distribution not only in Guangxi, South China, but also in Da Hinggan Ling, Northeast China, and in Gansu province, Northwest China. They have been assigned to Graciloporella Tchi 1982 and to Gracilopora Tchudinova 1964; the former is believed to be synonymous with Beiliupora. They all occur in Lower Devonian Emsian beds; commonly within the so-called Zdimir-limestone. Some tabulate corals with small corallites and peculiar colonial form described as species of Gracilopora in the former Soviet Union Territory may be a form of Beiliupora. A form occurring in the Zdimir-bearing limestone beds near Oviedo, Spain, once recognized by Yu during a field-trip, might also be referred to Beiliupora.</ABSTRACT>

66139 <TITLE>New data on the morphology and microstructure of the genus Caliapora Schlueter 1889 (Tabulata, Middle Devonian): systematic implications and reflections on the function of squamulae.</TITLE>

66140 <SOURCE>Boletin de la Real Sociedad Espanola de Historia Natural, Seccion Geologica 91, 1/4: 261-271.</SOURCE>

66141 <ABSTRACT>The examination of exposed calices as well as of thin sections of coralla overgrown by stromatoporoids has revealed that, in addition to the swallow-nest shaped squamulae, pillars in the corners of the calices rising above the colony surface and leaving large open gaps between them are important characters of the genus Caliapora. This character corresponds with the microstructure and the arrangement of growth bands delineating former growth stages. The pillars are centres, from which the fibres constituting the skeleton originate and rise steeply to the middle of each wall. The function of the squamulae seems to have been to enlarge the surface of the digestive and resorptive tissue of the polyp and to improve the stability of the polyp, which is assumed to have been necessary due to the large gaps between the pillars, which was probably spanned by soft tissue. The family Caliaporidae Mironova 1984 is regarded as valid and separate from the Favositidae as well as from the Alveolitidae because of the peculiar characters described.</ABSTRACT>

66152 <TITLE>Evolution of intraspecific morphological variability and its relationship to environment (Caliapora battersbyi, Devonian).</TITLE>
66153 <SOURCE>Vestnik Ces. geol. ustavu 73, 1: 61-74.</SOURCE>
66154 <ABSTRACT>Quantitative evaluation of morphology including parameters of environment provided these results: Morphological variability of the species decreased slowly but continuously, beginning from the stage of its initial biotic radiation. Episodes of increased variability corresponded to agitated water and strokes of sedimentary clasts. Local maxima of variability are correlated with the longevity of coral colonies. Surprisingly, the changes of morphological variability are almost independent of the changes of diversity of accompanying corallomorph fauna and flora. Variability displayed negative correlation with direct biological attack during the initial 3/5 of the Givetian history of the species. Then a change arose and during the remaining times until the end of the Givetian, the variability displayed a negative correlation with the direct biological attack. The weakly positive correlation of variability with the density of the populations has been documented. Similar but not identical complexes of morphological features in conjunction with a specific decrease/increase in variability were found during several ecological crises during the Middle and Late Givetian (a primary control by marine regressions on carbonate platforms). To conclude, the study about C. battersbyi indicates that the intraspecific morphological variability of tabulate corals is not only dominantly controlled by energy of waves and quality of the sedimentary substrate, as it would correspond to state-of-art of the discipline before this study. The morphological variability reflects distinctively also the ecological and evolutionary situations.</ABSTRACT>

66166 <SOURCE>Coral Research Bulletin 05: 247-264.</SOURCE>
66167 <ABSTRACT>The forgotten genus, with type species Actinotheca parallela Frech 1889 (Lower Visean of Germany, probable senior synonym Trachypora siemensii Frech 1885), is classified as a member of Palaeacidae Roemer 1883 (with synonym Trachypsammidae Gerth 1921). Some of their genera were treated as doubtful Tabulata, perhaps being even Porifera or Octocorallia. Two misidentified Rugosa are transferred to Actinotheca, Petraia tenuicostata Muenster 1839, and synonym Pseudamplexus granulatus Rozkowska 1969. This second species of Actinotheca is of Middle-Upper Famennian age; the genus reaches into Upper Visean beds and should be the ancestor of Middle Permian Trachypsammia Gerth 1921. Actinotheca tenuicostata (Muenster 1839) occurs in the Clymenia and Wocklumeria genozones of Mid-European Variscan Mountains (Renohercynian Rhenish and Holy Cross Mountains; Saxothuringian Upper Franconia, Thuringia, and Lower Silesian Sudetes), and in Prolobites horizon and Clymenia genozone of the Asian Southern Urals (Russian Kia section, Kazakhstani Kara-Dzhar section.</ABSTRACT>

66191 <TITLE>Dimorphism in two new genera of Devonian tabulate corals.</TITLE>
66192 <SOURCE>US Geol. Surv. Prof. Paper 743-D: 1-11.</SOURCE>
66193 <ABSTRACT>"Dimorphism" in most tabulate corals consists of a bimodal distribution of corallite diameters; this can better be termed "dimetrisism". Demonstration of a morphologic difference, other than size, between forms has been rare. "Favosites" canadensis (Billings) has two kinds of corallites - large ones with squamulae and small ones with normal, complete tabulae. "Favosites" arbor Davis also has two kinds of corallites - one with a deep calice and possibly two distinct ontogenetic stages and a second that is smaller, having a shallow calice and possibly only the second ontogenetic stage. * Dimorphism, corallite ontogeny, and microstructure are emphasized in descriptions of the species and two new genera: Lecfedites (type species F. canadensis) and Bractea (type species F. arbor). The genera are known only from rocks of Emsian and Eifelian ages in the Eastern North American Biogeographical Province.</ABSTRACT>

66217 <TITLE>Evolution of tabulate assemblages and paleobiogeography around the Frasnian-Famennian boundary.</TITLE>
66218 <SOURCE>Coral Research Bulletin 7: 039-046. [Dieter Weyer**'**s 65th birthday commemorative volume; S. Schröder, H. Löser **&**; K. Oekentorp (eds)]</SOURCE>
66219 <ABSTRACT>The evolution of species assemblages of Tabulata corals in the Salair, Altai and West Siberian Seas, which were located in Siberia in the Devonian Period, is discussed. Three species assemblages are established in the Salair and Altai Seas: Early Frasnian, Late Frasnian and Famennian. In the West Siberian Sea only one specific assemblage has been found, namely Early Frasnian. Tabulate assemblages in the Famennian consisted of solitary species. Evolution of tabulate assemblages is discussed for the entire Late Devonian. It is recognised that a major reconstitution of tabulate species assemblages occurred across the Frasnian-Famennian boundary. This reconstitution is expressed not only in a sharp change of taxonomic composition, but also in the mass extinction of many groups of corals and other organisms. Based on the analysis of temporal-spatial distribution of tabulates it is concluded that seas in Australia and Eurasia in the Frasnian could be treated as one Australia-Eurasian paleobiogeographical province.

66256 <TITLE>Review of occurrences of Halysitid corals in Devonian strata.</TITLE>
66257 <SOURCE>Alcheringa 04: 183-202.</SOURCE>
66258 <ABSTRACT>A review of reported and new occurrences of 'Devonian ' halysitids indicate that most are older than Devonian. Reports of Emsian halysitids from Chios are best attributed to errors in the compilation of Bassler (1950). The occurrences of halysitids in Quebec in strata considered Early Devonian provide the only plausible examples of the existence of this family in the Devonian. Thus, only Cystihalysites and Quepora appear to linger into the Devonian. Five Australian occurrences, yielding seven taxa, are described and interpreted as Silurian or older halysitids. All are from allochthonous material in the Early Devonian of New South Wales and include: Schedohalysites murrmirra sp.nov., Halysites suesmilchi Etheridge and an indeterminate specimen from the Mullamuddy Formation near Mudgee; Schedohalysites sp. cf. S. ? chillagoensis from the Sutchers Creek Formation, also near Mudgee; Quepora sp. indet. from the Jesse Limestone at Limekilns; cf. S. orthopteraides (Etheridge) from the Nubrigyn Formation near Stuart Town; and ? Halysites sp. indet. from the Sharpeningstone Conglomerate near Bowning. The type material of Schedohalysites ? chillagoensis (Etheridge) is redescribed and a lectotype is selected.</ABSTRACT>

66323 <ABSTRACT>A comprehensive review of Middle and Upper Devonian reefs, based on about 350 papers describing the reef development within 44 areas all over the world, resulted in the recognition of four reef megacycles (Upper Eifelian; Givetian; Uppermost Givetian to Frasnian; Upper Frasnian to Lower Famennian). These megacycles are characterized by the occurrence of typical reef types and by characteristic microfacies associations. Twelve microfacies associations can be distinguished using lithological, paleontological and microfacies criteria; each microfacies association includes several standard microfacies types.</ABSTRACT>

66335 <SOURCE>Courier Forschungsinstitut Senckenberg 75: 1-415.</SOURCE>
66336 <ABSTRACT>The present volume of the Courier of the Senckenberg Research Institute is entirely devoted to articles (29) relevant to Devonian stratigraphy of the world. They particularly concentrate on scope and bearing of the new intra-Devonian Series Boundaries. The Subcommittee on Devonian Stratigraphy (SDS) of the International Commission on Stratigraphy had stimulated the Devonian stratigraphers of the world in 1973 to work toward a revision of series and stage boundaries. More than a dozen regional field trips and meetings by SDS and numerous scientific articles and Devonian symposia have promoted the work since then. [from the foreword]</ABSTRACT>

66386 <TITLE>Reef development at the Frasnian-Famennian mass extinction boundary.</TITLE>
66387 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 181, 1-3: 27-65.</SOURCE>
66388 <ABSTRACT>A newly compiled global reef database indicates that the 5-6 Myrs long Frasnian (Late Devonian) metazoan reef episode had relatively low diversity compared to middle Devonian highs (with over 200 genera of calcitic rugose and tabulate corals). Following an initial early rise after late Givetian coral and stromatoporoid extinctions, reefs expanded for the last time during mid-Frasnian sea-level highstands but declined markedly in the late Frasnian (rhenana-linguiformis conodont zones) below the Frasnian/Famennian (F/F) boundary. Globally metazoan reefs were wiped out by the end Frasnian: some Famennian reefs while partly retaining the structure of the underlying carbonate platform, were built by cyanobacterial consortia such as Rothpletzella, Girvanella and Epiphyton. During the Famennian, foraminifera with calcite walls became abundant for the first time in the Phanerozoic adding a new dimension to carbonate platforms. Colonial rugose corals (phacelloid, cerioid and thamnastraeoid modules) were absent in the early post-extinction phases up into the mid-Famennian and very rare and non-reefbuilding later, but solitary deep-water Lazarus corals survived locally. Coral-sponge reefs are unknown from the 21 Myr long Famennian, also a time of very low platform carbonate production. Rare small isolated stromatoporoid sponge and lithistid sponge patch reefs returned episodically during the Famennian in North America, western Europe, Australia, and China. The aragonitic stromatoporoids became

extinct at the end of the Famennian. During a late Devonian tectonically very active collisional Caledonian mountain-building phase, oceanic and atmospheric cooling accompanied by sea-level lowstand systems, exposed most carbonate platforms accelerating coastal erosion and karsting. This increased the amount of clastics in the shelf-slope setting, in the last 1-3 Myrs prior to the F/F boundary often burying reefs. Immediately following there were protracted losses in practically all major tropical shelf marine invertebrates exceeded only by the end-Permian extinctions in severity. There is no apparent link between black organic-rich horizons and reef demise at, or close to, the F/F boundary. The F/F boundary not also (sic) marks the largest change from widespread flooded Early and mid-Paleozoic continental cratons to narrow distal shelves but also spikes the largest known global Paleozoic shift in atmospheric O₂ enrichment and CO₂ draw down. This threshold matched the rise of the first tropical rainforests and expansion of terrestrial biomes on the tropical central lowlands formerly occupied by carbonate platforms.

66412 <TITLE>Megareefs in Mid-Devonian supergreenhouse climates.</TITLE>

66413 <SOURCE>Geological Society of America Special Paper 370 [Extreme depositional environments: mega end members in geologic time]: 209-230.</SOURCE>

66414 <ABSTRACT>A newly refined reef database, modified to calculate reef tracts in relation to major tectonic plates, and with new paleogeographic maps, indicates that the largest known, and latitudinally most widespread Phanerozoic reefs developed during the Middle Paleozoic (Siluro-Devonian), with an acme in the Middle Devonian. Expanding during times of exceptional sea-level highstands and widespread epicontinental shallow seas, this 26 m.y. long acme of coral-sponge reef growth coincided with the warmest global temperatures known for the Phanerozoic, i.e. with a "supergreenhouse"; climate mode well above Holocene interglacial norms. During the Middle Paleozoic, reefs were particularly abundant, occupying large, continental seaboard, carbonate platforms, and vast inland epicontinental seas. Examples of such "extremes" occurred mostly on passive margin settings, and extensively flooded continental interiors, e.g. the 1700-3000km long tracts of the western Canada Sedimentary Basin, Canadian arctic (Innuitian platform), eastern

Laurentia "Old Red Continent" (linked United Kingdom to Poland), eastern Russian Platform (northeast Laurussia), Ural "Fold Belt" (eastern slopes of Urals), Siberia, northwest Africa, and South China. Smaller scale reef belts between 700 and 1300km long were constructed on isolated tectonic terranes facing Gondwana on the north (Pyrenees, Afghanistan-Pakistan), Mongolia, Kolyma-Chukotka, and North China. Large basins and flooded shelf areas, and the reefs featured within them, were not persistently developed throughout the Middle Paleozoic. They especially characterized the middle Emsian through Givetian (late Early Devonian - Middle Devonian). The following Frasnian (Late Devonian) showed more restricted and confined distribution of coral - stromatoporoid reefs, and during the Famennian, coral-stromatoporoid reefs "crashed" and were replaced by calcimicrobial reefs and platforms. During the latter phases of the Frasnian / Famennian mass extinctions, such microbial reefs were confined to relatively small areas, and metazoan reefs were nearly entirely obliterated, being confined to rare stromatoporoid patch reefs or lithistid mounds. Coral reefs were completely absent during the 21 m.y. long Famennian interval, and no real recovery of "keystone" frame-building, colonial corals took place in reef settings. The Famennian coincided with repeated glaciations, sharp sea-surface cooling events, sea-level drawdowns, and concurrent, matching stable isotope excursions. [original abstract] </ABSTRACT>

66425 <TITLE>The Upper Devonian Reef Crisis: Insights from the Carbon Isotope Record.</TITLE>

66426 <SOURCE>Goettinger Arbeiten zur Geologie und Palaeontologie, Special Volume 2 [Reitner J., Neuwiller F. & Gunkel F. (eds): Global and Regional Controls on Biogenic Sedimentation I. Reef Evolution]: pp ???</SOURCE>

66427 <ABSTRACT>Perturbations in the Upper Devonian carbon cycle are evidenced by prominent variations in the inorganic carbon isotope record. The decline of the Devonian stromatoporoid - coral reef ecosystem is interpreted to be caused by the ultimate consequences of these perturbations. The Frasnian is characterized by a second order sealevel rise culminating in a maximum sealevel highstand and maximum greenhouse conditions near the Frasnian / Famennian boundary. High sea-surface temperatures, a sluggish oceanic circulation and low fertility may have stressed low latitude shallow-water habitats. Superimposed transgressive - regressve cycles resulted in a maximum flooding of the epicontinental shelves, maximum formation of warm saline deep waters and the spread of sub-pycnocline anoxic waters onto the shallow water platforms. The latter resulted in the deposition of organic rich sediments (Kellwasser Horizons) inducing climatic cooling especially in high latitudes. Reduction of benthic habitats, upwelling of sulfidic waters or toxic algal blooms represent possible consequences of the transgressive pulses. The Devonian stromatoporoid - coral ecosystem may have been highly stressed during the Late Frasnian and superimposed transgressive pulses resulted in an increase of ecological stress that may have been lethal especially for low latitude shallow water ecosystems.</ABSTRACT>

66440 <ABSTRACT>The microfacial and geochemical investigation of seven profiles comprising the transition of reef to non-reef facies showed that especially the Devonian biostromal reefs were highly susceptible to any kind of change in the continental hinterland which might have influenced the equilibrium of the reef habitat. As regards the Devonian stromatoporoidal reefs, living conditions disimproved during the Frasnian stage (doIß/γ) leading to cyclic reef growth mainly on the unprotected shelf platform of the Eifel/Ardennes. One of the main factors controlling stromatoporoidal reef-growth turned out to be the periodical blooming of microorganisms (e.g. phytoplankton) which was triggered off by the periodical influx of nutrients from the Old Red Continent. This led to a widespread depletion of oxygen and light plus to an increased sedimentation of organic matter in the reef habitat, thus inhibiting growth of reef dwellers, causing latilaminae in stromatoporoids and also leading to cyclic reef growth. A prolonged and more widespread event of this kind finally terminated stromatoporoidal reef growth at the southern rim of the Old Red Continent and resulted in widespread deposition of euxinic sediments in Europe (Matagne-shales, doIδ). In further works light should also be shed on the concurrent effects on associated platform dwellers like corals, brachiopods and possibly conodonts. Investigation of further Devonian profiles should render more spatial conclusions if the obtained results were also valid at a larger scale.</ABSTRACT>

66451 <TITLE>Facies Models for Middle to Late Devonian Shallow-marine Carbonates, with Comparisons to Modern Reefs: a Guide for Facies Analysis.</TITLE>
66452 <SOURCE>Facies 30: 155-176.</SOURCE>
66453 <ABSTRACT>Shallow marine tropical Devonian carbonates commonly were deposited in two major geologic settings, i.e., shallow shelf with shelf margin reef, and gently sloping ramp that grades into peritidal to supratidal, in places evaporitic facies. The facies types within these two settings can be grouped into a few distinct zones on the basis of water energy, texture, amount of micrite, porosity, fossil assemblages, and indicator fossils. These zones have been integrated into a composite facies model for shallow marine, tropical Devonian carbonates. The facies zones are easily recognizable in hand specimen and core, and can be used for fast and accurate facies analysis. Some facies recognizable in hand specimen or core do not easily fit into the integrated model and represent facies of short-lived depositional events, such as hurricanes or slump deposits, or spatially restricted areas, such as channel fills. Such facies have to be interpreted on a

case-by-case basis by comparison to the surrounding facies and depositional framework through time. Comparisons with Cenozoic reefs reveal a number of similarities. In particular, large metazoans in both Devonian and Cenozoic reefs display a range of growth forms that is not species-specific. Furthermore, several metazoans display comparable growth forms in equivalent facies zones. For example, dendroid stromatoporoids, such as Stachyodes, and branching corals, such as Porites porites, occur in equivalent facies zones.</ABSTRACT>

66529 <TITLE>Eutrophication by decoupling of the marine biogeochemical cycles of C, N, and P: A mechanism for Late Devonian mass extinction.</TITLE>
66530 <SOURCE>Geology 28, 5: 427-430.</SOURCE>
66531 <ABSTRACT>The Late Devonian mass extinction was unusually protracted and ecologically selective, with preferential diversity losses among reef-building organisms and tropical, shallow-water faunas in general. We have investigated the link between the extinction's unique characteristics and changes in biogeochemical cycling through analyses of the δ13C and C:N:P atomic ratios of organic matter buried across the Kellwasser Horizons in western New York State. Each horizon is characterized by (1) a long-term, +4%-5% excursion in δ13C, ~3% of which occurs within the horizon, and (2) a dramatic increase in the burial ratios of C:N:P, from values of ~100:15:1 to an average of ~5000:170:1. On the basis of these results, we propose that (1) increased efficiency of biolimiting nutrient recycling, resulting from cyclic water column stratification and mixing, promoted eutrophication during Kellwasser deposition in New York, and (2) the isotope excursions represent the composite effect of long-term, global organic C burial, and local changes in photosynthetic C isotope fractionation related to nutrient availability. This eutrophication model forges a

- mechanistic link between proposed Late Devonian climatic cooling and the selective demise of taxa likely to have been narrowly adapted to oligotrophic conditions. [original abstract] </ABSTRACT>

- 66542 <TITLE>The 'multiple impacts hypothesis' for mass extinction: a comparison of the Late Devonian and the late Eocene.</TITLE>
- 66543 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 176, 1-4: 47-58.</SOURCE>
- 66544 <ABSTRACT>Application of the lag-time multiple impacts hypothesis [Poag 1997b: Palaios 12: 582-590; Poag et al. 2001: Columbia Univ. Press] to the Late Devonian leads to the prediction that the Frasnian-Famennian pulsed extinctions were triggered by a rapid drop in global temperature that followed an impact-produced anomalous warm interval, which interrupted the global cooling trend from the Middle Devonian greenhouse to the Early Carboniferous icehouse. In actualistic comparison with the late Eocene, the lag-time multiple impacts hypothesis would predict that a Frasnian interval of multiple impacts should have occurred between 367.7 and 366.7 Ma. The fact that three impacts (the Alamo, Siljan and Flynn Creek) do occur either within this predicted interval, or close to it in time, is corroborative evidence that the lag-time multiple impacts hypothesis may indeed provide the causal mechanism for the Frasnian-Famennian mass extinction. Based on the application of the lag-time multiple impacts hypothesis to the Frasnian-Famennian mass extinction, it is here suggested that future searches for evidence of impact events in the Late Devonian be concentrated in strata that occur in the Frasnian transitans to Early hassi zonal interval, and not in strata immediately below or above the Frasnian-Famennian boundary. - 66555 <TITLE>Conodont apatite δ180 signatures indicate climatic cooling as a trigger of the Late Devonian mass extinction.</TITLE>
- 66556 <SOURCE>Geology 30, 8: 711-714.</SOURCE>
- 66557 <ABSTRACT>The oxygen isotope composition of conodont apatite from two Frasnian-Famennian boundary sections was measured in order to reconstruct variations in marine paleotemperatures during the late Frasnian extinction event. The measured conodont δ180 values reveal two positive excursions with maximum amplitudes of +1‰ to +1.5‰ that parallel positive excursions in the carbonate carbon isotopic composition. The +3‰ excursions in carbonate δ13C have been interpreted as consequences of enhanced organic carbon burial rate resulting in a decrease in atmospheric CO₂ concentrations. Climatic cooling as a potential consequence of lower atmospheric CO₂ concentration is confirmed by the conodont δ180 records, which translate into cooling of low latitude surface waters by 5-7°C. Repeated cooling of the low latitudes during the late Frasnian had a

severe impact on the tropical shallow-water faunas that were probably adapted to warm surface-water temperatures and severely affected during the late Frasnian crisis. These prominent variations in ocean-water temperatures were stressful to the tropical shallow-water fauna and potentially culminated in low origination rates of new species, one of the major factors of the decline in diversity during latest Frasnian. 66568 <TITLE>Strength, timing, setting, and cause of mid-Palaeozoic extinctions.</TITLE>

66569 <SOURCE>Palaeogeography, Palaeoclimatology, Palaeoecology 181, 1-3: 5-25.</SOURCE>

66570 <ABSTRACT>Much has been written over the last 20 yr on the Upper Kellwasser Event (Frasnian/Famennian or F/F boundary) as the major extinction event of the Middle Palaeozoic (Devonian) and as the fifth largest extinction event in the Phanerozoic; this opinion was based on analysis of family range data. These views are misleading. A current analysis of family extinction data, largely based on The Fossil Record 2, but updated in some respects, supersedes the data base of Raup and Sepkoski (1982) and shows that the Famennian has the highest total family extinction of marine taxa, with the Givetian in second and Frasnian in third place. If these new data are related to current (unreliable) estimated length of stages, then the severest extinction rates are: first, the Givetian at 14.2 family extinctions per Ma, secondly the Frasnian at 11.2 and thirdly the Eifelian at 6.8. Many short-term events have been named for the Devonian based on short-term distinctive sedimentary and/or faunal perturbations. A review of these shows how they are often transgression/regression couplets, many with an association of anoxia and poor in benthos, or spreads of pelagic faunas, and some are phased and complex. Evidence is presented to suggest that the transgressive pulses correspond to warm temperatures which are terminated by cooling. Possible links with orbitally forced patterns are considered. A common explanation seems required, not just for the Kellwasser Event, but for all these events. The relation of the family stage extinctions, especially the Kacak, Taghanic, Kellwasser and Hangenberg Events, which are of much more limited duration, is discussed particularly in relation to new and more precise data of the extinction events known within these stages. In the absence of detailed studies for many groups, those that have been well documented may serve as a temporary proxy for others. [original abstract]</ABSTRACT>

66594 <TITLE>Late Devonian sea-level changes, catastrophic events and mass extinctions.</TITLE>
66595 <SOURCE>Geological Society of America, Special Paper 356 [C. Koeberl & K.G. MacLeod (eds): Catastrophic Events and Mass Extinctions; Impacts and Beyond]: 473-487.</SOURCE>
66596 <ABSTRACT>Late Devonian history is explained through event stratigraphy comprising a sequence of 18 sea-level changes, catastrophic events and mass extinctions. Generally rising sea level during the initial Frasnian Stage, beginning with the Taghanic onlap and ending with a sea-level fall and major mass extinction, was interrupted by several exceptionally rapid, very high rises of sea level. These rises may be related to a series of comet showers, as suggested by the coincidence of the Alamo Impact in Nevada and the older Amonau Event in Germany with two of the sea-level rises. The sub-critical, off-platform marine Alamo Impact is demonstrated to have produced greatly different effects in deep water from those previously recorded on the carbonate platform. * The series of comet showers, most notably those around the Frasnian-Famennian boundary, evidenced by microtektites in widely separated regions, not only produced the late Frasnian mass extinction, but also induced global cooling. This cooling resulted in Southern Hemisphere glaciation. Generally falling sea level during the later Famennian Stage was interrupted by several warmer, interglacial episodes, evidenced by glacio-eustatic rises. Another, less severe mass extinction occurred during an abrupt sea-level fall near the end of the Famennian. This glacio-eustatic fall is interpreted to have resulted from a severe, terminal glacial episode. * Interpretation of Late Devonian history suggests that impacts and comet showers coincided with sea-level rises, whereas mass extinctions occurred during, not at the start of, sea-level falls. 66699 <SOURCE>Boletin de la Real Sociedad Espanola de Historia Natural, Seccion Geologica 91, 1/4: 99-106.</SOURCE>
66700 <ABSTRACT>Colonial species showing a Heterocorallia-like septal pattern have been considered by Fedorowski (1991) to belong not to the Rugosa, but to the Dividocorallia, a subclass also including the Heterocorallia. Chinese and French colonial species characterized by a Heterocorallia-like pattern of the major septa, such as those assigned to Stylostrotion Chi by Fedorowski (1991), are reassigned to the Rugosa under the name Heterostrotion Poty & Xu. The heterocorallian shape of the septa is considered to be the result of a pinnate connection and not of a Heterocorallian septal genesis. The corallites of Heterostrotion sometimes develop an aulos and become identical to those of the genus Solenodendron. The two genera also share increase patterns and septal carinae, suggesting a close relationship, with Solenodendron evolving from Heterostrotion.</ABSTRACT>

66725 <SOURCE>Bulletin de l'Institut royal des sciences naturelles de Belgique, Sciences de la Terre 61: 21-105.</SOURCE>
66726 <ABSTRACT>The new concept of taxonomy and phylogeny of some extinct Devonian and Carboniferous Anthozoa is supported by an increase in septa distinct from other Anthozoa and common for all members of the Dividocorallia n. subclass. Presence or absence of calices permits to divide the subclass into the orders Calyxcorallia and Heterocorallia respectively. Presence or absence of the dissepimentarium is a family level feature in the Calyxcorallia, whereas the microstructure of an external wall plays that role in the Heterocorallia. Primitive, caliculate Lower Devonian Rugosa were most probably ancestral to the Dividocorallia. This idea is supported by insertion of a single septum at the beginning of septogenesis in both subclasses. Deviation towards the Heterocorallia took place already during the Lower Devonian time, perhaps through neoteny.</ABSTRACT>

66803 <SOURCE>Facies 30: 177-192.</SOURCE>
66804 <ABSTRACT>Analysis of the taxonomic composition, diversity and guild

structure of five typical reef and mud mound communities ranging in age from Late Devonian to Early Carboniferous indicates that each of these aspects of community organization changed dramatically in relation to three extinction events. These events include a major or mass extinction at the end of the Frasnian; reef communities were also effected by less drastic end-Givetian and mid-late Famennian extinctions of reef-building higher taxa. Peak Paleozoic generic diversities for reef-building stromatoporoids and rugose corals occurred in the Eifelian-Givetian; reef-building calcareous algal taxa were long-ranging with peak diversity in the Devonian. These three higher taxa dominated all reef-building guilds (Constructor, Binder, Baffler) in the Frasnian and formed fossil reef communities with balanced guild structures. The extinction of nearly all reef-building stromatoporoids and rugose corals at the end of the Frasnian and the survival of nearly all calcareous algae produced mid-late Famennian reef communities dominated by the Binder Guild. Despite the survival of most calcareous algae and tabulate corals, the mid-late Famennian extinction of all remaining Paleozoic stromatoporoids and nearly all shelf-dwelling Rugosa brought the already diminished Devonian reef-building to a halt. These Devonian extinctions differ from mass extinctions by the absence of a statistically significant drop in taxonomic diversity and by their successional and cumulative effects on reef communities. Tournaisian mud mounds contain communities markedly different from the frame-building communities in Late Devonian and Visean reefs. Mound-building biotas consist of an unusual association dominated by erect, weakly skeletonized members of the Baffler Guild (chiefly fenestrate Bryozoa; Pelmatozoa) and laterally expanded, mud binding algae / stromatolites and reptant Bryozoa. The initial recovery to reefs with skeletal frameworks in the Visean was largely due to the re-appearance of new species of abundant colonial rugose corals (Constructor Guild) and fenestrate Bryozoa. This Frasnian-Visean evolution in the taxonomic composition and structure of the reef-building guilds is also expressed by abrupt changes in biofacies and petrology of the reef limestones they produced. Thus typical Frasnian reef limestones with balanced guild structures are framestones-boundstones-bafflestones, Famennian reefs are predominantly boundstones, Tournaisian mud mounds are bafflestones and Visean reefs are bafflestones-framestones.

66815 <TITLE>Upper Palaeozoic coral studies: where we are and where we should be.</TITLE>

66816 <SOURCE>Bulletin of the Tohoku University Museum 1 [Proceedings of the 8th International Symposium on Fossil Cnidaria and Porifera]: 001-006.</SOURCE>

66817 <ABSTRACT>The utility of the Upper Palaeozoic rugose coral studies depends on their accuracy. The status and achievement level in various aspects of these studies are critically reviewed from the historical viewpoint. Ontogeny, blastogeny and astogeny, calice morphology, microstructure and diagenesis and applied methods are analysed. Only precise and generally accepted criteria can form the basis for proper taxonomy and only well founded taxonomy is useful for further, more specific or general studies. Thus, standards for description of new species and the revision of existing taxa are proposed. Application of Upper Palaeozoic rugose coral studies to stratigraphy, palaeogeography,

- palaeoecology, and investigations of evolutionary relationships and mass extinction are briefly discussed. </ABSTRACT>

- 66830 <ABSTRACT>Microstructures of Permian corals were investigated concerning their primary structure. It could be shown that the microstructures of the skeleton were affected by diagenetic processes causing secondary textures and thickenings by cement precipitation veiling the original septal structure. Signs indicating such structural changes are: irregularity of the microtextural pattern, diversity of so-called primary structures, unusual reduction or growth of grain size, formation of frontal zones ("Stirnzonen") as well as a pseudolamellar and a zigzag-pattern. The diagenetic history of the coral skeletons as well as the primary composition of the skeletal carbonates are discussed: aragonit versus calcite. The nature of present secondary textures, as formation of diagenetic processes and corresponding recrystallizations in Triassic Scleractinia inevitably lead to the conclusion that the primary skeleton in Permian Rugosa was composed by aragonite.</ABSTRACT>

- 66856 <ABSTRACT>La aplicacion de la microscopia de catodoluminiscencia (CL) al estudio de la evolucion de los procesos diageneticos que han afectado a diversos corales fosiles del Palaeozoico superior (Viseense y Kasimoviense) ha puesto de manifiesto su utilidad fundamentalmente en

tres aspectos: - Identificación de las microestructuras originales de los corales. Microestructuras que son irreconocibles con la microscopía convencional, son visibles con CL. Se han podido reconocer como primarias las tres microestructuras características de los corales paleozoicos: fibronormal, trabecular y microlamelar.- Diferenciación de los procesos diagenéticos destructivos que han afectado a sus estructuras esqueléticas. La microscopía CL permite reconocer claramente películas de micritización que con luz normal son difícilmente visibles. Asimismo zonas recristalizadas de las estructuras esqueléticas que presentan una luminiscencia característica.- Reconocimiento de las generaciones de cementos relacionadas con los corales. Se han diferenciado dos tipos de secuencias de cementos, una rellenando cavidades internas y la otra localizada en el caliz. Ambas reflejan el progresivo enterramiento de los corales, desde ambientes de cementación submarina hasta condiciones de enterramiento relativamente profundo.

66867 <TITLE>List of names proposed for genera and subgenera of late Paleozoic corals, 1828-1989.</TITLE>
66868 <SOURCE>FC&P 19, 2.2: 1-21.</SOURCE>
66869 <ABSTRACT>The following list presents some basic information on names that have been proposed for Carboniferous and Permian coral genera and subgenera. Taxa represented belong to Subclasses Rugosa and Tabulata as defined by Hill (1981). * Rugosa (R), Tabulata exclusive of chaetetids (T), chaetetids (C), and taxa of uncertain classification (U) are indicated by letters in parentheses at the end of each citation. * Names that do not appear in Hill (1981) are preceded by asterisks. * Taxa that have pre-Carboniferous type species are indicated by # after the name; some names in this category have been omitted from the list because of insufficient evidence of their applicability to late Paleozoic corals. [excerpt from introduction to the list]</ABSTRACT>

66880 <TITLE>The origin and significance of zigzag microstructure in late Paleozoic Lophophyllidium (Anthozoa, Rugosa).</TITLE>
66881 <SOURCE>Journal of Paleontology 77, 19: 16-30. [19 ???]</SOURCE>
66882 <ABSTRACT>In late Paleozoic solitary Rugosa, the zigzag microstructure as defined by Schindewolf (1942) is related to presence of an elevated magnesium content within biogenic calcite (intermediate magnesian calcite, IMC) and its subsequent loss during diagenesis by microdissolution and neomorphism. This particular microstructure has been recognized with certainty only in some Carboniferous and Permian rugose corals (e.g. Lophophyllidium spp.). Septal and other skeletal microstructures in those corals are dominantly (oblique) sloping-lamellar, which is also interpreted as diagenetic in origin. Two directions of oblique lamellae commonly occur in thickened skeletal

elements, forming chevrons that make up zigzag microstructure with its orientation determined by presence of microdolomite blebs within skeletal calcite. Geochemical studies of corals from the Mississippian Imo Formation of Arkansas, the Pennsylvanian Buckhorn asphalt of Oklahoma and Pennsylvanian Kendrick Shale of Kentucky all indicate that magnesium content in skeletal calcite of the corals was elevated, with a maximum in the neighbourhood of six to eight percent CaCO₃, thereby forming intermediate magnesium calcite. Corals with this zigzag microstructure apparently only occurred during the late Paleozoic interval of *aragonite seas*; as a result, this diagenetic behaviour of rugose corals can serve as a proxy for secular change in marine chemistry and/or climate.

66893 <TITLE>The Upper Palaeozoic tetracoral genera Lophophyllidium and Timorphyllum.</TITLE>
66894 <SOURCE>Palaeontology 17, 3: 441-473.</SOURCE>
66895 <ABSTRACT>The morphology of Lophophyllidium-like genera and their relationships are described and discussed. In early growth stages, Lophophyllidium has a zaphrentoid arrangement of septa with an elongate counter septum; the genus is characterized by a pseudo-columella that is extremely variable in morphology, both ontogenetically and between individuals; septal microstructure is trabecular. The synonymy of Lophophyllidium includes Sinophyllum Grabau, Malonophyllum Okulitch and Albritton, Stereostylus Jeffords, Agarikophyllum Fomitshev, and Khmerophyllum Fontaine; each was originally distinguished on the basis of pseudocolumella morphology. * Timorphyllum differs from Lophophyllidium in ontogeny and microstructure; macrostructural similarities reflect homeomorphy.</ABSTRACT>

- 66934 <ABSTRACT>Late Paleozoic and early Mesozoic fusulinids, sponges, corals, spongiomorphs, brachiopods, bryozoans and other tropical reef organisms of western North America and the former Tethys region share remarkably close similarities over a vast ocean that once separated the two regions. These relationships were an anomaly to earlier workers, who assessed these faunas within the paleogeographic context of Tethys and Pangaea. The nearly exclusive occurrences of these faunas in exotic and displaced terranes of the North America Cordillera, have fueled even greater discussions about paleogeography. Several ideas explain the North American Tethyan connection: 1) Long-range trans-Pacific dispersal of larvae, 2) stepping stones, 3) beached funeral Viking ships, 4) staging posts and Noah's arks, and 5) the Hispanic Corridor. Viable ideas need not be mutually exclusive but must be tested against endemism, diversity trends, and commonality of reef organisms in the former Tethys region and in displaced terranes of western North America. Results must be integrated with data on ecology, climate, sea level change, ocean circulation, terrane movement and global circum-Pacific events in and around the Pacific rim.</ABSTRACT>

67024 <SOURCE>Roy. Scot. Mus., Information Series, Geology 4; 72 pp.</SOURCE>
67025 <ABSTRACT>A catalogue of the Carboniferous corals held within the Royal Scottish Museum, Edinburgh, is given. This cites verified type and figured specimens and also incorporates the reserve collection material, making a total of 2117 specimens with a distribution of 68% from Scotland, 13% from England, 4% from Wales, 1% from Ireland, 1% from the Isle of Man and 13% from the rest of the world. The numerical distribution of species is shown while systematic and locality lists provide two directions of reference. The provenance and identity of each specimen has been authenticated as far as possible in order to establish a comprehensive record. Full references are given according to the World List of Scientific Periodicals 4th Edition and the work represents the first phase of a complete review of the entire collection.</ABSTRACT>

67116 <ABSTRACT>Chaetetids, extinct demosponges, were common frame-builders in small reef mounds during the Middle Carboniferous. Chaetetids from the Coal City Limestone Member (Pawnee Limestone, Middle Pennsylvanian) in Appanoose County, Iowa, contain the remains of a cryptic community attached to the undersurfaces of the colonies. Identified coelobites include the attached brachiopods Cooperina sp., Teguliferina sp., Heteralosia sp., and Composita sp.; the encrusting bryozoans Fistulipora sp. and Metelipora sp.; the holdfasts of fenestrate/ramose bryozoans; the worm Spirorbis sp.; the rugose coral Lophophyllidium sp.; the foraminiferid Tetrataxis; and the boring traces Caulostrepsis and Rogerella l Zapfella. Small echinoid plates and spines are associated with some of these cavities suggesting that they may have also lived there. Cross-cutting relationships reveal no clear pattern of encrustation by these cryptic dwellers.</ABSTRACT>

67127 <TITLE>Paleoecology of Upper Carboniferous Chaetetetes - morphology, growth style, and spatial distribution.</TITLE>
67128 <SOURCE>Courier Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, vol. 2]: 365-372.</SOURCE>
67129 <ABSTRACT>Chaetetetes growth styles correspond to the two most common species. Colonies having a planar growth style and tabular or stacked-tabular columnar morphology correspond to C. milleporaceus. Colonies having an axial growth style and tabular, hemispherical, columnar, or massive to branching compound columnar morphology correspond to C.favosus. Colonies of different growth style do not co-occur; colonies of different morphology do, to a limited extent. Both morphology and growth style are poorly correlated with the major environmental parameters of water depth, water energy, and sedimentation rate. Chaetetetes is infrequent in stratigraphic sections, but is commonly abundant where present, dominating a low-diversity community and forming biostromes. Four spatial distribution patterns can be recognized: scattered small colonies, widely spaced (several m) large compound columnar colonies, patches of colonies in living position, and patches to continuous beds of colonies out of living position except for the last generation. Chaetetetes did not play a binding or encrusting role, nor form reefs. It used a range of other organisms as substrate, but with a generally weak attachment so that concurrent sedimentation was necessary for the colony to remain in living position.</ABSTRACT>

- 67140 <TITLE>New observations on some Carboniferous Heterocorallia.</TITLE>
67141 <SOURCE>Boletín de la Real Sociedad Española de Historia Natural, Sección Geológica 91, 1/4: 163-176.</SOURCE>
67142 <ABSTRACT>Fedorowski (1991) proposed the new subclass Dividocorallia, divided into two orders, the Calyxcorallia and Heterocorallia. Justification for the new subclass is based on a unique method of septogenesis, observed in specimens from the Devonian but not in Heterophyllia and Hexaphyllia, which have simple skeletal elements. New observations on the septogenesis of Carboniferous Heterocorallia by serial transverse sections have revealed that: 1) both the corallite diameter and the number of septa ontogenetically increased stage by stage; 2) all septa had equal potential for bifurcation; 3) septal shifting and detachment frequently occurred during corallite growth; 4) bifurcation began in the external wall. This study casts doubt on the criteria used by some specialists for establishing new taxa in the Heterocorallia.</ABSTRACT>

67192 <TITLE>New offset-associated structures in some Carboniferous rugose corals.</TITLE>
67193 <SOURCE>Lethaia 16, 2: 129-144.</SOURCE>
67194 <ABSTRACT>Tubular structures termed ducts, which extend from the base of offsets axially and upwards through the dissepimental tissue of the parent corallite, are described from some Carboniferous rugose corals. Two ducts are usually associated with each offset, one from each extremity where the offset wall meets that of the parent. The ducts may merge to form a tangentially elongate slit at higher levels in the dissepimentarium of the parent. The structures served to prolong gastric and nervous communication between parent and daughter polyp following budding. Ducts and slits are well developed in cerioid Lonsdaleia but are absent in fasciculate Lonsdaleia, a distinction lending credence to the recognition of the former group of species as a distinct genus, Actinocyathus, within the Axophyllidae. In addition, less well developed ducts are present in at least some cerioid species of Lithostrotion, whereas they are absent from fasciculate species, supporting separation of the latter from Lithostrotion sensu stricto and their assignment to the genus Siphonodendron. The form and distribution of ducts also confirms polyphyly in Thysanophyllum. The separation of T. pseudovermiculare (as Dorlodotia}, without ducts, from Thysanophyllum sensu stricto, with weak ducts similar to those in some Lithostrotion. spp., is supported. Both are assigned to the Lithostrotionidae. T. praedictum has well developed ducts, however, which reinforce other evidence suggesting its removal from Thysanophyllum and classification in the Axophyllidae in close affinity with Actinocyathus.</ABSTRACT>

67219 <SOURCE>Abhandlungen und Berichte für Naturkunde 28: 23-35.</SOURCE>
67220 <ABSTRACT>The taxon Tetralasma Schindewolf 1942 (proposed as a subgenus of Polycoelia King 1849) is evaluated as a clear subjective synonym of Calophyllum Dana 1846. There exists only the not well preserved holotype of its type species Calophyllum quadrisepatum (Schindewolf 1942) from the late Upper Tournaisian Erdbach Limestone of the Rhenish Mountains. Two further records from the same formation in the Harz Mountains (Germany) and from the upper Moscovian of the Buekk Mountains (Hungary) are misidentifications. The original subgeneric diagnosis violated the principles of homology when comparing an unfinished phase of the primary calyx ontogenesis in Tetralasma with final phases of the secondary postcalyx ontogenesis in Calophyllum. Both structures are nothing but successive growth stages within one coral specimen.</ABSTRACT>

67232 <SOURCE>Acta Palaeontologica Polonica 25, 3-4: 467-471.</SOURCE>
67233 <ABSTRACT>In some species of the fasciculate rugosan, Siphonodendron, the morphology of the fossula, columnella and connecting processes is controlled by ecological conditions. A colony in a turbulent environment would have numerous connecting processes, a strong columnella and a well-marked fossula, with a preferential orientation of the corallites if the water movement was in the form of a persistent current. In a quiet environment, the connecting processes are generally absent, the cardinal fossula is indistinct and the columnella is weak or absent. In some species of Diphyphyllum, the morphology of the fossula and the disposition of the corallites are also controlled by ecological conditions.</ABSTRACT>

67244 <TITLE>On lithostrotionelloid corals.</TITLE>
67245 <SOURCE>Acta Palaeontologica Sinica 28, 4: 522-545.</SOURCE>
67246 <ABSTRACT>The lithostrotionelloid colonial corals were put forward representing Stelechophyllum, Aulostylus, Acrocyathus, Petalaxis, Huanglongophyllum, Thysanophyllum, Actinocyathus, Lonsdaleia and Kleopatrina (Porfirievella), which had very similar internal features in corallites and flourished in the Carboniferous, mainly based on Sando 's studies (Sando 1982, 1983). Their coloniality has been discussed, with the conclusion that the fasciculate corals basically

acted on lateral increase and the cerioid on peripheral increase, and that although both of the polyps were similar to solitary corals and with no common tissue between each other in adults, the latter was obviously superior in connection between corallites, intensity of skeleton structure, utilization of all the available space and reduction in the surface area of the exposed skeleton. Also discussed are their axial features, by which most of the lithostrotionelloid genera are distinguished, such as the developed or undeveloped axial tabellae, the axial aulos, septal lamellae or radial carinae, the concentric trace of tabulae, the continuous or discontinuous axial structure, etc. The lithostrotionelloid corals described in the present paper were collected from the Lower Profusionella zone in Nandan, Northern Guangxi, containing 24 species and subspecies (including 7 new species and subspecies) within 5 genera, namely: *Acrocyathus*: *A. pennsylvanicus* (Shimer), *A. hsujiulingi* (Yoh), *A. tingi* (Chi), *A. tingi proliferus* subsp.nov., *A. grechovkae* (Degtyarev), *A. yohi* sp.nov.; *Actinocyathus*: *A. lutugini* (Fomichev), *A. densiconus* (de Groot); *Lonsdaleia*: *L. cf. chutsingensis* (Chi), *L. huangi* Chi; *Petalaxis*: *P. nandanensis* sp.nov., *P. simplex* (Hayasaka), *P. monocyclicus* (de Groot), *P. rosicum* Zjeng, *P. confertus* Kozyreva, *P. sexangulus* (de Groot), *P. major* (de Groot), *P. grootae brevisseptatus* subsp.nov., *P. sinensis* sp.nov.; *Huanglongophyllum*: *H. longhuoense* (X. Yu), *H. elegantum* sp.nov., *H. cf. parasimplex* X. Yu., *H. distans* sp.nov., *H. minor* (Wu et Zhao).

67270 <TITLE>Siphonodendron and Dorlodotia: pedomorphic evolution in Carboniferous rugose corals? </TITLE>

67271 <SOURCE>Courier Forschungsinstitut Senckenberg 164: 127-130. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 1]</SOURCE>

67272 <ABSTRACT>The relationship of early species of Siphonodendron and the recently discovered Dorlodotia in Arundian (Lower Visean) limestones of northern England is examined. The discovery of coralla which possess the morphological characteristics of both genera suggests a closer relationship than has sometimes been supposed. The early ontogenetic stages of Dorlodotia are morphologically similar to adult Siphonodendron which suggests a possible phylogenetic relationship between these genera based on the theory of recapitulation. The stratigraphic distribution of Dorlodotia through the Chadian with

Siphonodendron ranging from Arundian to Brigantian, suggests that reverse recapitulation has occurred as a result of the evolutionary process of paedomorphosis. Only a small change in the ontogeny of Dorlodotia is necessary to produce all of the morphological differences between it and Siphonodendron. A complete phylogeny of lithostrotionids from Chadian through to Brigantian can now be proposed. </ABSTRACT>

67283 <TITLE>Heterochronic processes in some Lower Carboniferous rugose corals.</TITLE>

67284 <SOURCE>Courier Forschungsinstitut Senckenberg 164: 141-152. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, vol. 1]</SOURCE>

67285 <ABSTRACT>Some evolutionary trends in Lower Carboniferous rugose corals, such as changes in corallite diameter or number of septa, and loss or change of colonial increase, correspond to heterochronic processes. This is particularly suggested by lineages in four Visean genera: Siphonodendron, Lithostrotion, Diphyphyllum and Dorlodotia. The evolution giving rise to the genus Lithostrotion is the result of a neotenic process affecting fasciculate colonies of a species of Siphonodendron, probably for better adaptation to turbulent environments. The trends characterized by a decrease in corallite diameter and number of septa and dissepiments in Siphonodendron, Lithostrotion and Diphyphyllum correspond to progenetic processes. The trend characterized by an increase of these characters in Diphyphyllum is due to a hypermorphosis. The rise of Corphalia mosae from Dorlodotia briarti, mainly characterized by a decrease in size and number of septa and the loss of coloniality, corresponds to a progenetic process during a change in the environment.</ABSTRACT>

67309 <TITLE>Semi-daily growth bands in *Bothrophyllum* (?) *proteum* (Rugosa, Upper Carboniferous).</TITLE>
67310 <SOURCE>Courier Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, vol. 2]: 215-222.</SOURCE>
67311 <ABSTRACT>An elementary banding is described along the fibrous wall of *Bothrophyllum* (?) *proteum*, a rugose coral from the Upper Carboniferous of the Bechar Basin (Algeria). Observations in polarizing microscopy and with SEM show a succession of alternate zones composed of fibre bundles, the direction of which is perpendicular to the wall (the narrower F.P. stria) and oblique (the wider P.O. stria). A couple of striae is about 60 µm wide and corresponds to one external minor banding. In analogy with fine ridges described in living and fossil corals, minor bands are supposed to be daily and elementary bands to be semi-daily (P.O. diurnal and P.P. nocturnal). The mean annual growth rate is estimated to be 23 mm.y⁻¹. This rhythm is macroscopically found in a well marked major banding. Elementary striae show a regular and sharp alternation through the coral length. These growth increments represent the lowest time units defined up to now in fossil corals. They will provide, in relation with other growth markings in the same corals, a finer definition of palaeoastronomical cycles and thereby new data on their palaeogeophysical implications.</ABSTRACT>

67336 <SOURCE>Journal of Paleontology 47, 1: 121-135.</SOURCE>
67337 <ABSTRACT>The name *Acrocyathus* d'Orbigny 1849 is a senior synonym of *Lithostrotionella* Yabe and Hayasaka 1915. The name *A. floriformis* d'Orbigny 1849 is a senior synonym of *L. castelnaui* Hayasaka 1936. The genotype of *Acrocyathus* is redescribed. Omaliosoid retreat is defined as progressive shortening of absolute lengths of septa. It is suggested that amplexoid retreat be restricted to its original meaning of describing apparent shortening of septa lying only on upper portions of tabulae. The new septal terms, inner region and outer region, are

- defined to differentiate these amplexoid portions from the persistent medial region. Functional septal morphology of lonsdaleioid and lithostrotionoid corals is discussed. </ABSTRACT>

- 67427 <SOURCE>Palaeontology 52, 3: 569-591.</SOURCE>
- 67428 <ABSTRACT>Lectotypes of Pentaphyllum armatum and P. caryophyllum, both of De Koninck (1872) have been sectioned for the first time and are completely illustrated; both are preserved as silicified outer shells with inner structures dissolved. The morphology of the calices strongly suggests that they have different taxonomic positions. Thus, their synonymy, suggested by Schindewolf (1942), is rejected. P. armatum, selected as type species for the genus by Hinde (1890) possesses six, not five leading major septa. Consequently, all taxa except Hexalasma Soshkina, 1928, and perhaps Pseudocryptophyllum Easton, 1944, are unrelated to Pentaphyllum. It is proposed to restrict the name Pentaphyllum to the lectotype. The well established Cryptophyllum Carruthers, 1919, which includes P. caryophyllum is considered valid. In addition to a brief analysis of Lower Carboniferous corals included here in Cryptophyllum, a few specimens from the British Tournaisian are described and illustrated to show morphological variability of specimens from the same bed. Review of earlier studies on these types of corals, discussion on the difference between zaphrentoid and cryptophylloid early ontogeny and its bearing

- on taxonomy, and description of taxa, are also included.</ABSTRACT>

- 67439 <TITLE>Appearance of fasciculate rugose corals in the Visean and Serpukhovian: A review.</TITLE>
- 67440 <SOURCE>Palaeoworld 19, 3-4: 306-315.</SOURCE>
- 67441 <ABSTRACT>Appearances of new fasciculate rugose corals are especially abundant in the Visean-Serpukhovian interval. Fasciculate corals may have two different origins. (1) Development of colonialism from solitary corals (e.g., *Corwenia* from Dibunophyllum); (2) morphological changes of the established fasciculate taxa that produce new species or genera. Most new fasciculatites occur in shallow-water carbonate shelf environments, but the first occurrence is not always easy to identify from published data. One of the typical environments for their first occurrence during the Visean was the top of microbial mud-mounds. The microbial mounds perhaps have provided isolated areas of shallower water above the sea bottom. These isolated elevated areas could have provided more favourable environments where pioneer coral colonies may have evolved. All Visean and Serpukhovian coral assemblages with new colonial corals are dominated by phaceloid species. Consequently, the explanation should be rejected that new colonial corals occur only in empty ecological niches. Most of these assemblages also contain solitary corals, including the ancestral parent species. * All these observations pose new questions concerning the origin of the fasciculate colonial forms in rugosans. There are evidences that single specimens develop colonial forms as a response to environmental factors. Development of colonialism is possible for single specimens of some solitary genera. However, the capacity for developing persistent colonial growth forms depends on multiple factors, including genetic and environmental ones. [original abstract]

67465 <TITLE>The taxonomic status of the geyerophyllid corals.</TITLE>
67466 <SOURCE>Acta Geologica Polonica 35, 3-4: 277-288.</SOURCE>
67467 <ABSTRACT>The geyerophyllid rugose corals comprise several genera broadly distributed during the Middle and Upper Carboniferous. Their specific and generic variability is so great that some authors have recently considered most of the geyerophyllids as synonyms of the genera Geyerophyllum and Kionophyllum. The present paper analyses the relationships between the solitary geyerophyllid genera in order to prove whether they constitute a simple genus or a true family. In the author's opinion, fully justified is their family status, viz. the Geyerophyllidae Minato 1955.</ABSTRACT>

67532 <ABSTRACT>The wall microstructural composition of the genus *Syringopora* Goldfuss 1826 has been investigated by polished ultra-thin sections from Lower Carboniferous specimens from France and Belgium. The following succession has been recognized from the outer part to the inner part of the wall: a thin cortical layer of fibres and fibroids followed by a slightly thicker layer composed of cupular microlamellae and, finally, by a well-developed periluminal layer of undulating lamellae. The tabulae are lamellar and the septal spines fibrous. These microstructural data should be incorporated in the generic diagnosis of *Syringopora*.</ABSTRACT>

- 67558 <ABSTRACT>The mechanisms of carbonate formation and the possible significance of the decomposition of soft sponge tissue have been investigated in pleoidal and micritic Lower Carboniferous sediments of different depositional environments. Evidence can be found in the calcareous nodules formed around siliceous sponges in the Glencar Formation of northwestern Ireland comprising peloidal and micritic fabrics. Sponge relics found within minipeloidal and micritic fabrics in the basinal crenistria-Limestone of the eastern Rheinische Schiefergebirge suggest their important contribution to the formation of these beds. Sponges are virtually absent from the shallow subtidal and peritidal sediments of England and South Wales. Peloidal and micritic carbonate forming stromatolitic bioherms and biostromes and microbial spars was derived from microbial calcite precipitation consuming organic matter located between the filaments of cyanobacteria.</ABSTRACT>

- 67570 <SOURCE>Bulletin Geological Society of America 101: 377-390.</SOURCE>
- 67571 <ABSTRACT>Geochemical data of the most-altered samples suggest that the diagenetic fluids which affected Boggy sediments and fossils were similar in composition to meteoric water. Moreover, the dissolving aragonite, through diffusion-controlled dissolution, determined the elemental as well as isotopic chemistry of the diagenetic calcite in the altered shells. It is postulated that similar diagenetic waters and processes affected sedimentary units of the Breathitt (Pennsylvanian, Kentucky), Brush Creek (Pennsylvanian, Pennsylvania-Ohio), Lukow (Jurassic, Poland), Bear Paw-Lea Park (Cretaceous, western Canada), and Nugsuaq (Cretaceous, Greenland) Formations which contain well-preserved aragonitic molluscan faunas. - 67648 <SOURCE>Courier Forschungsinstitut Senckenberg 164: 021-036. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 1]</SOURCE>
- 67649 <ABSTRACT>The history of research on Carboniferous and Permian corals, which began with the first published record in 1683, may be divided arbitrarily into three periods: 1) discovery in the 17th and 18th centuries, 2) organization and definition in the 19th c., and 3) development and application in the 20th c. Statistics on the volume of published research, analyzed by decades since 1680, record a progressive increase from decade 23 (1900-09) to decade 30 (1970-79), interrupted by two major declines related to the two world wars. Research production declined in the last two decades (1970-89) and will continue to decline into the 21st c. Data on the geologic age, geography, and demography of the research, and on the development of the main topics of research are also presented.</ABSTRACT>

- 67662 <ABSTRACT>The production history of 803 valid generic (including subgeneric) names for Carboniferous and Permian corals published from 1814 to the end of 1994 is analyzed by means of a computerized data base (GLIST) that includes 1.021 generic names. Production of valid generic names was concentrated in western Europe in the 19th century but shifted mainly to China, USSR/CIS, and USA in the 20th century, where it increased significantly as a result of government-funded paleontologic research in support of expanded exploration for mineral and energy resources after world War II. More than a fifth of the names were produced in China during the decade that began in 1980. Production declined dramatically worldwide after 1989 during downsizing of the paleontologic workforce and a decline in funding for coral research. Assessment of the number of currently acceptable genera is practically impossible because of the subjective nature of genera. Application of quality tests, based on knowledge of the type material of type species and on opinions of generic synonymy, reduces the number of valid names to approximately 300 to 450 that are currently acceptable. More attention must be given to upgrading knowledge of type material in order to provide a firmer foundation for concepts of late Paleozoic biostratigraphy, phylogeny, and biogeography. Chinese generic names

pose a serious problem because they constitute such a large proportion of the total valid names and because many Chinese names are of poor quality. The best solution to this problem is upgrading of these names by the next generation of Chinese specialists.

67675 <ABSTRACT>The senior author has been accumulating references on Carboniferous and Permian corals in a card file since the early 1960s. This card file was updated by searching various bibliographic sources in 1989-1991 to provide data for a paper on the history of late Paleozoic coral research (Sando, in preparation). As the work proceeded, it became necessary to identify various aspects of research in the published papers examined and to devise a system for collating data used to analyze historical trends. This paper describes the computer programs developed by the junior authors and used by the senior author to compile and access the reference file. [introductory part of a short note]</ABSTRACT>

67727 <ABSTRACT>Analysis of the rugose coral fauna of the Carboniferous / Permian transition strata is discussed, with special emphasis on corals from the Pseudoschwagerina Zone. Two distinct realms: the Tethys Realm and the Cordillera-Arctic-Uralian Realm were developed in the Carboniferous-Permian time. Recently Introduced taxonomic, biostratigraphic and paleogeographic data and interpretations are evaluated in terms of their global and regional value. It is postulated that corals have some importance as a supplementary group for establishing the lower limit of the Permian System.</ABSTRACT>

- 67766 <ABSTRACT>By using SEM and optical microscope, the microskeletal structures of some compound rugose corals in the Late Carboniferous and Early Permian (including Protoivanovia, Antheria, Nephelophyllum, Szechuanophyllum, wentzellophyllum, Parawentzellela) from South Guizhou and Central Hunan are studied, and four types of septa are divided: non-trabeculae septa, trabeculate septa (including typical trabeculae and unclear trabeculae), the septa with a trabecula in its axis, and normal fibrous septa. Then the stratigraphic distribution and systematic significance of the microskeletal structures are discussed on the basis of the SEM and optical microscope analysis.</ABSTRACT>

67790 <TITLE>Not Heritschioides in Europe Yet.</TITLE>
67791 <SOURCE>Permophiles 31: 15.</SOURCE>
67792 <ABSTRACT>The colonial rugose coral Heritschioides Yabe 1950 is an index fossil for uppermost Pennsylvanian and Lower Permian marine rocks of western USA plus western and Arctic Canada (Wilson 1980 and later reports by several authors). Kossovaya (1996, 1997) referred to a Late Carboniferous coral from North Timan (NE European Arctic Russia) as Heritschioides aff. H. carneyi Wilson 1982, but did not describe or figure it. H. carneyi originally was described from the Upper Pennsylvanian-Lower Permian McCloud Limestone of northern California. This apparent intercontinental geographic range extension of the genus may not be justified. I have corresponded with Kossovaya (1995) and reviewed photographs of her thin sections of the North Timan coral. The corallites are poorly preserved and somewhat crushed and the short cardinal septum, an obligatory character for the Family Heritschioidae Sando 1985, is not observable. The coral, therefore, cannot be firmly referred to Heritschioides. Furthermore, Kossovaya's coral is so unlike H. carneyi in numbers of septa and lengths of minor septa that it cannot be placed in the same species group (Wilson 1982: fig. 17) even if it did belong to the genus. Firm identification of the North Timan coral awaits examination of better preserved specimens. Until then, this range extension of such an important index coral genus should be regarded with caution.</ABSTRACT>

67817 <SOURCE>Jap. Journ. Geol. and Geog. 41, 1: 1-14.</SOURCE>
67818 <ABSTRACT>In terms of coral distribution in the Upper Paleozoic, two major biogeographic provinces may be recognized: waagenophyllidae and Durhaminidae Provinces. The Waagenophyllidae Province corresponds to the so-called Tethys, and is conceivable to have been a tropical sea region stretching from east to west. On the other hand, the Durhaminidae Province was situated further north, and may have been

probably subtropical. In contrast there was an Eurydesma Province in the southern hemisphere, which was characterized by a colder fauna almost lacking corals. Synopsis of the classification of waagenophyllidae and Durhaminidae, together with their phylogenetic relations, are briefly presented.</ABSTRACT>

67829 <TITLE>Revision of Lithostrotionella (Coelenterata, Rugosa) from the Carboniferous and Permian.</TITLE>

67830 <SOURCE>US Geol. Survey Prof. Pap. 1247: 1-52.</SOURCE>

67831 <ABSTRACT>Species of predominantly massive colonial rugose corals from the Carboniferous and Permian that were referred previously to Lithostrotionella Yabe & Hayasaka are reassigned to the following genera: Acrocyathus d'Orbigny (including probable junior synonym Lithostrotionella Yabe & Hayasaka), Stelechophyllum Tolmachev (including junior synonym Eolithostrotionella Zhizhina), Petalaxis Milne-Edwards & Haime (including junior synonym Hillia de Groot and Eastonoides Wilson & Langenheim), Aulostylus Sando, Kleopatrina McCutcheon & Wilson, Lonsdaleia McCoy (subgenus Actinocyathus d 'Orbigny), and Thysanophyllum Nicholson & Thomson. One of the species referred to Cystolonsdaleia Fomichev is reassigned to Petalaxis. * Stelechophyllum and Aulostylus are referred to the Family Lithostrotionidae d'Orbigny. A new Family, the Acrocyathidae, is created for the genus Acrocyathus. Petalaxis is placed in the Family Petalaxidae Fomichev, Thysanophyllum and Lonsdaleia are referred to the Family Lonsdaleiidae Chapman, and Kleopatrina is assigned to the Family Durhaminidae Minato & Kato. * The principal lithostrotionelloid genera are Stelechophyllum, Aulostylus, Acrocyathus, and Petalaxis. Stelechophyllum ranges in age from Late Devonian(?) into the late Visean and is represented in the Carboniferous by 15 nominal species allocated to five species groups; the genus occurs in the USSR, USA, Canada and Mexico. Aulostylus is represented by two middle Tournaisian species in the USA and Canada and a possible species from the Visean of China. Acrocyathus is represented by 14 nominal species (one new) from the lower to upper Visean of the USSR, USA, Canada and China. Petalaxis is represented by 41 nominal species (six new) allocated to five species groups that range from the upper Visean into the Permian; the genus occurs in the USSR, USA, Canada, Spain, Japan, and possibly China and Spitzbergen. * Stelechophyllum may have been derived from Endophyllum in the Devonian. Aulostylus, Acrocyathus and Petalaxis are regarded as offshoots from the Stelechophyllum stock in the Carboniferous. Lonsdaleia, Thysanophyllum and Kleopatrina do not seem to be closely related to Stelechophyllum and its derivatives. Hayasaka 's type specimen of Lithostrotionella species from North America are reassigned to Acrocyathus, Stelechophyllum, Petalaxis and Aulostylus and are revised specifically. Three new species and two new subspecies are based on specimens studied by Hayasaka. [original summary]</ABSTRACT>

67842 <TITLE>On Pentamplexus Schindewolf, 1940 (Anthozoa, Rugosa) and its possible relatives and analogues.</TITLE>
67843 <SOURCE>Palaeontology 52, 2: 297-322.</SOURCE>
67844 <ABSTRACT>Three ampleximorphic taxa are revised and their most important characters are discussed in terms of possible or apparent relationships. Re-interpretation of its early ontogeny allows the assignment of Pentamplexus Schindewolf, 1940 to the family Polycoeliidae de Fromentel, 1861. Stereolasma variabilis Vojnovsky-Krieger, 1934 is established as the type species of Vojnovskytes gen. nov. It resembles the family Polycoeliidae in some characters and the Antiphyllidae Ilina, 1970 or the Laccophyllidae Grabau, 1928 in others. Thus, its family status is not established. Revision of the type material of Fasciculophyllum tripus Schindewolf, 1952 allows its inclusion within the new genus Silesamplus, probably related to the family Laccophyllidae Grabau, 1928. Amplexoid morphology is further shown to be inadequate for the establishment of relationships on the family or subfamily level. Early ontogeny is most important in that respect, but biform vs normal morphology in the tabularium and free vs contratingent development of minor septa must also be considered, where appropriate.</ABSTRACT>

67855 <TITLE>A new synthesis of Permo-Carboniferous phylloid algal reef ecology.</TITLE>
67856 <SOURCE>SEPM Special Publications 78 / AAPG Memoir 83 (Permo-Carboniferous carbonate platforms and reefs): 171 -188.</SOURCE>
67857 <ABSTRACT>The phylloid algal genera Eugonophyllum and Archaeolithophyllum are common constituents of Virgilian and Wolfcampian reef limestones in the Hueco Mountains of Texas. These algae form bioherms and biostromes and are volumetrically important contributors to both the reef and offreef sediment budget. Reefs constructed by phylloid algae have long been considered as ecologically simple communities that lack dominant framebuilding organisms. The previously accepted constructional mechanism for reef formation has been inferred to be sediment baffling and trapping, mainly by erect phylloid algae. This new, detailed analysis of phylloid algal growth framework, however, clearly shows that these algae were in fact capable of forming a rigid framework. Phylloid algae, mostly Eugonophyllum, together with the problematicum Tubiphytes and the red alga (?) Archaeolithoporella, formed complex, multiple encrustations (both in vivo and post mortem) and were a fundamental element of reef construction. Much of the micrite in these reefs, often regarded as a sediment, has been identified as microbialite; this microbialite is important in binding and stabilizing the initial reef framework created by the phylloid algae. A dominant ecological succession was identified from the Eugonophyllum communities: (1) a pioneer community of phylloid algae would initially stabilize the substrate; (2) this would enable an encrusting community of mostly Tubiphytes, Archaeolithoporella, and microbialite to develop, followed by (3) a climax community of larger calcisponges. In the Archaeolithophyllum communities, the thalli were largely constratal (organisms not substantially elevated above the substrate) and lacked any obvious microbialite association. The

- resultant Archaeolithophyllum communities therefore did not develop any significant depositional relief and thus formed biostromes. [original abstract]

67870 <ABSTRACT>During the Carboniferous, changes in the biogeographical distribution of shelf-dwelling, benthic marine invertebrates were made in response to changes in physical paleogeography and climatic variations. Calcareous foraminifers and bryozoans are principal examples of the general trends during the Early Carboniferous, which show that Tournaisian and early and middle Visean faunas were broadly cosmopolitan in a circum-equatorial belt and that latitudinal diversity gradients were relatively minor. During the later part of the Visean and early part of the Namurian, the Hercynian orogeny, caused by the collision of Euramerica with Gondwana, disrupted these cosmopolitan equatorial faunal patterns. This was also a time of progressively cooler temperatures throughout the world, of dramatic reduction in faunal diversity, and of high rates of extinction of both species and genera.</ABSTRACT>

67894 <TITLE>Annotated checklist of post-Devonian "stromatoporoid" genera and their type species.</TITLE>
67895 <SOURCE>FC&P 21, 1.2: 1-22.</SOURCE>
67896 <ABSTRACT>We do not regard the post-Devonian "stromatoporoids" covered in the present paper as monophyletic. Indeed, spicule findings clearly indicate that even calcified demosponges are a polyphyletic group (eg. wood, Reitner & west 1989). The following checklist

includes all calcareous fossils from Carboniferous through Cretaceous-age rocks that have been referred to as stromatoporoids, sphaeractinoids, hydrozoans, spongiomorphids, or hydractinids, and Tertiary-age fossils referred to specifically as stromatoporoids. Chaetetids, certain tabulatormorph hydrozoans, and genera designated as sclerosponges are not included in the checklist. [fragment of introductory part; the checklist is accompanied by 73 annotations and by 152 literature references]

67946 <TITLE>Trachypsammia Gerth 1921 (Cnidaria, Permian): new data on the structure and microstructure.</TITLE>
67947 <SOURCE>Courier Forschungsinstitut Senckenberg 164: 347-358. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 1]</SOURCE>
67948 <ABSTRACT>The four Permian species hitherto assigned to the genus Trachypsammia Gerth 1921 have been revised; they are from Timor, Xizang (Tibet), and Sicily. They share the same morphological and microstructural characters. Trachypsammia shows, from the center towards the periphery, the following zones: 1) the lumen of the central corallite; 2) a medullar zone, composed of radial fibres, with trabeculae and centripetal growth; 3) an annular zone, composed of trabeculae showing distal growth direction; 4) a canalicular zone, with a network of vertical canals connected by horizontal tubules; 5) a large cortical zone of numerous trabeculae with a serrate longitudinal outline and a square cross-section, showing centrifugal growth, arranged in vertical plates and surrounded by a fibrous stereoplasm disposed into two layers. These trabeculae correspond to the longitudinal flexuous files of granulae observed between the scattered calices on the surface of the branches. These peculiarities emphasize the affinities of Trachypsammia to the genus Palaeacis Haime in Milne-Edwards 1857 and assignment to the family Palaeacidae Roemer 1883, in a somewhat indefinite position within the evolution of the Cnidaria. The previously supposed affinities with Hexacorallia can be rejected, those with Octocorallia are worked out.</ABSTRACT>

67960 <SOURCE>Geobios 27, 4: 421-432.</SOURCE>
67961 <ABSTRACT>The increase in Trachypsammia dendroides Gerth 1921 from the Permian of Timor is studied by serial acetate peels. Its main features are as follow: the lumen of the bud originates from one or two units of the canalicular zone of the parent-corallite, the canal system of the bud proceeds from those of the parent-corallite, during the early stage of increase the new corallite is connected with the parent-corallite, the bud is always located on the back of the parent-corallite. The increase is described as "intra-canalicular", it is quite different from the lateral increase dominant in the Tabulata sensu stricto but it looks like that of the Octocorallia.</ABSTRACT>

- 67986 <SOURCE>Zeitschrift der geologischen Wissenschaften 7, 11: 1315-1341.</SOURCE>
- 67987 <ABSTRACT>Ampleximorphous Plerophyllidae are revised both morphologically and taxonomically. Using the length of the cardinal septum as diagnostic feature, two separate genera may be accepted: Paracania Chi 1973 (Kasimovian - Dzhulfian), and Pentamplexus Schindewolf 1940 (Leonardian - Dorashamian). The former includes the subjective junior synonyms Pleramplexus Schindewolf 1940, and Pseudobradyphyllum Dobrolyubova 1940; its ancestor is Ufimia Stuckenberg 1895 (with synonym Tachylasma Grabau 1922). The latter descends from Pentaphyllum de Koninck 1872 (with synonyms Plerophyllum Hinde 1890, and Cryptophyllum Carruthers 1919). The much enlarged record of assigned species (24 valid names, nine species named in open nomenclature) is an uncritical compilation without attempts to improve the present unsatisfactory state of taxonomy at the specific level. The holotype of Pentamplexus simulator Schindewolf 1940 (Leonardian of Timor Island) is described. New topotypes of Paracania nikitini (Stuckenberg 1888), Paracania variabilis (Soshkina 1941), and Pentamplexus leptonicus (Abich 1878) are figured (Gzhelian and Kazanian of Russian platform, Baisalian of Armenia). Holotype illustrations of three probably middle Permian Chinese species of Paracania (sinensis, kaoi, grabau) are reproduced from the generally inaccessible paper of Chi (1937), using emended identifications of protosepta. Paracania and Pentamplexus are common members of Permian Rugosa communities of Cyathaxonia facies type, with a wide regional distribution throughout the palaeotethys and the boreal realm of Eurasia. These corals are typical Rugosa (four points of septal insertion according to the law of Kunth, origin of new septa from bipartition of old major septa). Orientation of septal apparatus is indicated by bifurcated tabulae. Though originating each in but one genus, both Paracania and Pentamplexus are polyphyletic taxa. (original summary) </ABSTRACT>

68011 <TITLE>The First Aragonitic Rugose Coral.</TITLE>
68012 <SOURCE>Journal of Paleontology 64, 3: 335-340.</SOURCE>
68013 <ABSTRACT>Microstructural and compositional data support the view that the skeletons of rugose corals consisted of (probably high-Mg) calcite, unlike the skeletons of scleractinian corals which are predominantly aragonitic. Total transformation of a late Permian rugose coral skeleton into neomorphic calcite and a significant trace element composition, however, show that aragonite was present in some Rugosa shortly prior to the extinction of this order. This finding sheds new light on the possible phylogenetic relationship between Rugosa and Scleractinia, which still possess a different mode of septal insertion and remain separated by an as yet coralfree interval in the Lower Triassic.</ABSTRACT>

68024 <TITLE>Diachronism in the development and extinction of Permian Rugosa.</TITLE>
68025 <SOURCE>Geologos 2: 59-164.</SOURCE>
68026 <ABSTRACT>The formation of Pangea resulted in an unique global geography which in turn influenced the distribution, development and extinction pattern of the Rugosa. Free connection between the main oceans existing up to the Gshelian allowed common roots to develop for several Permian rugosa coral lineages. Two of those lineages, represented by four large families (Kepingophyllidae - waagenophyllidae in the East and Durhaminidae - Hetitschioididae in the west) appeared as early as the Bashkirian-Moskavian but were permanently restricted geographically to become characteristic of two distinct faunal realms which appeared near the end of the Carboniferous as a result of the formation of Pangea. These realms were: (1)The Cordilleran-Arctic-Uralian Realm, extending from the Ural Mountains along the northern and western shelves of Pangea and including carbonate oceanic platforms (future American accreted terranes), located not far off shore in the Palaeopacific Ocean, (2) The Thetys Realm, extending westward from China and Indochina to Tunisia. The history of development and extinction of rugosa coral faunas in the two realms was almost totally different in timing and faunal content. [first part of extensive summary].</ABSTRACT>

68037 <TITLE>The Permian rugosan Huayunophyllum: ist phylogenetic

- relationship and implications for extinction patterns of Rugosa.</TITLE>
68038 <SOURCE>Biotic and Geol. Develop. Paleo-Tethys in China 63-71.</SOURCE>
68039 <ABSTRACT>The Late Permian Rugosa were characterized by the presence of Middle Permian holdovers, and some of them survived into the latest Permian. The colonial waagenophyllid waagenophyllum (Huayunophyllum, with its simple axial structure and wide transverse tabulae, occurs as high as the uppermost Permian. Huayunophyllum is treated as a cohesive group at the supraspecific level, and its ancestor should be Waagenophyllum (Liangshanophyllum). The morphological simplicity, stress-resistant forms, would have enabled that group to survive the end-Maokouan crisis into the latest Permian. Provisional strategies might have been adopted by each Late Permian representative but only within restricted phylogenetic constraints characteristic of the Rugosa. However, the Rugosa became extinct just prior to the end of the Permian, since extremely large-scale environmental deterioration far exceeded their adaptive abilities. A new species of Huayunophyllum from the upper part of the Middle Permian of Guangxi, China, is described herein as waagenophyllum (Huayunophyllum) taipingense.</ABSTRACT>

68050 <TITLE>Die Entwicklung der rugosen Korallen im hohen Perm.</TITLE>
68051 <SOURCE>Verh. Geol. B.-A. 1: 146-161.</SOURCE>
68052 <ABSTRACT>During the Upper Permian the evolution of the Rugosa shows a gradually disappearance of the genera (tab 2) after a kind of evolution characterized by the survival of the primitive forms. Firstly the genera with the most complicate morphology die out, as for instance the cerioid form with dissepiments (Wentzelella, Maoriphyllum e.g.) or with dissepiments and presepiments (Polythecalis). The next step is the extinction of the fasciculoid genera with dissepiments (waagenophyllum, Liangshanophyllum e.g.) and the forms with a septal columella (Lophophyllum). Therefore the highest faunas of the Permian (Plerophyllum-fauna) comprise only solitary corals with a primitive skeletal morphology (Ufimia, Plerophyllum, Pleramplexus, Cryptophyllum e.g.) (tab 3). It is interesting that elements of this primitive Plerophyllum-fauna occur firstly in the Lower- and Middle Devonian. But in this time and also in the Carboniferous we find these genera only locally in ecologic niches, especially in sediments of deeper water. Firstly in the Lower and Middle Permian forms of the Plerophyllum-fauna appear worldwide besides the other rugose corals. The last named corals disappear during the Upper Permian: In the Yabeina-zone we still know some Rugosa from Greenland, China, Japan, Cambodia, New Zealand, Near East and other localities however in the following Codonofusiella-zone they appear only in Hungaria, Jugoslavia, Near East, China and NE-Siberia. In the uppermost Permian time, the Palaeofusulina-zone, we find only genera of the Plerophyllum-fauna and these forms only in the central region of the Tethys between Iran and Nepal. The last 2 species of Plerophyllum and Pleramplexus, die out in the lower part of Triassic of Djulf. </ABSTRACT>

68076 <TITLE>Paleoecological and phylogenetic implications of asexual reproduction in the Permian scleractiniamorph Numidiaphyllum.</TITLE>
68077 <SOURCE>Journal of Paleontology 78, 1: 84-97.</SOURCE>
68078 <ABSTRACT>Numidiaphyllum is one of the Paleozoic scleractiniamorphs. The genus is characterized by a poorly integrated, uniserial fasciculate form with an epithecal wall and simple morphological traits. Parent corallites are divided into several daughter corallites using one mode of division among several theoretically possible alternatives. Bipartite increase is most common, followed by hexapartite and then tripartite increase. Daughter corallites possess relatively large diameters from the beginning, along with a robust colonial pattern. This parricidal increase caused the morphologies of both parent and daughter corallites to be greatly altered and to show high morphological variability. Foreological and structural reasons, co-occurring daughter corallites generally are equal or subequal in size. Daughter corallites initially show a bilateral symmetry in both outline and septal arrangement during the course of hystero-ontogeny. However, this symmetry results only from structural necessity and is transitory. It is not homologous with the bilaterality of body plans characteristic of anthozoan groups. The morphological simplicity, related parricidal reproduction, and resulting poorly integrated growth form as seen in Numidiaphyllum, all suggest conservative features that could have resulted from phylogenetic antiquity within the scleractiniamorph body plan. Those generalized features are not themselves related to immediate phylogenetic relationships with any simply constructed rugosan group, nor would they have been due to surrounding, stressful ecologic conditions. They may have been phylogenetic-specific.</ABSTRACT>

68117 <ABSTRACT>while this specimen [stdied by the author] represents only a single "sample", nevertheless, we can say that tabulae do not confirm cnidarian affinity, and that lack of fusion of the walls despite extensive lateral contact are cause to question that a specimen is a coral. The wrapping of tubes around other tubes also appears to be a feature found among worm-tubes, but not generally expected among cnidarians. [concludes Laub his short note on dubious colonial annelids or tabulate corals]</ABSTRACT>

68141 <TITLE>Middle and Late Permian Reefs - Distributional patterns and reservoir potential.</TITLE>
68142 <SOURCE>SEPM Special Publications 72: 339-390.</SOURCE>

- 68143 <ABSTRACT>Important Permian reefbuilders are microbes, Archacolithoporella, Shamovella (formerly Tubiphytes), coralline sponges, rugose corals, calcareous algae, bryozoans, and brachiopods. Algal-cement reefs with various percentages of microbial precipitates are a common reef type, lacking only in the high latitudes, and have a cosmopolitan character; Shamovella, Archaeolithoporella, and sponges are common and widespread reefbuilders. * Permian reef evolution is discontinuous and characterized by pulses of growth as well as the final demise of late Paleozoic communities followed by the severe gap without true metazoan reefs during the Scythian. The end-Permian mass extinction is twofold, comprising a pre-Lopingian and a Changhsingian event. The latest Permian reefs are restricted to the equator and are characterized by high diversities. Intercalated sediments enriched in calcareous algae indicate global warming. [fragments of extensive summary]</ABSTRACT>

68181 <SOURCE>Acta Palaeontologica Polonica 34, 1: 47-70.</SOURCE>
68182 <ABSTRACT>The Permian stage of evolution within Rugosa and Tabulata took place in two distinct realms, isolated by the Palaeo-Pacific Ocean and the Pangea: the Palaeo-Tethys Realm and the Cordillera-Arctic-Uralian Realm. The corals discussed disappeared from the first Realm in the upper part of the Changxingian Palaeofusulina sinensis Subzone and from the second one in lower Djulfian. The fairly long time span between these events excluded acting of any rapid and common factor. The combined effect of global factors such as lowering of sea level and warming of climate and local factors such as tectonics, currents, absence of carbonate banks, etc. led to the successive disappearance of corals from individual areas of realms. The Chinese microcontinent was the last area colonized by corals.</ABSTRACT>

68219 <TITLE>The development of reefs across the end-Permian extinction.</TITLE>
68220 <SOURCE>Jour. Geol. Japan 101, 11: 857-865.</SOURCE>
68221 <ABSTRACT>Late Permian stratigraphic reefs, constructed by calcisponges and algae, survived into the latest Permian in a few tropical refuges,

indicating the continuation of favourable conditions for reef formation. However, all kinds of reefs collapsed prior to the large-scale biotic crisis of reef-dwelling and level-bottom communities at the Permian-Triassic boundary. This affected even the tropical refuges. Different elements of the reef-forming biota showed distinct patterns of extinction. Whatever the main causes of biotic decline, the reefs did not disappear at the very end of the Permian catastrophically, but had already been strongly affected by the extinction in the Midian (late Guadalupian). Reefs were not developed until Anisian (Middle Triassic), and at that time radiolarian bedded chert also began to be formed commonly in pelagic environments, indicating global removal of the protracted inhibiting conditions in the ocean. The main reef-builders and their role in reef communities are similar in both Late Permian and Middle Triassic reefs. However, the community structure was later modified by a change in domination among components, such as Scleractinia which acquired algal symbiosis and more efficient skeletal growth. Long-lasting unfavourable marine environment on a global scale, rather than the severity of the end-Permian extinction itself, hindered biotic recovery everywhere during Early Triassic time despite the presence of Permian holdover groups as potential organisms for reef-building. Both external environmental and biological factors acted together in delaying Triassic reef development. The end-Permian extinction resulted in the restructuring of reef-forming biota in the Middle Triassic from Permian survivors rather than the introduction of a new community.</ABSTRACT>

 68232 <TITLE>Permian-Triassic boundary interval as a model for forcing marine ecosystem collapse by long-term atmospheric oxygen drop.</TITLE>
 68233 <SOURCE>Geology 31, 11: 961-964.</SOURCE>
 68234 <ABSTRACT>Ecological traits of reefs across the Permian-Triassic boundary interval coincide with a modeled decline of atmospheric oxygen throughout the Permian Period. Selective extinction and recovery patterns within the reef system are observed both at the end of the middle Permian (end-Guadalupian) and at the Permian-Triassic boundary. The end-Guadalupian event selectively affected corals and broke down the cool-water carbonate factory. Sponges, however, were largely unaffected and bloomed in reefs toward the end of the Permian. The end-Permian total destruction of the metazoan reef system only left behind poorly diverse microbial communities. The temporal reef patterns are thus similar to spatial patterns of modern benthic communities approaching oxygen minimum zones. This observation suggests that a decline in oxygen concentrations was at least partly involved in the destruction of reefs, even where there is no direct evidence of oceanic anoxia. - 68286 <ABSTRACT>A series of samples, mostly of compound and solitary coral skeletons from Middle-Upper Triassic strata (San Cassiano strata) near

Cortina d'Ampezzo (Dolomites, Italy) have been analyzed by X-ray diffractometric and spectrophotometric method. * All the Triassic samples appear entirely composed of aragonite, with a high strontium content (7000-8000ppm) and absence of magnesium. The matrix is a compact pelmicrite, entirely calcitic, with 2.04% of magnesium. * The amount of strontium is roughly correspondent to the strontium concentration in living corals. * Strontium concentration of 7000-8000ppm cannot be responsible for aragonite preservation under subaerial conditions, at normal temperature and pressure, for more than 200 million years. The pelmicritic matrix cannot be interpreted as a cause of inhibition of aragonite inversion to calcite. * Only the highly developed fabric and texture of the skeleton and probable occurrence of organic material can explain the long preservation of both original skeletal tissue and mineralogical and chemical composition. * A paleoclimatologic inference on the base of aragonite/strontium ratio correspondent to warm water corals cannot be attempted since cold and/or deep water corals analyzed in the present study appear to have the same strontium content. Only the bahamitic character of the matrix and the luxuriant fossil community of the outcrops near Cortina may justify the supposition of a tropical environment and certainly a warm and shallow water deposit. </ABSTRACT>

68310 <TITLE>Middle Triassic coral growth bands and their implication for photosymbiosis.</TITLE>

68311 <SOURCE>Palaios 25, 12: 754-763.</SOURCE>

68312 <ABSTRACT>In living zooxanthellate corals, photosymbiosis explains increased metabolism and accelerated skeletal growth, accounting for the success of these corals in shallow-water tropical reefs. Mesozoic corals of the order Scleractinia appeared in the geologic record during the Middle Triassic, but it was not until the Late Triassic that these corals became prominent reef builders - a change hypothesized to coincide with the advent of photosymbiosis. There is considerable discussion, however, concerning algal symbiosis and the timing of their co-evolution with corals. Thus, the beginning of photosymbiosis in the earliest corals of the Middle Triassic has not been established, nor whether their paleoecology was similar to that of modern corals. Many massive colonial reef-building corals lay down thick, discrete bands in their skeletons that record annual growth. We discovered and illustrate here growth bands in Middle Triassic corals from central Nevada, in

particular *Cerienstella variabilis*, whose skeletal structure and bands are well-preserved in Middle Triassic biostromes of central Nevada. To test the photosymbiosis hypothesis we studied colony growth forms in these fossil corals and performed a quantitative analysis of the bands, both in *C. variabilis* and in a morphologically similar living zooxanthellate reef coral, *Montastraea faveolata*. Results of these analyses revealed growth bands and colony shapes almost identical in both living and fossil corals. These findings suggest that photosymbiosis was present in Middle Triassic corals at a very early stage in their Mesozoic history. Scleractinians were also likely zooxanthellate from the onset of their Middle Triassic occurrence but for unexplained reasons were not as efficient as modern corals in building reefs. 68323 <TITLE>Evolution of the coral-zooxanthellae symbiosis during the Triassic: a geochemical approach.</TITLE>

68324 <SOURCE>Paleobiology 21, 2: 179-199.</SOURCE>

68325 <ABSTRACT>Scleractinian corals first appeared during Triassic time in tropical shallow water environments. Controversy surrounds the paleoecology of scleractinian corals of the Late Triassic. Were they like their living counterparts, capable of supporting reefs, or had they not yet coevolved the important association with zooxanthellae that facilitated reef growth and construction? Indirect evidence suggests that some upper Triassic corals from the Tethys played important constructional roles as reef builders within tropical carbonate complexes of the Tethys. To evaluate this idea, we have employed a geochemical approach based on isotope fractionation to ascertain if Late Triassic corals once possessed zooxanthellae. We have determined evidence for the ancient presence of algal symbiosis in 13 species of Triassic scleractinians from reef complexes in Turkey and northern Italy. In contrast, two higher latitude Jurassic species used as a control group for isotope analysis, lacked isotopic indications of symbiosis. These findings, together with stratigraphic and paleoecologic criteria, support the contention that Late Triassic scleractinian corals inhabiting shallow-water carbonate complexes of the Tethys were predominantly zooxanthellate, like their living counterparts from present day reefs. We view the zooxanthellate condition in calcifying reef organisms as a necessary prerequisite for constructional reef development. Our results emphasize the power of stable isotope studies in helping to answer paleobiological questions.</ABSTRACT>

68338 <ABSTRACT>The calcitic skeleton of Triassic Demospongiae produces intense fluorescent radiations when they are exposed to UV (365 nm) under the microscope. This fluorescent light has been analysed by spectrophotometry, and the skeletal response is also correlated with data obtained by X-rays mapping. These results suggest that UV epifluorescence can be used for in situ characterization of the skeletal carbonate materials in fossils, and also, after further analysis of the emission parameters, for research dealing with their diagenetic evolution.</ABSTRACT>

68375 <TITLE>Enhanced skeletal details and diagenetic processes of Triassic corals revealed by cathodoluminescence.</TITLE>
68376 <SOURCE>Courier Forschungsinstitut Senckenberg 164: 339-346. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, vol. 1] </SOURCE>
68377 <ABSTRACT>Triassic scleractinian corals from the Zlambach Marls of Austria and the Cassian Formation of northern Italy, display various diagenetic transitions, from unaltered original skeletal aragonite to neomorphic calcite. Many neomorphosed specimens contain calcitized

aragonite needle structures, whereas others are either totally recrystallized or are in transition to coarse neomorphic spar. In most samples, the relic microstructure is so obliterated as to preclude taxonomic study. We applied cathodoluminescence (CL) to thin sections of these diagenetically altered corals. CL not only aided in understanding the process of diagenetic replacement but also allowed original details of skeletal structures to be distinguished even in some of the most recrystallized specimens. The application was also successful with severely recrystallized Triassic corals from Nevada. Diagenetic alteration appears to have taken place by selective, preferential solubility of aragonite (and later neomorphic calcite skeletal elements) over calcite of the void cements. In carbonate material, Mn is the trace element responsible for producing the characteristic red-orange luminosity on CL where Fe may be a quencher affecting intensity. Mn and Fe concentration gradients remain distinct in the void and pore-filling cements of these corals and significant amounts are not incorporated into the skeletal elements during neomorphic alteration. Our research has direct application in taxonomy and systematic study of fossil corals. It shows the utility of CL techniques in distinguishing lost microstructure in a variety of scleractinians. CL is an important but neglected tool in systematic study of diagenetically altered fossil corals.

68389 <SOURCE>Geobios 26, 4: 405-412.</SOURCE>

68390 <ABSTRACT>Among Triassic Scleractinia, three distinct architectural types of porous skeletons can be recognized: discontinuity between adjacent trabeculae in Araiophyllum; contraction of the septal plane in the Spongiomorphid family; occurrence of lacunae in the vertical growth of septa in representatives of the genus Seriastraea. The comparison of structural and microstructural features between these three architectural organizations provides evidences for their very unequal values from taxonomic point of view. However, the presence of these various trends to realize porous architectures among Triassic corals, demonstrates the importance of the evolutionary process at this period, before the strong taxonomic collapse of the Trias / Lias boundary.

68453 <TITLE>Triassic roots of the Amphistraeid Scleractinian corals.</TITLE>
68454 <SOURCE>Journal of Paleontology 75, 1: 34-45.</SOURCE>
68455 <ABSTRACT>The early Carnian (Upper Triassic) phaceloid coral originally

described by Volz (1896) as *Hexastraea fritschi*, type species of *Quenstedtiphyllia* Melnikova, 1975, reproduced asexually by *Taschenknospung* (Pocket-budding), a process documented herein for the first time. This type of budding is recognized only in the *Amphiastraeidae*, a family thus far recorded only from Jurassic-Cretaceous strata. Similar to *amphiastraeids*, *Quenstedtiphyllia fritschi* (Volz, 1896) has separate calcification centers and a mid-septal zone built of serially arranged trabeculae. The most important discriminating characters of the new *amphiastraeid* subfamily *Quenstedtiphyllinae* are one-zonal endotheca and radial symmetry of the corallite in the adult stage (in contrast to two-zonal and bilateral symmetry in the adult stage in *Amphiastraeinae*). *Quenstedtiphyllia fritschi* shares several primitive skeletal characters (plesiomorphies) with representatives of Triassic *Zardinophyllidae* and, possibly, Paleozoic *plerophylline rugosans*: e.g. thick epithecal wall and strongly bilateral early blastogenetic stages with the earliest corallite having an axial initial septum. To interpret the phylogenetic status of *amphiastraeid* corals, we performed two analyses using *plerophylline rugosans* and the solitary scleractinian *Protoheterastraea*, respectively, as the outgroups. The resulting phylogenetic hypotheses support grouping the *Zardinophyllidae* with the *Amphiastraeidae* in the clade *Pachythecaliina* (synapomorphy: presence of *pachytheca*). *Taschenknospung* is considered an autapomorphy for the *Amphiastraeidae*. This study is the first attempt to analyse the relationships of the Triassic corals cladistically. </ABSTRACT>

68506 <SOURCE>Paleontologicheskii Zhurnal 1971, 2: 21-35.</SOURCE>
68507 <ABSTRACT>An exposure of skeletal structural details and microstructure in the genus Astraeomorpha is given for the first time. A revision of morphological features and the microstructure of the skeleton of the Upper Triassic genus Thamnasteria has permitted the distinction of two independent genera: Thamnasteriomorpha gen. nov. (type-species Thamnastraea frechi) and Pamiroseris gen. nov. (type-species Thamnastraea meriani). The genus Thamnasteriomorpha is close to Astraeomorpha and both belong to the family Astraeomorphaeidae; a diagnosis of this family and the distribution of its genera is given. The generic type species of Astraeomorpha is described in detail as well as the new species A. multisepta and Th. dranovi. Skeletal features and septal microstructure place Pamiroseris in the family of Thamnasteriidae. The type-species of this genus is described in detail.</ABSTRACT>

</TITLE>
68545 <SOURCE>Memorie di Scienze Geologiche 46: 245-253.</SOURCE>
68546 <ABSTRACT>The finding of ferroan calcite pseudomorphs of spicules within the aragonitic basal stromatoporoid skeleton of *Stromatowendtia triassica* n.gen. n.sp. indicate the poriferan affinity of this Triassic form. A new Family, the *Stromatowendtidae*, is erected for the unique combination of the spicular skeleton and irregular aragonitic microstructure of the secondary calcareous skeleton. On the basis of spicule type and organization, together with the apparent absence of microscleres, the new family is tentatively assigned to the Order Halichondrida. The secondary calcareous skeleton is preserved in its original mineralogy with a relatively high Sr content (7,000 - 8,000 ppm). The microstructure is of irregular type like that of the living sphinctozoan *Vaceletia crypta* (Vacelet). The biomineralization process of the vertical elements, the pillars, occurred in sealed off spaces delineated by phragmas, now observable as discontinuities or remains of insoluble organic matrix. The incipient diagenesis of aragonitic skeleton is minimal and of aggrading type. We recognized two cements filling intraskeletal cavities: a primary marine isopachous cement consisting of aragonite crystallites that grow on the skeletal tissue, and a late cement of blocky anhedral ferroan calcite engulfing the primary and/or the calcareous skeleton.</ABSTRACT>

68557 <TITLE>Evolution of Triassic reefs: current concepts and problems.
</TITLE>
68558 <SOURCE>Facies 06: 297-328.</SOURCE>
68559 <ABSTRACT>The paper is concerned with some key questions resulting from current studies of Triassic reefs and reef biota. A survey of the distribution of the reefs in time and space indicates the existence of Anisian buildups (starting in the Pelsonian), and significantly restricted to the southern part of Europe. Ladinian and Carnian reefs exhibit a larger distribution pattern, including Europe, Asia and western North America as well as Peru. Even broader is the distribution of Norian and Rhaetian reefs, which are known from many parts of the Tethys but have been studied in detail only in Europe, Central Asia and in western North America. The exact age of many Triassic reefs is controversial because of the strong facies control of reef biota. The composition of the frame building fauna (especially calcisponges and corals) can only differentiate an Anisian to Carnian time interval from a Late Upper Triassic interval. The current state of research is characterized geographically by strongly biased information (more than 75% of the Triassic reefs studied in more detail are situated in the Alpine-Mediterranean region and in the Cordilleran of western North America). Information about the composition of the frame building and binding communities as well as about facies types is generally good, but there is a strong need for more study of the reef-dwelling organisms and especially of the diagenetic history of reef carbonates. <ABSTRACT>The study of the taxonomic composition of Triassic reef-building and reef-dwelling biota reveals the existence of four major time-dependent biotic units occurring in the Upper Anisian, Ladinian-Cordevolian, Tuvanian-Julian (and Lower Norian?) and Norian-Rhaetian time intervals. Lower Triassic reef organisms as well as undisputed Permian holdovers are missing. The change in the biotic composition of Anisian to Ladinian-Cordevolian reefs represents a gradual transition characterized by the replacement of taxa whereas the change near the Carnian / Norian boundary corresponds to an extinction event of reef organisms. Anisian reefs are characterized by Olangocoelia and sponges; corals and microbial crusts are of no major importance. Ladinian and early Carnian (Cordevolian) reefs are characterized by the abundance of sponges, significant microbial contributions, occurrence of corals and frequency of carbonate cement. The biotic composition of Middle and Late Carnian reefs is similar to that of Ladinian-Cordevolian but diversity is higher. Norian and Rhaetian reef biota differ distinctly from Middle Triassic and Carnian reef organisms in taxonomic composition, diversity and importance of microproblematica different from Middle Triassic and Carnian biota. Some Norian taxa show morphological similarities with Upper Permian taxa indicating homologies or a survival of Late Paleozoic taxa until late Triassic time.</ABSTRACT>

68637 <ABSTRACT>The current state of Triassic reef research is characterized
geographically by strongly biased information: more than 75% of the
Triassic reefs studied in more detail are situated in the
Alpine-Mediterranean region (Alps, Sicily, Slovenia, Greece, Anatolia)
and in the Cordillera of western North America. Information regarding
the composition of the framebuilding and binding communities as well as
about facies types is generally good. However, there is a strong need
for more investigations on the reef-dwelling organisms. [first part of

68700 <TITLE>Extinction, survival and recovery of corals from the Triassic to Middle Jurassic time.</TITLE>
68701 <SOURCE>Terra Nova 21, 1: 57-66.</SOURCE>
68702 <ABSTRACT>Recognizing extinction events and determining their cause at the Triassic/Jurassic (T/J) transition and near the Pliensbachian-Toarcian (Lower Jurassic) boundary is a field of growing interest. We provide arguments for these events through a literature based new evaluation of coral diversity from Triassic to Dogger and a new palaeobiogeographical map. The T/J extinction of corals is clearly related to the breakdown of reef environments. Origination curves show that Hettangian (the lowest Jurassic stage) was not only a survival phase but already rather a recovery phase. Post-extinction evolution of reefs and their survival only in the northernmost margin of the Tethys support the hothouse hypothesis for the T/J extinction event. During Pliensbachian, many new taxa appear, but mostly solitary corals, not really framebuilders. Many of these taxa do not occur anymore during the following stages. The new increase in diversity is related to the development of Bajocian (Middle Jurassic) reefs. [original abstract]

68713 <TITLE>Catalogue of the Mesozoic corals at the Tohoku University Museum.</TITLE>
68714 <SOURCE>Bulletin of the Tohoku University Museum 2: 47-76.</SOURCE>
68715 <ABSTRACT>The Mesozoic corals held at the Tohoku University Museum were recorded in a computer database. The collection encompasses Mesozoic corals described by Beauvais & Mori (1988), Eguchi (1934, 1936, 1942ab, 1944, 1948, 1951), Mori (1963), Murata (1962), Yabe & Eguchi (1933, 1936) and Yabe & Sugiyama (1933, 1939). All specimens and thin sections were compared to the illustrations in the literature. The numbers of the specimens given in the literature were compared to the specimens in the collection as well. As a result, type specimens and figured specimens were isolated. The collection is not complete. A certain number of specimens were not to be found in the collections.</ABSTRACT>

68765 <TITLE>A project for an illustrated catalogue of Mesozoic coral genera.</TITLE>
68766 <SOURCE>FC&P 11, 2: 8.</SOURCE>
68767 <ABSTRACT>The need for an up-to-date illustrated catalogue of coral genera is strongly felt among all those who are concerned with coral identification and classification. After much hesitation, we have decided to undertake this work with the hope of creating a useful standard reference in the relatively near future. To do so we intend to accumulate precise descriptions of each genus which will be condensed into a maximum of one or two pages. Diagnoses and illustrations will be followed by details of geographic distribution, age and related bibliographic references. The volume will present the generic descriptions in alphabetical order. When possible, a proposed systematic position for each genus will be indicated separately in an adjoining paragraph. * We count on the collaboration of all those who feel able and willing to propose a good overall summary of one or more genera, and as of now would appreciate suggestions for the treatment of individual genera. Each contribution will be signed by its author(s). Final editing is reserved for the organizers. English has been chosen as the language of publication. * Individual Technical Draft for Generic Treatment: (1) name (2) type species - locality, age and collection number(s) of the specimen(s) concerned in the description (3) diagnosis - detailed, including characteristic dimensions and septal layout (4) illustration(s) - preferably 3 oriented sections (transverse, radial & tangential) in thin sections, peels or polished surfaces under adequate magnification; general form; highly magnified diagnostic details (5) distribution - I geographic (eventually map) and stratigraphic; main references (6) species - major forms and overall commentary (7) bibliography - main sources (8) systematics - supposed position with argumentation [original note, with minor layout changes]</ABSTRACT>

68870 <SOURCE>Eclogae Geologicae Helvetiae 87, 3: 869-893. [in French, with English summary]</SOURCE>
68871 <ABSTRACT>The holotype of the type species of the genus Heliocoenia has not been found. Specimens from the type-locality (Valfin, Jura) have been investigated. Wall and perithecium structures, septal microstructure and development of the septal apparatus are specified. The systematic position is more accurately defined: Heliocoenia Etallon is placed in the family Agatheliidae, between the suborders Stylinida and

- Heterocoeniida. variability and correlation of the calicinal diameter and the number of septa of the 35 species described by the authors show that only 10 species and 2 subspecies may be valid. The possibility of a monospecific genus is taken under consideration. </ABSTRACT>

- 68897 <ABSTRACT>The bibliography has been compiled from data banks made available by Dragica Turnsek (Ljubljana, Yugoslavia) - Triassic and Additions, Bernard Lathuiliere (Nancy, France) - Jurassic, and Hannes Loser (Dresden, Germany) - Cretaceous and General Topics. * The bibliography quotes papers published between 1940 and 1990 on subjects related to the taxonomy, systematics, morphology, palaeoecology and palaeogeography of post-Palaeozoic Scleractinia as well as the geology of coral-bearing deposits. * The list (as complete as possible) is a partial printout of a computer data bank with more than 1600 entries based on the data banks of the above-named colleagues. Within the project presented by Loser & Lathuiliere (Data Banks In Palaeontology and the Need for Standardization) the data bank is available for IBM-PC XT/AT compatible computers in all usual data formats. The object in publishing this bibliography is not only to document coral research in the past fifty years but also to demonstrate the efficacy of transnational cooperation in building up data banks. 68935 <SOURCE>Proceedings of the 8th International Coral Reef Symposium Panama City 2: 1657-1662.</SOURCE>
68936 <ABSTRACT>The history of Early Mesozoic reefs is recorded in the Tethys after the Permo-Triassic mass extinction. From this time through the Paleogene, at least four stable reef ecosystems are recognized. Each is preceded by mass extinctions of either first or second-order importance and a perturbation phase characterized by an eclipse of reefs. A recovery interval after the eclipse leads to a new stable reef ecosystem. Following an early Triassic reef eclipse and a middle to early Late Triassic recovery phase, a new ecosystem developed toward the end of the Triassic. Following a small-scale Late Triassic extinction zooxanthellate corals became dominant reef-builders. The end-Triassic extinction abruptly terminated reefs and there followed an early Jurassic eclipse interval and a Middle Jurassic recovery. This led to coral-algal dominated ecosystems of the Jurassic. Following a second-order mass extinction at the end of the Jurassic, a coral-dominated ecosystem resumed. This was interrupted by a rudist takeover later in the Cretaceous. The rudist-dominated ecosystem lasted until near the end of the Cretaceous when a first-order mass extinction disrupted reef ecosystems. This allowed surviving scleractinians to reclaim reef ecosystems of the Cenozoic. Important physical, chemical and biological themes seem relevant throughout the Mesozoic history of reefs.</ABSTRACT>

68947 <TITLE>Platy coral assemblages: 200 million years of functional stability in response to the limiting effects of light and turbidity.</TITLE>
68948 <SOURCE>Proceedings of the 9th International Coral Reef Symposium, Bali, Indonesia, pp 255-265.</SOURCE>
68949 <ABSTRACT>Ecological assemblages of platy corals occur through most of the geological record of the Scleractinia (late Triassic to Recent) but they have received almost no detailed attention. Recent studies have suggested that they represent a photoadaptive response by photosymbiotic corals to reduced illumination in deeper and/or more turbid waters. As an informal working group, we have aimed to establish (1) if this model applies more generally to the geological record, and (2) if so, what implications this may have for long-term stability of tropical marine ecosystems (e.g. role of photosymbiosis). Here we discuss preliminary results compiled from our own independent projects in 32 study areas ranging from late Jurassic to mid Miocene age. We set out simple descriptive concepts of platy corals and platy coral assemblages and provide other palaeoecological and geological information that characterises these assemblages. Sedimentological and palaeoecological evidence supports the photoadaptive nature of platy coral assemblages ('euphotic floor model'), and indicates their ecological functional stability since the late Triassic. We recognise seven variants of such assemblages according to the role of turbidity in different spatiotemporal settings. Preliminary work so far has failed to reveal closely comparable modern analogues.</ABSTRACT>

68960 <TITLE>Verfahren einer von der Taxonomie unabhängigen paläobiogeographischen Analyse post-paläozoischer Korallen.</TITLE>
68961 <SOURCE>Mathematische Geologie 6: 15-43.</SOURCE>
68962 <ABSTRACT>Various unconventional methods which are described in detail were used to analyse the palaeobiogeography of post-palaeozoic corals. In view of the complicated species concept in the group of organisms investigated, traditional taxonomy was abandoned and operational taxonomical units (OTUs) were derived exclusively from samples, using methods of numerical taxonomy. The homogeneous units thus obtained are much more likely representatives of species than the taxa were in the literature. This method is practically a new approach not only to corals since large scale palaeobiogeographical analyses covering a long time span were up to now mainly based on data from the literature. The distribution data thus obtained were tested by various methods to discover invariant factors and patterns in the distribution of the organisms. This mainly involves calculating the correlation of the distribution of the OTUs with operational geographical units (OGUs), stratigraphy, palaeo-latitude as well as palaeo-longitude. The specificity of various correlation coefficients is discussed. Other methods not used in this study are explained and their applicability and reliability are discussed. The structures of the data and the

- software used to record, process and estimate the data are briefly described. The need for transparent data structures and evaluation methods is pointed out.</ABSTRACT>

- 68988 <ABSTRACT>In this note we try to prove with some examples taken from the post-paleozoic corals, that the mineralogic transformations of the fossil madreporarian skeleton, consequently of the diagenesis, plays a primordial role in the microstructures observed under the light microscope. In fact, mineralogic analysis made upon some triassic and cretaceous specimens have showed that, in certain conditions, the skeletal elements of the Madreporaria can be entirely or partially kept in aragonite. In the case where they are kept in aragonite, the Corals we have studied, have the same fibrous structure than the one of the living Madreporaria. But all the Madreporaria which showed under the light microscope a fibro-lamellar or a granulo-lamellar structure, are entirely or in part changed into calcite. So, we can think that the microstructure of the fossil Corals is subordinate to their state of preservation and that only the mineralogic analysis of their skeleton allows to prove that the microstructure observed is a primitive one.</ABSTRACT>

69038 <TITLE>Révision et essai de classification des Chaetetida (Cnidaria) post-paléozoïques.</TITLE>
69039 <SOURCE>Annales de Paléontologie, Invertébrés 56; 72 pp.</SOURCE>
69040 <ABSTRACT>Habitually considered as exclusively Paleozoic, the Chaetetida group is particularly ignored, probably because the difficulties posed by the study of its systematics. In none of the treatises of paleontology are found the few representatives of this group that have been described in post-Paleozoic beds. The present work, which treats these Mesozoic and Cenozoic organisms successively placed near the Alcyonaria, Tabulata and Bryozoa, shows that a good number of them belong to the order Chaetetida, whose phylogenetic duration, in consequence, is considerably extended. The author, first of all, strives to specify the general characteristics, the methods of study and the terminology concerning these organisms. He proposes next a new definition of the Chaetetida and confirms their position

(Cnidaria, Hydrozoa). Then, after having searched to determine in what should consist the diverse criteria of familial, generic and specific rank, he proposes a new classification which recognizes nearly 40 post-paleozoic species, distributed in 3 families and 11 genera or subgenera. A last chapter is devoted to doubtful organisms, insufficiently characterized or which are preferably excluded from the Chaetetida.</ABSTRACT>

 69051 <TITLE>Mesozoische und rezente desmentragende Demospongiae (Porifera, "Lithistida") (Paläobiologie, Phylogenie und Taxonomie).</TITLE>
 69052 <SOURCE>Berliner geowissenschaftliche Abhandlungen E10: 73 pp., 21 figs, 27 pls.</SOURCE>
 69053 <ABSTRACT>within the demosponges in all main taxa, irregular spicules, the desmas are observed. Therefore, the polyphyletic "Lithistida " Schmidt 1870 is eliminated. Desma-bearing demosponges are known since the Middle Cambrian. The desma-types are differentiated by their axial symmetry. In the present theory, the character desma probably evolved from a regular tetraxonid calthrops through "secondary" (intracellular) silification within the scleroblast. This is indicated by the ornamentation and zygomes (ends of these spicules) of this special type of spicules. First the tetraxonid desmas (tetraclones) evolved. Then a possible reduction of two calthrops rays to diactine forms, like oxeas, and the reduction of three rays to monactine spicules, like styles, took place. The monaxonid desmas (rhizoclones, dicranoclones, dendroclones) are derived from "normal" spicules, such as styles. The hypothesis is that the reduction of rays of the calthrops first lead to normal monaxonid spicules, and monaxonid desmas evolved by "secondary" silification.  69064 <TITLE>The Hexactinellida from the Mesozoic until today: paleobiology, phylogeny, evolutionary ecology.</TITLE>
 69065 <SOURCE>FC&P 21, 1.1: 38-39.</SOURCE>
 69066 <ABSTRACT>The Hexactinellida (earliest Cambrian - Recent) may be the best established monophylum within the Porifera. They are the adelphotaxon ("sister group") of the Pinacophora (Demospongiae/Calcarea-taxon), from which they have evolved separately at least since the earliest Cambrian. Because of the syncytial organization of their soft tissues, Hexactinellida fundamentally differ from all other sponges. Contrary to other current phylogenetic assumptions, the closest relatives of the Demospongiae within the Porifera probably are not the Hexactinellida but the Calcarea. The siliceous spicules of Hexactinellida appear to have evolved convergently to those of Demospongiae as a true functional and constructive morphological homoplasy. Thus follows consequently the

conclusion that spicules do not belong to the poriferan basic pattern. Spicules of rectilinear triaxial symmetry (basic type is the regular hexactin), with an axial filament that is square in cross section, represent a unique character within the Porifera. [initial fragment of Thesis]

69090 <TITLE>Structure and composition of organic reefs and carbonate reef mounds: concepts and categories.</TITLE>
69091 <SOURCE>Earth-Science Reviews 58, 1-2: 163-231.</SOURCE>
69092 <ABSTRACT>Defined here as 'essentially in place calcareous deposits created by sessile organisms'; Organic Reefs are diverse and complex structures with a long geological history. Their classification has been the subject of fierce debate, often characterized by reliance on subjective features such as wave-resistance and qualitative attempts to discriminate between 'first' and 'second class' reefs. In contrast, emphasis is here placed on the objective characteristic of the type of sedimentary support, which largely determines the sedimentary composition of the deposit. * Constructional and depositional processes result in three principal sedimentary components: matrix (M), essentially in place skeletons (S) and cavity/cement (C), whose proportions can be represented on MSC triangular plots. Separately or

together, these components also provide the structural support for the reef. On these compositional and structural bases, three main categories of Organic Reef are recognized: (1) Matrix-supported reefs (Agglutinated Microbial Reefs, Cluster Reefs, Segment Reefs), (2) Skeleton-supported reefs (Frame Reefs), (3) Cement-supported reefs (Cement Reefs). 69118 <ABSTRACT>The Mesozoic families Microsolenidae, Latomeandridae, Synastraeidae and Cunnolitidae were separated from the suborder Fungiina and a new suborder Microsolenina is proposed. The suborder is characterized by possessing collar-like structures (pennulae sensu Gill 1967), spaced along the trabeculae, tending to merge into more or less continuous falnges parallel to the septal distal margin, distributed on each face of the septa. The suborder Fungiina show trabeculae with granulations set off the the trabecular axis towards interseptal space (vepreculae according to Jell 1974). The fungiids are considered to be more close to the faviids.</ABSTRACT>

- 69157 <ABSTRACT>The review of the stratigraphic record, including excursions into Palaeozoic lineages, concentrates on recognizable genera and families of demosponges, relying chiefly on isolated spicules. Lithistid suborders are reviewed with reference to de Laubenfels' (1955) erroneous treatment and to newer systematic accounts. 715 individual spicules, including examples from living species for comparison, are illustrated in 35 figures in systematic order. They are redrawn from various fully quoted articles, including those in the Initial Reports of the Deep Sea Drilling Project. The notes on fossil faunas, palaeoecology, and palaeobiogeography elaborate on several aspects previously neglected or widely scattered in the literature.</ABSTRACT>

69182 <SOURCE>Profil 11: 199-324.</SOURCE>
69183 <ABSTRACT>Sedimentary rocks characterized by siliceous sponges occur during several time episodes in Earth history. The spongiolithic facies culminates in the Late Jurassic. On the northern shelf of the Tethys and in the adjacent North Atlantic basins, siliceous sponges formed a discontinuous reef belt extending over more than 7000 km. The scope of this study is the palaeoecological analysis of post-Palaeozoic siliceous sponges in order to obtain a valuable tool for the environmental and genetic interpretation of siliceous sponge-bearing rocks. Methodically, the actualistic or uniformitarianistic concept was applied to the group of siliceous sponges for the first time. The knowledge of the biology and the ecology of recent siliceous sponges is an important fundamental prerequisite for transforming the results to the fossil record. The heterogeneous group of siliceous sponges belong either to the desma-bearing demosponges ("Lithistida") or to the Hexactinellida. Both siliceous sponge groups differ fundamentally in their biology (e.g., anatomy, reproduction, nutrition). Consequently, they also differ remarkably in their ecological demands. Ecologically important factors are bathymetry, substrate, water energy, temperature, quantity and quality of food, sedimentation rate, settling density, available space, space competition, water chemistry, and reproduction rate. Usually, these factors do not work independently. Their interaction determines the occurrence, spatial distribution and the dominance of siliceous sponge groups. Most demosponges are active filter feeders. Owing to the minute size of their ostia, bacteria are their main food source. Demosponges are able to host bacteria to a great amount in their mesohyl. Most of these sponges can live either on the hosted bacteria itself or on the metabolic products of the bacteria. [part of very extensive summary]</ABSTRACT>

69195 <SOURCE>Palaeontology 27, 3: 537-538.</SOURCE>
69196 <ABSTRACT>Annual banding evident from epithecal increments and associated internal structural changes in phaceloid and massive Oxfordian corals show a range in growth rate from 5 to 10 mm yr⁻¹ in branching colonies (Thecosmilia) and 1.5 to 3 mm yr⁻¹ for massive colonies (Thamnasteria, Fungiastraea, Isastraea). High- and low-density growth bands are identified in massive colonies. The denser part of each couplet is consistently the broader, in contrast with that of most shallow-water modern corals. This is interpreted as due to high local turbidity. The formation time for two sections is estimated with gross carbonate production of 2000 to 3300 g CaCO₃ m² yr⁻¹.</ABSTRACT>

evolution.</TITLE>
69221 <SOURCE>Proceedings of the 8th International Coral Reef Symposium
Panama City, 2: 1663-1669.</SOURCE>
69222 <ABSTRACT>European Late Jurassic reef coral occurrences from comparable
environments (subtropical climate, shallow agitated water, raised
nutrient levels) were evaluated with respect to variations in
bioerosion. Net-sedimentation rate obviously was the most important
ecofactor regarding intensity of bioerosion as well as the organisms
involved. Lower sedimentation rates favour dead-coral borers
(Lithophaginae and Sipunculida / Polychaeta) and strong bioerosion;
increased sedimentation leads to dominance of live-coral borers
(Gastrochaenidae) with relatively much reduced boring activity. Boring
sponges (Clionidae) are the prominent macroborers in Neogene reefs;
however, with grazing reef fish not yet evolved, they could become
important only under special circumstances: in microbial-coral reefs,
bacterial mats provided their nutrition and excluded competitors such
as encrusters and dead-coral borers.</ABSTRACT>

examples.</TITLE>
69325 <SOURCE>Acta Palaeontologica Polonica 27, 1-4: 157-193.</SOURCE>
69326 <ABSTRACT>Four Malmian corals of different microstructures have been
described: *Thamnasteria concinna*, *Dimorphastraea* sp., *Actinaraeopsis*
exilis and *Isastraea* cf. *bernensis*. Aragonite coral tissue being
preserved, histological observations have been initiated. Taxonomical
value of microstructure and histology, as decisive for suprageneric
division, is confirmed. In four discussed species, trabeculae are of a
branched morphology and non-sclerodermite structure. Each species
represents a different variety of trabecular histology. A restricted
significance of synapticalae for taxonomical purposes is confirmed.
Vertical adtrabecular bars are described, a new skeletal element in *Th.*
concinna.</ABSTRACT>

69351 <SOURCE>Palaeontographica A248: 145-162.</SOURCE>
69352 <ABSTRACT>Dendraraea d'Orb. 1849 is a branching ramose Jurassic coral having a fundamentally pennular perforate septal structure. This long ignored pennular character is more or less obliterated in the slow growth directions where predominance of horizontal tabuloid dissepiments gives rise to a layered pattern. The way in which the obliteration of pennular structure occurs introduces a new feature to be taken into account in the classification of Mesozoic perforate corals. The revision of Jurassic species using discriminant analysis sketches evolutionary patterns through four stages: Bajocian (D. dendroided), Bathonian (D. excelsa, D. pauciradiata and D. sp.), Callovian (D. sp. 2 and sp. 3) and Oxfordian (D. racemosa). The analysis of the colonial ontogeny (astogeny) permits a better understanding of some ecological aspects particularly the role of two factors: the bioerosion and the distance between the top of the colony and the sea floor.</ABSTRACT>

69363 <TITLE>Mise au point sur les genres Confusastrea d'Orbigny et Complexastrea d'Orbigny (Scleractinia - Jurassique).</TITLE>
69364 <SOURCE>Annales de Paleontologie (Vert.-Invert.) 80, 4.</SOURCE>
69365 <ABSTRACT>The revision of the specimen figured by Leymerie (1846) and appointed by d'Orbigny (1849) as the example of Complexastrea, as well as the study of additional material belonging to the same species, permits to give the diagnosis emended of this genus: Corallum plocoid appearing subcerioid; septocostae compact, non confluent (sometimes subconfluent) and composed of thick trabeculae probably with triangular teeth on upper edge. Lateral surface with few opposite carinae; axial edge entire. Vesiculoid endotheca. Budding is intracalicular but extracalicular budding can be present too. The nomenclatural problem concerning the type species of Complexastrea is resolved. The type species is: Complexastrea subburgundiae d'Orbigny (1850) and the holotype is the specimen figured by Leymerie (1846, p. 252, pl. 10, fig. 13) and named by him Astrea burgundiae. The following species are not synonymous of Confusastrea subburgundiae: 1803 - "Madrepore petrifie…" Faujas de St. Fond, p. 99, pl. 4 1830 - Astrea burgundiae Blainville, p. 339 1834 - Astrea burgundiae Blainville, p. 373. The name Astrea burgundiae should be reserved to the specimen figured by Faujas de St. Fond (1803). The study of thin sections of the holotype of Agarida crassa, figured by Goldfuss and appointed by d'Orbigny as the exemple of Confusatrea, shows that this specimen belongs

to the genus *Isastrea*. Consequently *Confusastrea* is a senior synonym of *Isastrea*. *Astrea rustica* DeFrance would not be considered a valid species because it was described from a not figured specimen and of unknown age and origin, and on top of that is lost. Thus, *Astrea rustica* could not be mentioned as type species of *Complexastrea* as it was made by some authors.</ABSTRACT>

69403 <SOURCE>C. R. Acad. Sci. Paris, sér. D, 274: 2459-2462.</SOURCE>

69404 <ABSTRACT>A downward growth of the skeleton analogous to the one observed in *Chomatoseris* is now recorded in *Genabacia*, a small microsolenid colonial genus from the Bathonian of western Europe. As in *Chomatoseris* the author suggests for this genus the ability to move independently; such an ability in the case of a colony, requires a close coordination of polyps. Similar structural features were already mentioned by the author within diverse taxonomic groups of solitary corals, notably *Chomatoseris* (Dogger), *Combophyllum* (Devonian), *Micrabacia* (Cretaceous-Recent). It is also the case with *Fungia* and *Cycloseris* (Diasseris). This autonomous mobility enables these corals to prosper in both very soft substrates and on mobile, high energy, coarse, sandy bottoms - environments where sessile forms do not thrive.
